On the other hand, contestability theory does not lend support to the proposition that the unrestrained market automatically solves all economic problems and that virtually all regulation and antitrust activity entails unwarranted and costly intervention. The economy of reality is composed of industries which vary widely in the degree to which they approximate the attributes of perfect contestability. Before the theory of contestability can be legitimately applied to reach a conclusion that intervention is unwarranted in a specific sector, it must first be shown that the sector lies unprotected by entry barriers and that the force of potential entry therefore actively constrains the behaviour of incumbent firms. This then becomes the appropriate first stage in an analysis of efficient government policy towards an industry. Only where the conditions of contestability are found to characterize the reality of an industry can there be validity in applying the normative conclusions of contestability theory concerning the power of potential competition actually to enforce efficient behaviour on incumbents.

Even where contestability is absent in reality, the formulation on efficient regulation can be usefully guided by the theory of contestable markets instead of the theory of perfectly competitive markets. The first-best lesson of the perfect competition model, calling for prices to be set equal to marginal costs, has no doubt contributed to the common regulatory ethos which *equates* price to *some* measure of cost. This doctrine has been used frequently where it is completely inappropriate and without logical foundation, that is, in cases where prices should be based on demand as well as cost considerations, because of the presence of economies of scale and scope. Such arbitrary measures as fully distributed costs cannot substitute for marginal cost measures as decision rules for proper pricing, and the search for a substitute is a remnant of inappropriate reliance on the

model of perfect competition for guidance in regulation.

In contrast, contestability theory suggests cost measures that are appropriate guideposts for regulated pricing – incremental and stand-alone costs. The incremental cost of a given service is, of course, the increment in the total costs of the supplying firm when that service is added to its product line. In perfectly contestable markets, the price of a product will lie somewhere between its incremental and its stand-alone cost, just where it falls in that range depending on the state of demand. One cannot legitimately infer that monopoly power is exercised from data showing that prices do not exceed stand-alone costs, and stand-alone costs constitute the proper cost-based ceilings upon prices, preventing both cross-subsidization and the exercise of monopoly power. A simple example will show why this is so.

First, suppose that a firm supplies two services, A and B, which *share no costs* and that each costs 10 units a year to supply. The availability of effective potential competition would force revenues from each service to equal 10 units a year. For higher earnings would attract (profitable) entry, and lower revenues would drive the supplier out of business. In this case, in which common costs are absent, incremental and stand-alone costs are equal to each other and to revenues, and the competitive and contestable benchmarks yield the same results.

Next, suppose instead that of the 20 unit total cost 4 are fixed and common to A and B, while 16 are variable, 8 of the 16 being attributable to A and 8 to B. If, because of demand conditions, at most only a bit more than 8 can be generated from consumers of A, then a firm operating and surviving in contestable markets will earn a bit less than 12 from B. These prices lie between incremental costs (8) and standalone costs (12), are mutually advantageous to consumers of both services, and will attract no entrants, even in the absence of any entry barriers. In contrast, should the firm attempt to raise the revenues obtained from B above the 12 unit stand-alone cost, it would lose its business to competitors willing to charge less. Similarly, the same fate would befall it in contestable markets if it priced B in a way that earned more than 8 plus the common cost of 4, less the contribution towards that common cost from service A.

Thus, the forces of idealized potential competition in perfectly contestable markets enforce cost constraints on prices, but prices remain sensitive to demands as well. Actual competition and potential competition are *effective* if they constrain rates in this way, and in such circumstances regulatory intervention is completely unwarranted. But if, in fact, market forces are not sufficiently strong, then there may be a proper role for regulation of natural monopoly, and the theoretical guidelines derived from the workings of contestable markets are the appropriate ones to apply. That is, prices must be constrained to lie between incremental and stand-alone costs. (This is the approach recently adopted by the Interstate Commerce Commission to determine maximum rates for US railroad services, and the method has already withstood appeals to the federal courts.)

The theory of general competitive equilibrium was originally developed for environments where no uncertainty prevailed. Everything was certain and phrases like 'it might rain' or 'the weather might be hot' were outside the scope of the theory. The idea of *contingent commodity,* that was introduced by Arrow (1953) and further developed by Debreu (1953), was an ingenious device that enabled the theory to be interpreted to cover the case of uncertainty about the availability of resources and about consumption and production possibilities. Basically, the idea of contingent commodity is to add the environmental event in which the commodity is made available to the other specifications of the commodity. With no uncertainty every commodity is specified by its physical characteristics and by the location and date of its availability. It is fairly clear, however, that such a commodity can be considered to be quite different where two different environmental events have been realized. The following examples clarify this: an umbrella at a particular location and at a given date in case of rain is clearly different from the same umbrella at the same location and date when there is no rain; some ice cream when the weather is hot is clearly different from the same ice cream (and at the same location and date) when the weather is cold; finally, the economic role of wheat with specified physical characteristics available at some location and date clearly depends on the precipitation during its growing season. Thus, specifying commodities by both the standard characteristics and the environmental events seems very natural, whereas the role of the adjective in 'contingent commodities' is simply to make it clear that one is dealing with commodities the availability of which is contingent on the occurrence of some environmental event. With this specification the model with contingent commodities is very similar to the classical model of general competitive equilibrium and thus questions like the existence of equilibrium and its optimality (with the additional aspect of efficient allocation of risk bearing) are answered in a similar way. Note that, although this model deals with uncertainty, no concept of probabilities is needed for its formal description.

To make things more explicit we look at a simple model with contingent commodities. Assume that, without referring to uncertain events, there are $k \geq 1$ commodities, indexed by i, and that there are $n > 1$ mutually exclusive and jointly exhaustive events (or states of nature), indexed by s, where k and n are finite. Thus a contingent commodity is denoted by x_{is} and the total number of these commodities is kn, which is greater than k but still finite. Consumption and production sets are thus defined as subsets of the kn-dimensional Euclidean space, and the economic behaviour of firms and consumers naturally follows from profit maximization (by firms) and utility maximization (by consumers). The price p_{is} of the contingent commodity x_{is} is the number of units of account that have to be paid in order to have the ith commodity being delivered at the sth event. It is assumed that the market is organized before the realization of the possible events. Thus payment for the contingent commodity x_{is} is done at the beginning while delivery takes place after the realization of events and only in case event s has occurred. Note that the price of the (certain) ith commodity, that is, the number of units of account that have to be paid in order to have the ith commodity *for sure,* is the sum over s of the prices p_{is}. For example, assume that the price of one quart of ice cream if the weather is hot is \$2.00, the price of one quart of the same ice cream if the weather is cold is \$1.00 and that $n = 2$ (either it is hot or cold). Thus the price of having one quart of that ice cream for sure is \$2.00 + \$1.00 = \$3.00.

It should be noted that, although the probabilities of the possible events do not explicitly enter the model, the attitude towards risk of both consumers and producers is of interest and does play a significant role in this framework. The preference relations of consumers defined on subsets of the kn-dimensional Euclidean space reflect not only their 'tastes' but also their subjective beliefs about the likelihoods of different events as well as their attitude towards risk. Convexity of consumers' preferences, for example, is interpreted as risk aversion while, in the same spirit, profit maximization

of firms is interpreted as risk neutrality. It should be mentioned that both Arrow and Debreu basically assume expected utility maximizing behaviour, in the sense of the Savage (1954) framework. A more general approach to such preference relations can be found in Yaari (1969), where, again, convexity is taken to mean risk aversion.

A unified and more formal treatment of time and uncertainty using contingent commodities can be found in Debreu (1959, ch. 7). Radner (1968) presents an extension of the above model to the case in which different economic agents have different information.

Contingent Valuation

Trudy Ann Cameron

Abstract

'Contingent valuation' methods are used to generate demand data, usually from household surveys, when real markets do not supply reliable revealed preference data about demands for certain types of goods. A number of significant lawsuits have promoted their use in estimating demand for environmental goods. They are also used by transportation economists, health economists and market researchers. Although the degree of acceptance of these methods varies, many economists agree that a value based on stated preferences derived from carefully conceived and executed research is almost certainly preferable to no number at all.

Most economists would agree that no researcher should prefer demand data from hypothetical markets if data concerning the identical goods or services, based on real markets, are readily available. However, there are many situations when even the cleverest empirical economist cannot come up with revealed preference data from actual markets that can be relied upon for information about household demands for some types of goods. Environmental goods are one class of goods where real-market demands sometimes cannot be measured adequately. In the 1980s, environmental economists began in earnest to exploit stated-preference demand information, usually collected using household surveys. This demand information is used primarily to produce utility-theoretic measures of the social benefits of environmental protection measures for benefit–cost analyses.

Environmental economists called these methods 'contingent valuation methods' (CVM) because the valuations were elicited 'contingent upon the conditions described in the survey'. Research that focused on the development and assessment of CVM in environmental economics was well under way by the mid-1980s. However, two events in 1989 thrust the method to the forefront of the field. First, the *Exxon Valdez,* an ocean tanker, ran aground in Prince William Sound in Alaska, spilling 11 million gallons of oil in an environmental disaster that attracted a huge amount of media attention worldwide. Second, just a few months later, the US Court of Appeals held that the economic damages assessed for spills of oil or other hazardous substances could include 'lost passive use values', and that these values could legally be measured via CVM.

Plaintiffs and defendants in the Exxon Valdez case thus had a big incentive to advocate and derogate CVM, respectively. For at least a time, the discussion in the literature teetered on the brink of losing its polite academic tone. Given the escalation of the controversy over CVM, the US National Oceanic and Atmospheric Administration (NOAA) convened a panel of experts (untainted by any active role in the Exxon Valdez litigation) to assess CVM. This exercise, by Arrow et al. (1993), produced a set of pronouncements concerning best practices for the conduct of CVM studies. While the 1993 NOAA Panel report cannot be considered the last word on CVM, it was very influential, and there has since been strong pressure on researchers either to conform to the NOAA best practices or to fully justify any departures from them.

As a result of the Exxon Valdez case, much doubt about the reliability of stated preference data led to numerous comparisons of the implications of stated and revealed preference data (for example, Carson et al. 1996). CVM works best when respondents have a clear sense of the consequences of their choices – in terms of both their own budgets and the exact nature of the good that they are being asked to consider paying for – and when they are reasonably familiar with market transactions involving that good. This means that CVM is, unfortunately, most successful when it is least needed. The challenge for researchers is to ensure that demand information gathered using CVM, in less-than-ideal contexts, is as valid and useful as possible.

Myriad biases and qualifications may afflict poorly executed CVM studies. A partial list includes incentive compatibility, hypothetical bias (if the choice is perceived to have absolutely no real consequences), strategic bias (when people try to manipulate the outcome by misrepresenting their preferences), non-response bias (since people cannot be compelled to participate), starting-point bias (for surveys with iterative bids), interviewer bias (for in-person surveys), and information bias (when some portion of the value is constructed during the survey where it did not exist before). Other problems include yea-saying, part–whole bias or embedding, scenario rejection, and the potential for respondents not to pay sufficient attention to their real budget constraints.

Choice formats have been an important issue in the development of CVM. For example, in some early applications of CVM survey respondents were asked directly to identify the single highest dollar amount that they would pay to obtain some change in conditions. These were called open-ended CV questions. Researchers quickly realized that such a task was difficult for consumers who were unfamiliar with naming their own price, especially for goods they may never before have thought much about having to pay for. CVM elicitation techniques evolved fairly quickly to a dichotomous-choice format, where respondents are given a choice between two states of the world. One state is typically the status quo, while the other involves a specified change or set of changes (such as an improvement in environmental quality, or some other rationed public good) that come at a price (typically a lump-sum payment). This binary choice format was found to fit naturally into a random utility model (RUM) framework that had also become a popular approach to consumer choice problems, both real and hypothetical, in the transportation mode-choice literature and elsewhere in economics.

Respondents' preferences, based on their answers to dichotomous-choice CV questions,

can be characterized either in an ad hoc fashion or in a more formal utility-theoretic framework. One standard approach is to specify an indirect utility function shared by all respondents. In its simplest form, the level of indirect utility is assumed to depend on the individual's net income under each of the two alternatives, and upon a discrete indicator of whether there is a change in the rationed public good, or no change, under each alternative. Respondents can choose the environmental improvement programme along with its associated cost (implying lower net income), or decline the environmental improvement programme in order to avoid the cost (preserving their net income). If a respondent prefers the programme with its associated cost, the researcher assumes that the respondent's utility level is higher under that alternative. Equivalently, this means that the *net* indirect utility associated with the programme alternative is positive.

A discrete-choice econometric model, typically involving a binary logit estimator, is used to estimate the sample average marginal utilities of (*a*) net income and (*b*) the discrete bundle of changes represented by the programme in question. It is of course possible to allow for heterogeneity across the sample in these marginal utilities. Most often, heterogeneity is introduced by allowing the otherwise scalar marginal utility associated with going from 'no programme' to 'programme' to become a systematically varying parameter. Of course, if the identical programme is offered to all respondents, it is not possible to allow this marginal utility to vary with attributes of the programme. However, it can easily be allowed to vary with characteristics of the respondent.

Less commonly, the marginal utility of income is also allowed to vary across respondents, either with the respondent's income (to allow for diminishing marginal utility of income) or with other respondent characteristics. However, there is a premium on simplicity for the marginal utility of income, stemming from the need to use the estimated marginal utility of income parameter (s) to recover demand information. For this reason, many researchers will, if it is justified by the data, prefer a choice model that is linear and additively separable in net income under each alternative.

Linearity and additive separability in income is convenient (when warranted) because the willingness to pay (WTP) function associated with the fitted model is given by the marginal rate of substitution (MRS) between the programme and income. This MRS is given by the ratio of the marginal utility of the programme to the marginal utility of income, producing a result that can be expressed in dollars per 'unit' of the programme, where the program indicator is either zero or 1 in the simple binary case. In the non-stochastic case, for a simple dichotomous choice CVM model, this is a single number – 'WTP for the program' – if the researcher has assumed homogeneous preferences throughout the sample.

Some extra empirical housekeeping is necessary when it is acknowledged that this point estimate is constructed as the ratio of two estimated quantities, each of which (due to the use of maximum likelihood estimation methods for the logit or probit model) is an asymptotically normally distributed random variable. In theoretical terms, the ratio of two normally distributed random variables has an undefined mean, because zero is a possible value for the denominator. As a practical matter, some researchers use simulation methods to build up a sampling distribution for the estimated WTP. It is possible to use packaged software to make a large number of random draws from the joint distribution of the logit or probit parameters (based on the estimated parameter point estimates and the parameter variance–covariance matrix). One can then build up a sampling distribution for the needed ratio. Other strategies for dealing with this inconvenience involve estimating the model in 'WTP-space' rather than 'utility-space' or employing the newer mixed logit (random-parameters logit models) and stipulating that the marginal utility of income parameter be distributed lognormal (since it should be strictly positive, on average), rather than normal, so that the potential divide-by-zero problem goes away.

Over the 1990s contingent valuation researchers in environmental economics gradually made better contact with their counterparts working in other literatures who were confronted

by similar problems where there is a lack of market data for products or public goods that need to be valued. In the transportation literature, researchers had grappled early on with the problem of forecasting demand for public transportation projects, or new types of vehicles, that did not yet exist. Researchers began to introduce hypothetical new transportation options which could be characterized in the same terms as existing options (in 'attribute space') but which had some attributes that lay well outside the set of existing options on some dimensions, or which involved attributes that were not relevant for existing options (such as travel range or recharge time for prospective electric vehicles). One key difference from contingent valuation was the practice of asking survey respondents to consider more than just 'the status quo versus a single alternative'. Furthermore, the alternatives were more richly specified. Instead of using simply a dummy variable to indicate whether the policy, programme or public good was present or absent, each alternative was characterized in terms of an array of attributes.

Similar problems were also being addressed in the marketing literature, particularly in the context of 'pre-test' marketing. Companies considering whether to develop and introduce new products needed to know in advance about the likely demand for these products, perhaps as a function of alternative possible product configurations. Market researchers developed a set of techniques they called 'conjoint analysis'. In the marketing literature, the specifications used for the choice models were initially very ad hoc. Little attention was paid to the interpretation of the estimated coefficients as marginal utilities, and simple linear and additively separable specifications were very common. The slope coefficients were known as 'part-worths' rather than marginal utilities. However, much was learned about the degree of consistency between planned purchase behaviour and actual purchase behaviour.

CVM has also recently grown in popularity in other sub-disciplines, notably health economics. However, Smith (2003) surveys that literature and suggests that researchers in that field have not yet developed a set of best practices for the use of CVM with the types of choices that are most common in health economics contexts.

In the transportation and marketing literatures, the desired demand information often spanned a number of possible alternative products or services. Stated preference studies were often conducted not just to determine respondents' willingness to pay for a single well-defined good but to understand how willingness to pay might be affected by variations in the mix of attributes making up a prospective good. It was often necessary to anticipate demands for differentiated products, where each product could be characterized as a bundle of attributes and the levels of these attributes differed across alternatives.

In contrast, more of the impetus for CVM non-market valuation research in environmental economics stemmed from a number of significant lawsuits. In the legal context, there is a premium on simplicity in economic modelling so as not to confuse the jury or the judge. It is often best to produce one value for one clearly defined commodity. (Providing a judge or jury with a function that describes demand, where WTP depends upon a wide array of attributes, conditions or respondent attributes, can actually be a liability when attorneys are trying to make a simple, clear and persuasive case. In a legal context, it is most incisive to value one thing, and to value it as precisely as possible.) Eventually, however, environmental economists began to acknowledge the value of understanding the heterogeneity in demands for environmental goods, since this knowledge can be very helpful to policymakers who wish to consider how different versions of a policy might affect different constituencies.

There are many commonalities between the tasks faced by environmental economists and those faced by transportation economists and market researchers, but there is one key difference. In transportation economics and market research, it is often the case that the public transit system in question will actually be built, or the new product will actually be developed and put on the market. There is an opportunity to go back and see whether the level of demand predicted by the stated preference study actually materializes when there is a real market. In the environmental

economics literature, there are typically fewer opportunities to 'validate' the stated preference demand information with revealed preferences for the same product.

One common expectation for a good CVM study is now a demonstration that the demand function that has been estimated should 'walk and talk' like a demand function. For example, is willingness to pay to preserve big-game hunting opportunities lower, on average, for elderly women than for middle-aged males? Is willingness to pay to preserve air quality higher for people with lung disease or asthma, or for people who have family members with these illnesses? These tests are commonly called 'construct validity' assessments. Contingent valuation studies that pass a battery of plausibility tests such as these can generally be viewed as more reliable.

Another common test of contingent valuation estimates that these stated preference demand functions are typically expected to satisfy is something called a 'scope test'. This means that, on average, respondents' willingness to pay for an alternative that involves more of the 'good' in question should be greater than that for an alternative that involves less of the 'good'. It is of course possible that marginal utility may be positive (as the scope test implies) at low levels of the good, but also that it may go to zero if the quantity of the good is high enough for satiation to set in, and there is no theoretical basis for expecting willingness to pay to be proportional to the amount of the good in question.

CVM data can also sometimes be pooled with actual choice data. This can allow portions of the underlying indirect utility function to be anchored upon real choices, even though the variability in attributes in the real alternatives may not span the full domain relevant to pending policy decisions. The stated choice questions can be used to extend the domain of the estimated demand function.

While economists will remain uncomfortable about reliance upon stated preference information, many now acknowledge that there are circumstances where stated preference data are all that can be collected. In fact, the need for economists to rely upon survey data (what people say as opposed to what they actually do in markets) is now being acknowledged in the other contexts in economics. For example, expectations about future income or life expectancy figure prominently in a number of economic theories. These expectations typically cannot be measured directly, but can sometimes be elicited using surveys and put to good use empirically (see Manski 2004).

It is worth noting that not just stated preference data but also revealed preference data can be highly variable in its quality. Much revealed preference demand data is also drawn from consumer surveys. It is not always clear that the individual respondent sees the need for accuracy and completeness to be as critical as researchers using the data might hope. In consumer expenditure surveys, for example, interviewers prompt subjects for different types of expenditures, but the enthusiasm and engagement of the survey subject often determines the accuracy and completeness of the data. Rather than viewing revealed preference data as of unambiguously high quality and stated preference data (such as that produced by CVM) as of unambiguously low quality, it may be prudent simply to acknowledge that both types of data can have their problems.

A partial list of current frontiers in CVM-related research is possible. These frontiers include continuing assessment of (*a*) alternative elicitation formats (there are many candidates beyond the simple NOAA-recommended binary choice format), (*b*) the choice contexts presented to subjects, (*c*) the effects of allowing subjects to express uncertainty about their choices, (*d*) the effects of practice and fatigue when several CVM questions are presented to each respondent, (*e*) integrating stated choices with additional types of real market information, (*f*) how the degree of complexity of the CVM choice scenarios interacts with the cognitive capacity of the subject and/or the subject's inclination to pay attention, and (g) the neuroeconomics of real as opposed to stated choices.

Two of the classic books on CVM are Cummings et al. (1986) and Mitchell and Carson (1989). Following the Exxon Valdez case, a provocative debate was featured in the *Journal of Economic Perspectives* (Diamond and Hausman 1994; Hanemann 1994; Portney 1994). McFadden (1994) raised some specific concerns about the reliability of CVM data in the context of an empirical application to the existence value of wilderness areas in the western United States. In the intervening years, however, research concerning CVM has continued apace. Helpful expositions and discussions of recent innovations have made their way into textbook form, with one particularly useful summary being provided in Chapter 6 of Freeman (2003). A brief, accessible and very helpful introduction to CVM for non-specialists is contained in Carson (2000). Louviere et al. (2000) offer a comprehensive discussion of stated choice methods broadly defined, including experimental design, modelling, estimation and combining revealed and stated preference data, with illustrations in marketing, transportation and environmental economics. An inventory of the wide range of practical issues to consider in actually implementing a CVM study is provided by Boyle (2003), while Holmes and Adamowicz (2003) update the state of the art for attribute-based (conjoint choice) methods.

There is still considerable variation in individual researchers' levels of comfort with CVM and stated preference data more generally. We might reconsider the question posed by Diamond and Hausman (1994): 'Contingent valuation – is some number better than no number?' There are now many economists who would agree that a value based on stated preferences – from a study that is carefully conceived and executed, based on a sufficiently large sample that is representative of its intended population, that has been put through a battery of consistency and validity assessments, and that produces an implied demand function that behaves the way we would expect a 'real' demand function to behave – is almost certainly better than no number. This is especially true when 'no number' creates the risk that a value of zero would otherwise be imputed, by default, for use in policy decisions.

Continuity in Economic History

Donald N. McCloskey

Continuity and discontinuity are devices of story-telling, telling the story of monetary policy over the past few months or the story of modern economic growth. They raise certain questions in philosophy and lesser matters, such as precedence and politics.

It is well to have a case in mind. The most important is that of the British industrial revolution.

If it was a 'revolution', as it surely was, it happened sometime. There was a discontinuity, a before and after. When? Various dates have been proposed, down to the day and year: 9 March 1776, when the *Wealth of Nations* provided an ideology for the age; the five months in 1769 when Watt took out a patent on the high pressure steam engine and Arkwright on the cotton-spinning water frame; or 1 January 1760, when the furnaces at Carron Ironworks, Stirlingshire, were lit.

Such dating has of course an amateur air. A definite date looks handsome on a plaque or scroll but the precision does not fit well with sophisticated story-telling. The discontinuity is implausibly sharp, drawing attention to minor details. The Great Depression did not start on 24 October 1929; the deregulation of American banking was not completed with the fall of Regulation Q. Nicholas Crafts (1977) has pointed out that the detailed timing of the industrial revolution should not anyway be the thing to be studied, because small beginnings do not come labelled with their probabilities of developing into great revolutions. He is identifying a pitfall in story-telling. Joel Mokyr identifies another (1985, p. 44): rummaging among the possible acorns from which the great oak of the industrial revolution grew 'is a bit like studying the history of Jewish dissenters between 50 BC and 50 AD. What we are looking at is the inception of something which was at first insignificant and even bizarre', though 'destined to change the life of every man and woman in the West'.

What is destined or not destined to change our lives will look rather different to each of us. Each historian therefore has his or her own dating of the industrial revolution. Each sees another discontinuity. E.M. Carus-Wilson (1941, p. 41) spoke of 'an industrial revolution of the 13th century': she found that the fulling mill was 'due to scientific discoveries and changes in technique' and 'was destined to alter the face of medieval England'. A.C. Bridbury (1975, p. xix–xx) found in the late middle ages 'a country travelling slowly along the road … that [it] travelled so very much more quickly in Adam Smith's day'. In the eyes of Marxist writers the 16th century was the century of discontinuity, when capitalism set off into the world to seek its fortune. John U. Nef, no Marxist, believed he saw an industrial revolution in the 16th century, centred on coal (1932), though admittedly slowed in the 17th century. A student of the 17th century itself, such as D.C. Coleman (1977), finds glimmerings of economic growth even in that disordered age. The most widely accepted period for the industrial revolution is the late 18th century, especially the 1760s and 1770s (Mantoux 1928; Landes 1969), but recent students of the matter (Harley 1982; Crafts 1984) have found much to admire in the accomplishments of the early 18th century. W.W. Rostow (1960) placed the 'takeoff into self-sustained growth' in the last two decades of the 18th century, but others have observed that even by 1850 the majority of British people remained in traditional sectors of the economy. And later still there was a second industrial revolution (of chemicals, electricity, and internal combustion) and a third (of electronics and biology).

Wider perspectives are possible, encouraging the observer to see continuity instead. Looking at the matter from 1907, the American historian Henry Adams could see a 'movement from unity into multiplicity, between 1200 and 1900, …

unbroken in sequence, and rapid in acceleration' (p. 498). The principal modern student of the industrial revolution, R.M. Hartwell, appealed for continuity against the jostling throng of dates (1965, p. 78): 'Do we need an *explanation* of the industrial revolution? Could it not be the culmination of a most unspectacular process, the consequence of a long period of economic growth?'

Such questions of continuity and discontinuity are asked widely in economics, though sometimes half consciously. They should not be left to historians. Economics is mainly contemporary history, and faces the problem of deciding when a piece of history has been continuous or not. For instance the crucial discontinuity in the growth of big government, as Robert Higgs (1987) points out, might be placed when the institutions of centralized intervention were conceived (1900–1918) or made (1930–45) or expanded (1960–70). Even recent history faces this narrative problem. When, if ever, did purchasing power parity break down in the 1970s? When did policy on antitrust alter to favour mergers? When did monetary policy last become expansionary? Where is the break?

The difficulty in answering the question has often been misconstrued as philosophical. The philosophical difficulty was first articulated in the 5th century BC by Parmenides and his student Zeno: that if everything is perfectly continuous, change is impossible (Korner 1967). Everything is so to speak packed too tightly to move. The economist will recognize the point as analogous to an extreme form of economic equilibrium, or to the physicist's maximum entropy. If human nature doesn't 'really' change, then history will be a string of weary announcements that the more things change the more they stay the same. If the economy is 'really' in equilibrium all the time, then nothing remains to be done.

Alexander Gerschenkron, the economic historian who has contributed most to the understanding of continuity and discontinuity in economics, noted that such a metaphysics would close the book of history (1962, p. 12). A history of economics that began with the Parmenidean continuum would never speak.

For purposes of social science Gerschenkron rejects the transition from the connectedness of all change to an absence of change. True, if you squint and fit a curve then no economic change looks discontinuous in the mathematical sense; but it is wrong then to deduce that 'really' there is no change at all, or that the industrial revolution is a mirage. 'Continuity' in the strict mathematical sense must be kept distinct from 'continuity' in the story-telling sense.

Economists have often been muddled about this philosophical distinction, drawing surprising ideological implications from it. Alfred Marshall enshrined on the title page of his *Principles* the motto 'natura non facit saltum' (nature does not make a jump; Leibnitz had invented it as 'la nature ne fait jamais des sauts'). Marshall himself perhaps believed that the ability to represent behaviour with differentiable functions implies that marginalism is a good description of human behaviour. It is less sure that he believed that the lack of jumps in nature (this on the eve of quantum physics) implies people should not jump either, and should change society only gradually. Anyway, both implications are non sequiturs. Though both have been attributed to neoclassical economics, neither is necessary for it. Much bitter controversy has assumed that neoclassical economics depends on smooth curves and in consequence must advocate smooth social policies. The peculiar alliance between discrete mathematics and Marxian economics has this origin, as does the enthusiasm of some conservative writers for continuities in economic history. Gerschenkron cursed both their houses; the social scientist should study change and continuity 'unbothered by the lovers and haters of revolutions who must find themselves playgrounds and battlegrounds outside the area of serious scholarship' (p. 39).

In one sense of 'continuity' it is trivial that economic history is continuous. History has causes (the fourth of five historically relevant definitions that Gerschenkron distinguishes). Continuity, then, can be viewed as being merely an impressively long causal chain. The exploitation of Scottish iron deposits in the 18th century was caused by bold investments, but these depended on a reliable law of property and commerce, which depended on certain legal developments in the 16th century, and on the growth of

political stability in the early 18th century, which in turn depended on all manner of earlier events. Establishing continuities, as Gerschenkron remarks, is the historian's purpose – or, one might add, the economist's, who is doing historian's work when he is not doing philosopher's. The purpose might be to find a cause of, say, the Great Depression. It would be to find a chain of events the absence of which would have made a difference: the international irresponsibility of the United States, for instance, as Kindleberger argued; or the domestic irresponsibility of the Federal Reserve, as Friedman and Schwartz argued. Finding such chains has its own philosophical difficulties (see the article in this Dictionary on "► Counterfactuals)".

The main problems of continuity and discontinuity, however, are not solvable in seminars on philosophy. They are practical problems in the uses of measurement, and must be solved in the economic or historical workshop. When shall we say that the industrial revolution happened? Gerschenkron gives an answer confined to industry, for in common with most economic historians he regards agriculture and services as laggards in economic growth.

> In a number of major countries of Europe . . . after a lengthy period of fairly low rates of growth came a moment of more or less sudden increase in the rates, which then remained at the accelerated level for a considerable period. That was the period of the great spurt in the respective countries' industrial development . . .. The rates and the margin between them in the 'pre-kink' and the 'post-kink' periods appear to vary depending on the degree of relative backwardness of the country at the time of the acceleration. (pp. 33–4)

The level at which such discontinuity is to be observed is at choice. As Gerschenkron remarks,

> If the seat of the great spurt lies in the area of manufacturing, it would be inept to try to locate the discontinuity by scrutinizing data on large aggregate magnitudes such as national income . . .. By the time industry has become bulky enough to affect the larger aggregate, the exciting period of the great spurt may well be over. (pp. 34–5)

In a footnote to these sentences he remarks that 'Walt Rostow's failure to appreciate this point has detracted greatly from his concept of the take-off, which in principle is closely related to the concept of the great spurt as developed by this writer'.

The point is a good one, and applies to all questions of continuity in aggregate economics. Small (and exciting) beginnings will be hidden by the mass until well after they have become routine. Joel Mokyr has put it as a matter of arithmetic: if the traditional sector of an economy is growing at a slow one per cent per annum, and starts with 90 per cent of output, the modern sector growing at four per cent per annum will take three-quarters of a century to account for as much as half of output (1985, p. 5). We may call it the Weighting Theorem (or the Waiting Theorem, for the wait is long when the weight is small to begin with). There are parallel points to be made elsewhere in economics and in social science generally. In growth theory, for instance, as was noticed shortly after its birth, a century of theoretical time is needed in most models for a shift to yield growth as much as 90 per cent of its steady state. More generally, economists have long recognized the tension between microeconomic explanations and the macroeconomic things to be explained. And sociologists have been quarrelling along similar lines for a century, using even the same jargon of micro and macro.

In other words, the search for discontinuity in an aggregate time series raises the question of the level at which we should do our social thinking, the aggregation problem. Yet Gerschenkron himself did not answer the question well, and was hoist by his own petard. Calculating Italian industrial output he placed his 'big spurt' in 1896–1908, and wished to explain it with big banks founded in the 1890s. Stefano Fenoaltea, once his student, applied the Weighting Theorem to the case (Fenoaltea 1987). Surely, Fenoaltea reasoned, the components of the industrial index – the steel output and the chemical output – are the 'real' units of economic analysis (note the similarity of this rhetoric to that advocating a micro foundation for macroeconomics). If the components started accelerating *before* the new banks appeared, becoming bulky only later, then the new banks could not have been the initiating force. Alas, the components did just this. They spoil Gerschenkron's bank-led story: the

components accelerated not in the 1890s but in the 1880s, not after but before the banks. To paraphrase Gerschenkron on Rostow, by the time the progressive components of industry had become bulky enough to affect the larger aggregate, the exciting period was well over.

Yet the moral is still Gerschenkron's: that continuity and discontinuity are tools 'forged by the historian rather than something inherently and invariantly contained in the historical matter . . .. [A]t all times it is the ordering hand of the historian that creates continuities or discontinuities' (p. 38). Gerschenkron nodded, but in nodding made the point. The multiple datings of the industrial revolution make it, too. So does any choice of smoothness or suddenness in economic storytelling.

The point is that history, like economics, is a story we tell. Continuity and discontinuity are narrative devices, to be chosen for their storytelling virtues. Niels Bohr said once that 'It is wrong to think that the task of physics is to find out how nature is. Physics concerns what we can say about nature'. It is *our* say. We can choose to emphasize the continuous: 'Abraham begat Isaac; . . . begat . . . begat . . . and Jacob begat Joseph the husband of Mary, of whom was born Jesus'. Or the discontinuous: 'There was in the days of Herod, the king of Judea, a certain priest named Zacharias.' It is the same story, but its continuity or discontinuity is our creation, not God's. That it is out of God's hands does not make it arbitrary. Scholars speak of the industrial revolution as early or late, gradual or sudden. Other scholars believe or disbelieve their stories on the usual grounds.

Continuous and Discrete Time Models

Christopher A. Sims

Abstract

Most modelling of economic time series works with discrete time, yet time is in fact continuous. While in many instances simple intuitive

connections exist between results with discrete time data and the underlying continuous time dynamics, it is possible for discretization to create bias or have unintuitive effects. Some economics literature investigates such distortions. It is also possible to estimate explicitly continuous-time models, using discrete data. This approach raises its own difficulties, but has become more usable as computing power and the techniques to exploit it have improved.

Discrete time models are generally only an approximation, and the error induced by this approximation can under some conditions be important.

Most economists recognize that the use of discrete time is only as an approximation, but assume (usually implicitly) that the error of approximation involved is trivially small relative to the other sorts of simplification and approximation inherent in economic theorizing. We consider below first the conditions under which this convenient assumption may be seriously misleading. We discuss briefly how to proceed when the assumption fails and the state of continuous time economic theory.

Approximation Theory

Some economic behaviour does involve discrete delays, and most calculated adjustments in individual patterns of behaviour seem to occur following isolated periods of reflection, rather than continually. These notions are sometimes invoked to justify economic theories built on a discrete time scale. But to say that there are elements of discrete delay or time discontinuity in behaviour does not imply that discrete time models are appropriate. A model built in continuous time can include discrete delays and discontinuities. Only if all delays were discrete multiples of a single underlying time unit, and synchronized across agents in the economy, would modelling with a discrete time unit be appropriate.

Nonetheless, sometimes discrete models can avoid extraneous mathematical complexity at little cost in approximation error. It is easy enough to argue that time is in fact continuous and to show that there are in principle cases where use of discrete time models can lead to error. But it is also true in practice that more often than not discrete time models, translated intuitively and informally to give implications for the real continuous time world, are not seriously misleading. The analytical task, still not fully executed in the literature, is to understand why discrete modelling usually is adequate and thereby to understand the special circumstances under which it can be misleading.

The basis for the usual presumption is that, when the time unit is small relative to the rate at which variables in a model vary, discrete time models can ordinarily provide good approximations to continuous time models. Consider the case, examined in detail in Geweke (1978), of a dynamic multivariate distributed leg regression model, in discrete time.

$$Y\ (t) = A^{*}X(t) + U(t), \tag{1}$$

where * stands for convolution, so that

$$A^{*}X(t) = \sum_{s=-\infty}^{\infty} A(s)X(t-s). \tag{2}$$

We specify that the disturbances are uncorrelated with the independent variable vector X, that is, $\mathrm{cov}[X(t), U(s)] = 0$, all t, s. The natural assumption is that, if approximation error from use of discrete time is to be small, $A(s)$ must be

smooth as a function of s, and that in this case (1) is a good approximation to a model of the form

$$y(t) = a^*x(t) + u(t) \tag{3}$$

where

$$a^*x(t) = \int_{-\infty}^{\infty} a(s)x(t-s)ds \tag{4}$$

and y, a and x are functions of a continuous time parameter and satisfy $y(t) = Y(t)$, $x(t) = X(t)$ and $a(t) = A(t)$ at integer t. In this continuous time model we specify, paralleling the stochastic identifying assumption in discrete time, $\text{cov}[x(t), u(s)] = 0$, all t, s. If the discrete model (2) corresponds in this way to a continuous time model, the distributed lag coefficient matrices A(s) are uniquely determined by a and the serial correlation properties of x.

We should note here that, though this framework seems to apply only to the case where X is a simple discrete sampling of x, not to the time-averaged case where $X(t)$ is the integral of $x(s)$ from $t-1$ to t, in fact both cases are covered. We can simply redefine the x process to be the continuously unit-averaged version of the original x process. This redefinition does have some effect on the nature of limiting results as the time unit goes to zero (since the unit-averaging transformation is different at each time unit) but turns out to be qualitatively of minor importance.

Roughly speaking, sampling a unit-averaged process is like sampling a process whose paths have derivatives of one higher order than the unaveraged process.

Geweke shows that under rather general conditions

$$\sum_{s=-\infty}^{\infty} \|A(s) - \tau a(s\tau)\|^2 \to 0 \tag{5}$$

as the time unit τ goes to zero, where $\| \ \|$ is the usual root-sum-of-squared-elements norm. In this result, the continuous time process x and lag distribution a are held fixed while the time interval corresponding to the unit in the discrete time model shrinks.

This is the precise sense in which the intuition that discrete approximation does not matter much is correct. But there are important limitations on the result. Most obviously, the result depends on a in (3) being an ordinary function. In continuous time, well-behaved distributed lag relations like (3) are not the only possible dynamic relation between two series. For example, if one replaces (3) by

$$y(t) = \alpha(\mathrm{d}/\mathrm{dt})x(t) + u(t), \tag{6}$$

then the limit of A in (2) is different for different continuous x processes. In a univariate model with second-order Markov x (for example, one with $\text{cov}\ [x(t), x(t-s)] = (1+\theta|s|)\mathrm{e}^{-\theta|s|}\ \text{var}[x(t)]$, the limiting discrete time model, as τ goes to zero, is

$$\begin{aligned} y(t) = \ & a\{-0.02X(t+4) + 0.06X(t+3) - 0.22X(t+2) \\ & + 0.80X(t+1) - 0.80X(t-1) + 0.22X(t-2) \\ & - 0.06X(t-3) + 0.02X(t-4)\} + U(t) \end{aligned} \tag{7}$$

(see Sims 1971).

This result is not as strange as it may look. The coefficients on X sum to zero and are antisymmetric about zero. Nonetheless, (7) is far from the naive approximation which simply replaces the derivative operator with the first difference operator. In fact, if the estimation equation were constrained to involve only positive lags of X, the limiting form would be

$$\begin{aligned} Y(t) = \alpha\{ & 1.27X(t) - 1.161X(t-1) \\ & + 0.43X(t-2) - 0.12X(t-3) \\ & + 0.03X(t-4) - 0.01X(t-5)\} + U(t). \end{aligned} \tag{8}$$

The naive approximation of (3) by $Y(t) = \alpha[X(t) - X(t-1)] + U(t)$ is valid only in the sense that, if this form is imposed on the discrete model a priori, the least squares estimate of α will converge to its true value. If the resulting estimated model is tested for fit against (8) or (7), it will be rejected.

Although the underlying model involves only the contemporaneous derivative of x, (8) and (7) both involve fairly long lags in X. If x paths have

higher than firstorder derivatives (for example, if they are generated by a third-order stochastic differential equation) the lag distributions in (8) and (7) are replaced by still higherorder limiting forms. Thus, different continuous time processes for x which all imply differentiable time paths produce different limiting discrete A. Here the fact that the time unit becomes small relative to the rate of variation in x does not justify the assumption that approximation of continuous by discrete models is innocuous. In particular, the notion that discrete differencing can approximate derivatives is potentially misleading.

It should not be surprising that the discrete time models may not do well in approximating a continuous time model in which derivatives appear. Nonetheless, empirical and theoretical work which ignores this point is surprisingly common.

If a is an ordinary function, there is still chance for error despite Geweke's result. His result implies only that the mean square deviation of a from A is small. This does not require that individual $A(t/\tau)$'s converge to the corresponding $a(t)$ values. For example, in a model where x is univariate and $a(t) = 0, t < 0, a(0) = 1, a(s)$ continuous on $[0,\infty]$, the limiting value for $A(0)$ is 0.5, not 1.0. Thus, if $a(t) = e^{-\theta tt}$ on $[0, \infty)$, making a monotone decreasing over that range, $A(t)$ will not be monotone decreasing. It will instead rise between $t = 0$ and $t = 1$. This is not unreasonable on reflection: the discrete lag distribution gives a value at $t = 0$ which averages the continuous time distribution's behaviour on either side of $t = 0$. It should therefore not be surprising that monotonicity of a does not necessarily imply monotonicity of A, but the point is ignored in some economic research.

Another example of possible confusion arises from the fact that, if the x process has differentiable paths, $a(t) = 0$ for $t < 0$ does not imply $A(t) = 0$ for $t < 0$. The mean-square approximation result implies that when the time unit is small the sum of squares of coefficients on $X(t - s)$ for negative s must be small relative to the sum of squares on $X(t - s)$ for positive s, but the first few lead coefficients will generally be non-zero and will not go to zero as the time interval goes to zero. This would lead to mistaken conclusions about Granger causal priority in large samples, if significance tests were applied naively.

Geweke's exploration of multivariate models shows that the possibilities for confusing results are more numerous and subtle in that case. In particular, there are ways by which poor approximation of $\alpha_j(s)$ by $A_j(s/\tau)$ in some s interval (for example, around $s = 0$) can lead to contamination of the estimates of other elements of the A matrix, even though they correspond to x_j's and a_j's that in a univariate model would not raise difficulties.

In estimation of a dynamic prediction model for a single vector y, such as a vector autoregression (VAR) or dynamic stochastic general equilibrium model (DSGE), the question for approximation theory becomes whether the continuous time dynamics for y, summarized in a Wold moving average representation

$$y(t) = a^* u(t) \tag{9}$$

has an intuitively transparented connection to the corresponding discrete time Wold representation

$$Y(t) = A^* U(t). \tag{10}$$

In discrete time the $U(t)$ of the Wold representation is the one-step-ahead prediction error, and in continuous time $u(t)$ also represents new information about y arriving at t. There are two related sub-questions. Is the A function the same shape as the a function; and is the U vector related in a natural way to the u vector? The u vector is a continuous time white noise, so that U cannot possibly be a simple discrete sampling of u.

If y is stationary and has an autoregressive representation, then $U(t) = A^{-1} * a * u_t$, with the expression interpreted as convolution in continuous time, but with A^{-1} putting discrete weight on integers. The operator connecting U and u is then $A^{-1} * a$. There are cases where the connection between continuous and discrete time representations is intuitive. For example, if $a(s) = \exp(-Bs)$ (with the exponentiation interpreted as a matrix exponential in a multivariate case), then

$$U(t) = \int_0^1 e^{-Bs} u(t-s)ds \tag{11}$$

and $A(s) = a(s)$ at integers. This is a more intuitive and precise matching than in any case we examined above for projection of one variable on another. If $a(0)$ is full rank and right-continuous at zero and if $a(s)$ is differentiable at all $s > 0$, then a similar intuitively simple matching of A to a arises when the time unit is small enough.

However, non-singularity of $a(0)$ rules out differentiability of time paths for y. When time paths for y, or some elements of it, are differentiable, no simple intuitive matching between A and a arises as the time unit shrinks.

There is one clear pattern in the difference in shape between A and a that stands in contrast to the case of distributed lag projection considered above. If both the continuous time and the discrete time moving average representations are fundamental, then by definition the one-step-ahead prediction error in $y(t)$ based on $y(t-s)$, $s \geq 1$ is

$$\int_0^1 a(s)u(t-s)ds, \tag{12}$$

while the one-step-ahead prediction error in $Y(t)$ based on $Y(t-s)$, $s = 1, 2,...$ is $A_0 Y(t)$. Now the information set we use in forecasting based on the past of Y at integer values alone is smaller than the information set based on all past values of y, so the one-step-ahead error based on the discrete data alone must be larger. If we normalize in the natural way to give U an identity covariance matrix and to make var $(g*u(t)) = \int g(s)g'(s)$ (so u is a unit white noise vector), then it must emerge that

$$A_0 A_0 \geq \int_0^1 a(s)a(s)' ds, \tag{13}$$

where the inequality is interpreted as meaning that the left-hand-side matrix minus the right-hand-side matrix is positive semi-definite. In other words, the initial coefficient in the discrete MAR will always be as big or bigger than the average over (0,1) of the coefficients in the continuous MAR. This tendency of the discrete MAR to seem to have a bigger instant response to innovations is proportionately larger the smoother a is near zero.

More detailed discussion of these points, together with numerous examples, appears in Marcet (1991).

Estimation and Continuous Time Modelling

How can one proceed if one has a model like, say, (6), to which a discrete time model is clearly not a good approximation? The only possibility is to introduce explicitly a model for how x behaves between discrete time intervals, estimating this jointly with (6) from the available data. Doing so converts (6) from a single-equation to a multiple-equation model. That is, the device of treating x as 'given' and non-stochastic cannot work because an important part of the error term in the discrete model arises from the error in approximating $a*x$ by $A*X$. Furthermore, because separating the approximation error component of U from the component due to u is essential, one would have to model serial correlation in u explicitly. The model could take the form

$$\begin{bmatrix} y(t) \\ x(t) \end{bmatrix} = \begin{bmatrix} c(s) & a^* b(s) \\ 0 & b(s) \end{bmatrix} * \begin{bmatrix} w(t) \\ v(t) \end{bmatrix}, \tag{14}$$

where w and v are white noise processes fundamental (in the terminology of Rosanov 1967), for y and x. To give b and c a convenient parametric form, one might suppose them rational, so that (14) can be written as a differential equation, that is,

$$P(D)\, y(t) = P(D)a^* x(t) + w(t) \tag{15}$$

$$Q(D)x(t) = v(t), \tag{16}$$

where P and Q are finite-order polynomials in the derivative operator, $Q^1(D)v = b*v$, and $P^{-1}(D)w = c*w$.

A discrete time model derived explicitly from a continuous time model is likely to be nonlinear at

least in parameters and therefore to be more difficult to handle than a more naive discrete model. However with modern computing power, such models are usable. Bergstrom (1983) provides a discussion of estimating continuous time constant coefficient linear stochastic differential equation systems from discrete data, the papers in the book (1976) he edited provide related discussions, and Hansen and Sargent (1991), in some of their own chapters of that book, discuss estimation of continuous time rational expectations models from discrete data.

Estimating stochastic differential equation models from discrete data has recently become easier with the development of Bayesian Markov chain Monte Carlo (MCMC) methods. Though implementation details vary across models, the basic idea is to approximate the diffusion equation

$$dy_t = a(y_t)dt + b(y_t)dW_t, \tag{17}$$

where W_t is a Wiener process, by

$$y_t = e^{-a(y_{t-\delta})}y_{t-\delta} + b(y_{t-\delta})\varepsilon_t. \tag{18}$$

Such an approximation can be quite inaccurate unless δ is very small. But one can in fact choose δ very small, much smaller than the time interval at which data are observed. The values of y_t at times between observations are of course unknown, but if they are simply treated as unknown 'parameters it may be straightforward to sample from the joint posterior distribution of the y's at non-observation times and the unknown parameters of the model. The Gibbs sampling version of MCMC samples alternately from conditional posterior distributions of blocks of parameters. Here, sampling from the distribution of y at non-observation dates conditioning on the values of model parameters is likely to be easy. If the model has a tractable form, it will also be easy to sample from the posterior distribution of the parameters conditional on all the y values, both observed and unobserved. Application of these general ideas to a variety of financial models is discussed in Johannes and Polson (2006).

Another approach that has become feasible with increased computing power is to develop numerical approximations to the distribution of $y_{t+\delta}$ conditional on data through time t. Ait-Sahalia (2007) surveys methods based on this approach.

Modelling in continuous time does not avoid the complexities of connecting discrete time data to continuous time reality – it only allows us to confront them directly. One reason this is so seldom done despite its technical feasibility is that it forces us to confront the weakness of economic theory in continuous time. A model like (15)–(16) makes an assertion about how many times y and x are differentiable, and a mistake in that assertion can result in error as bad as the mistake of ignoring the time aggregation problem. Economic theory does not have much to say about the degree of differentiability of most aggregate macroeconomic time series. When the theory underlying the model has no believable restrictions to place on fine-grained dynamics, it may be better to begin the modelling effort in discrete time. As is often true when models are in some respect underidentified, it is likely to be easier to begin from a normalized reduced form (in the case the discrete time model) in exploring the range of possible interpretations generated by different potential identifying assumptions.

Recent developments in financial economics have produced one area where there are continuous time economic theories with a solid foundation. Stochastic differential equations (SDEs) provide a convenient and practically useful framework for modelling asset prices. These SDE models imply non-differentiable time paths for prices, and it is known (Harrison et al. 1984) that differentiable time paths for asset prices would imply arbitrage opportunities, if there were no transactions costs or bounds on the frequency of transactions.

However, there are in fact transactions costs and bounds on transactions frequencies, and no-arbitrage models for asset prices break down at very fine, minute-by-minute, time scales. Successful behavioural modelling of these fine time scales requires a good theory of micro-market structure, which is still work in progress.

It is worthwile noting that a process can have non-differentiable paths without producing white

noise residuals at any integer order of differentiation: for example, a model satisfying (3) with $a(s) = s^{0.5}e^{-s}$. Such a process has continuous paths with unbounded variation and is not a semimartingale. That is, it is not the sum of a martingale and a process with bounded variation, and therefore cannot be generated from an integer-order SDE. Similarly, if $a(s) = s^{0.5}e^{-s}$, the process has non-differentiable paths but is nonetheless not a semimartingale. The existence of such non-semimartingale processes and their possible applications to financial modelling is discussed in Sims and Maheswaran (1993).

Continuous-Time Stochastic Models

Robert C. Merton

Models in which agents can revise their decisions continuously in time have proved fruitful in the analysis of economic problems involving intertemporal choice under uncertainty (cf. Malliaris and Brock 1982). These models frequently produce significantly sharper results than can be derived from their discrete-time counterparts. In the majority of such cases, the dynamics of the underlying system are described by diffusion processes, whose continuous sample paths can be represented by Ito integrals. However, in selected applications, this assumption can be relaxed to include both non-Markov path-dependent processes and Poisson-directed jump processes.

An early application of this mode of analysis was the lifetime consumption-portfolio selection problem (Merton 1969, 1971). Under the assumptions of continuous trading and asset returns generated by diffusion processes, the derived structure of optimal portfolio demands produce portfolio-separation or mutual fund theorems like those derived in the static Markowitz–Tobin mean-variance model, but without the objectionable assumption of either quadratic preferences or Gaussian-distributed asset prices. Indeed, in the special, but prototypical, case of lognormally-distributed asset prices, the intertemporal optimal rules are identical to those of the mean-variance model. The continuous-time analysis thus provides a reconciliation of this classic model, with models of general expected utility maximization

in an environment where asset ownership has limited liability.

Using these same assumptions of continuous trading and lognormality of security prices, Black and Scholes (1973) derived a formula for pricing options that provided the foundation for subsequent development, of a unified theory of corporation liability evaluation and general contingent-claim pricing. Cox et al. (1985a) use the continuoustrading methodology with diffusion processes to derive a general theory for the term structure of interest rates.

Building on the continuous-time model of individual choice, Merton (1973), Breeden (1979), and Cox et al. (1985b) develop intertemporal models of equilibrium asset prices. Huang (1985) provides a stronger foundation for these models by showing that if information in an economy with continuous-trading opportunities evolves according to diffusion processes, then equilibrium security prices will also evolve according to diffusion processes.

In the intertemporal version of the Arrow–Debreu general equilibrium model with complete markets, the markets need only to be open 'once' because agents will have no need for further trade. The continuous-trading model is in this respect at the opposite extreme. Economies in which the dynamics of the system are described by diffusion processes will have a continuum of possible states over any finite interval of time. Thus, in the strict sense, to have complete markets in the continuous-time diffusion model requires an uncountable number of pure Arrow–Debreu securities. The continuoustrading model with diffusions, nevertheless, appears to have many of the important properties of the Arrow–Debreu model, but without nearly so many securities.

As is well known, in the absence of complete Arrow–Debreu markets, a competitive equilibrium does not in general produce Pareto optimal allocations. However, Radner (1972) has shown that an Arrow–Debreu equilibrium allocation can be achieved without a full set of pure time-state contingent securities if agents can use the available securities to implement dynamic trading strategies which replicate the payoff structure of the missing pure securities. There is much analysis to suggest that continuous-trading opportunities together with diffusion representations sentations for the evolution of the economy provide a particularly fertile environment for fulfilling the Radner conditions.

Under reasonably general assumptions about agents' preferences and endowments Breeden (1979) among others has shown that the intertemporal equilibrium allocations generated in economies with continuous trading in a finite number of securities can be Pareto efficient. In the analysis of the individual portfolio selection problem underlying these equilibrium models, the derived portfolio-separation theorems show that the set of individually-optimal portfolios can be generated by combinations of relatively few composite securities or mutual funds.

The extensive literature on options and contingent-claims pricing provides further evidence that continuous-trading opportunities make possible a large reduction in the number of securities markets without loss of efficiency. Although typically partial equilibrium in nature, these analyses show that continuous-trading dynamic portfolio strategies using as few as two securities can replicate a wide range of state and time-dependent payoff structures.

In perhaps the most general analysis to date, Duffie and Huang (1985) study the role continuous trading plays in successfully implementing Arrow–Debreu equilibria with infinite dimensional commodity spaces, using only a finite number of securities. In particular, they derive necessary and sufficient conditions for continuous-trading portfolio strategies with a finite number of securities to effectively complete markets in a Radner economy. By working with martingale representation theorems, Duffie and Huang show that the class of dynamics for which these results obtain extends beyond vector diffusion processes to include some non-Markov path dependent processes. They also show that having heterogeneous probability assessments among agents provides no important difficulties with the results, provided all agents' subjective

probability measures are uniformly absolutely continuous. Although there remain further technical issues to be resolved, it is evident that the continuous-trading models provide a strong foundation for the belief that a good substitute for having many markets and securities is to have fewer markets which are open for trade more frequently.

A sketch of the derivation of the portfolio separation theorem along the lines of Merton (1971, 1973, 1982a) and Breeden (1979) is a follows:

At each time t, each consumer-investor acts so as to

$$\text{Max } E_t\left\{\int_t^T U[c(\tau), S(\tau), \tau]d\tau + B[W(T), S(T), T]\right\} \tag{1}$$

where E_t is the conditional expectation operator, conditional on information available at time t. $S(t) = [S_1(t), \ldots, S_m(t)]$ is a finite-m vector set of state variables which together with the consumer's current wealth $W(t)$ is sufficient to describe the state of the economy at time t. $c(t)$ denotes the instantaneous consumption flow selected at time t. U is a strictly concave, statedependent utility function for consumption and B represents utility from bequests at date T.

The evolution of the state variables S is described by a Markov system of Itô stochastic differential equations

$$\mathrm{d}S_i(t) = G_i(S,t)\mathrm{d}t + H_i(S,t)\mathrm{d}q_i, i = 1, 2, \ldots, m \tag{2}$$

where $G_i(S, t)$ is the instantaneous expected change in $S_i(t)$ per unit time at time t, H_i^2 is the instantaneous variance of the change in $S_i(t)$, where it is understood that these statistics are conditional on $S(t) = S$. The $\mathrm{d}q_i$ are Wiener processes with the instantaneous correlation coefficient per unit time between $\mathrm{d}q_i$ and $\mathrm{d}q_j$ given by the function $\eta_{ij}(S, t)$, $i, j = 1, \ldots, m$. At each point in time, the consumer chooses a consumption flow and allocates his wealth among n risky securities and a riskless security whose instantaneous rate of return per unit time is the interest rate $r(t)$. The rate of return dynamics on risky security j can be written as

$$\mathrm{d}P_j/P_j = \alpha_j(S,t)\mathrm{d}t + \sigma_j(S,t)\mathrm{d}z_j, \quad j = 1, 2, \ldots, n \tag{3}$$

where α_j is the instantaneous conditional expected rate of return per unit time; σ_j^2 is the conditional variance per unit time; and $\mathrm{d}z_j$ is a Wiener process. Denote by $\rho_{jk}(S, t)$ the instantaneous correlation coefficient per unit time between $\mathrm{d}z_j$ and $\mathrm{d}z_k$, and denote by $\mu_{ij}(S, t)$ the instantaneous correlation coefficient between $\mathrm{d}q_i$ and $\mathrm{d}z_j$, $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$.

The accumulation equation for the consumer's wealth can be written as

$$\mathrm{d}W = [rW + y - c]\mathrm{d}t + \sum_{j=1}^{n} w_j W\left[\mathrm{d}P_j/P_j - r\ \mathrm{d}t\right] \tag{4}$$

where $y = y(S, t)$ is the consumer's wage income; w_j is the fraction of his wealth allocated to risky security j at time t, and $\left[1 - \sum_j^n w_j\right]$ is the fraction allocated to the riskless asset.

The optimal consumption and portfolio rules, $c^*(W, S, t)$ and $w^*(W, S, t)$, are derived by the technique of stochastic dynamic programming. Among the first-order conditions to be satisfied by these optimal rules are the n conditions for the optimal portfolio holdings at time t, which can be expressed as $j = 1, 2, \ldots, n$

$$0 = \left\{\alpha_j - r - \left(\sum_1^n w_i^*\sigma_i\sigma_j\rho_{ij}W + \sum_1^m A_i\sigma_j H_i\mu_{ij}\right)\Big/K\right\} \times \frac{\partial U}{\partial c}\frac{\partial c^*}{\partial W}W \tag{5}$$

where

$$K \equiv -\partial U/\partial c/\left[\partial^2 U/\partial c^2 \cdot \partial c^*/\partial W\right]$$

and

$$A_i \equiv -\left[\partial c^*/\partial S_i + (\partial^2 U/\partial c \partial S_i)/(\partial^2 U/\partial c^2)\right]/(\partial c^*/\partial W), \quad i = 1, 2, \ldots, m.$$

By inspection, the manifest characteristic of the system of Eq. 5 is that it is linear in the optimal demands for risky assets. Therefore, if none of the risky assets is redundant, then standard matrix inversion can be used to solve Eq. 5 explicitly for these demands. That is,

$$w_j^*(t)W(t) = K\sum_1^n v_{kj}(\alpha_\kappa - r) + \sum_1^m A_i \zeta_{ij}, \quad j = 1, 2 \ldots, , , n \tag{6}$$

where v_{kj} is the $k-j$th element of the inverse of the variance– covariance matrix of returns

$$\left[\sigma_\iota \sigma_j \rho_{ij}\right] \text{ and } \zeta_{ij} \equiv \sum_1^n v_{kj}\sigma_k H_i \mu_{ik}.$$

By inspection, K, A_1,. . ., A_m are the only elements in Eq. 6 that depend on the individual investor's preferences or endowment. As an immediate consequence, it follows that there exist $(m + 2)$ portfolios ('mutual funds') constructed from linear combinations of the available securities such that, independent of preferences, wealth distribution, or planning horizon, all investors will be indifferent between choosing their portfolios from combinations of just these $(m + 2)$ funds or combinations of all n risky securities and the riskless security. This portfolio-separation theorem is, of course, vacuous if $m \geq n + 1$. If, however, $m \ll n$, then it implies a non-trivial reduction in the number of securities required to generate the set of optimal portfolios.

Although not unique, a set of funds which meets the criterion of the theorem is: fund no. 1 holds the riskless asset; fund no. 2 holds fraction $\sum_1^n v_{ki}(\alpha_k - r)$ in security j, $j = 1$,. . ., n and the balance in the riskless asset; for $i = 1, 2$,. . ., n, fund no.$(2 + i)$ holds fraction ζij in security j, $j = 1$,. . ., n and the balance in the riskless asset. Funds nos. 1 and 2, together generate the set of portfolios with maximum expected return for a given variance of the return (i.e. the mean-variance efficient set). Fund no. $(2 + i)$ provides the maximum feasible correlation between its return and the stochastic component of the instantaneous change in state variable $S_i(t)$, $i = 1, \ldots, m$. As discussed in detail in the cited Breeden and Merton papers, these latter portfolios serve the function of providing the best feasible hedges against utility losses caused by unanticipated changes in the state variables of the economy.

In the important case where the set of available securities is such that the return on fund no. $(2 + i)$ is perfectly correlated with the change in state variable $S_i(t)$ for each i, $i = 1, \ldots, m$, Breeden (1979) shows that the resulting intertemporal equilibrium allocations are Paretoefficient. This is also the condition under which it is possible to replicate the payoff structure for the complete set of pure Arrow–Debreu securities using continuous-trading dynamic portfolio strategies with a finite number of securities.

The dynamic strategies for replicating the payoffs to pure Arrow–Debreu securities can be derived in a similar fashion to the derivation of contingent-claim prices in Merton (1977). Suppose that among the available traded securities, portfolios can be constructed whose returns are instantaneously perfectly correlated with changes in each of the state variables, $[S_1(t), \ldots, S_m(t)]$. Without loss of generality, assume that these portfolios are the first m risky securities (i.e. $\mathrm{d}z_i = \mathrm{d}q_i$, $i = 1, 2. . .$, m).

Let $F(S, t)$ satisfy the linear partial differential equation

$$0 = \frac{1}{2}\sum_1^m \sum_1^m H_i H_j \eta_{ij} \frac{\partial^2 F}{\partial S_i \partial S_j} + \sum_1^m \left[G_j - H_j(\alpha_j - r)/\sigma_j\right] \frac{\partial F}{\partial S_j} + \frac{\partial F}{\partial t} - rF \tag{7}$$

subject to the boundary conditions: $0 \leq F(S,t) < \infty$ for all S and $t < \tau$; $F(S, \tau) = \delta\left[\overline{S}_1 - S_1(\tau)\right] \ldots \delta\left[\overline{S}_m - S_m(\tau)\right]$, where $\delta[]$ is the Dirac delta function and $\overline{S}_k$ are given parameters, $k = 1$,. . ., m. Under mid regularity conditions on the functions and r, a solution to Eq. 7 exists and is unique.

Consider the continuous-trading portfolio strategy which allocates fraction $x_j(t) = (\partial F/\partial S_j) H_j/[\sigma_j V(t)]$ to security j, $j = 1,\ldots, m$ and $\left[1 - \sum_1^m x_j(t)\right]$ to the riskless security at time t, where $V(t)$ denotes the value of the portfolio. It follows from Eq. 3 and the prescribed allocation that the dynamics of the portfolio value can be written as

$$\begin{aligned} dV &= V\left\{\left[\sum_1^m x_j(\alpha_j - r) + r\right]dt + \sum_l^m x_j\sigma_j dz_j\right\} \\ &= \left[\sum_1^m \frac{\partial F}{\partial S_j} H_j(\alpha_j - r)/\sigma_j + rV\right]dt + \sum_1^m \frac{\partial F}{\partial S_j} H_j dq_j \end{aligned} \tag{8}$$

because $dz_j = dq_j; j = 1, 2,\ldots, m$.

As a solution to Eq. 7, F is twice-continuously differentiable. Thus, Itô's Lemma can be used to describe the stochastic process for F as

$$\begin{aligned} dF = &\left(\frac{1}{2}\sum_1^m\sum_1^m H_i H_j \eta_{ij} \frac{\partial^2 F}{\partial S_i \partial S_j} + \sum_1^m \left[G_j \frac{\partial F}{\partial S_j}\right] + \frac{\partial F}{\partial S_j}\right)dt \\ &+ \sum_1^m \frac{\partial F}{\partial S_j} H_j dq_j \end{aligned} \tag{9}$$

where F is evaluated at $S = S(t)$ at each time t. Because F satisfies Eq. 7, Eq. 9 can be rewritten as

$$\begin{aligned} dF = &\left[\sum_1^m \frac{\partial F}{\partial S_j} H_j(\alpha_j - r)/\sigma_j + rF\right]dt \\ &+ \sum_1^m \frac{\partial F}{\partial S_j} H_j dq_j. \end{aligned} \tag{10}$$

From Eqs. 8 and 10, $dF = dV = r(F - V)dt$, which is an ordinary differential equation with solution $F[S(t), t] - V(t) = [F(S(0), 0) - V(0)] \exp\left[\int_0^t r(u)du\right]$. If, therefore, the initial investment in the portfolio is chosen so that $V(0) = F[S(0), 0]$ then $V(t) = F[S(t), t]$ for $0 \le t \le \tau$.

Thus, a dynamic portfolio strategy using $(m + 1)$ available securities has been constructed that has a payoff at $t = \tau$ of $\delta\left[\overline{S}_l - S_1(\tau)\right] \ldots \delta\left[\overline{S}_m - S_m(\tau)\right]$. By inspection of this payoff structure, it is evident that this security is the natural generalization of Arrow–Debreu pure state securities to an environment where there is a continuum of states defined by $\overline{S}_k$ and τ. By changing the time and state parameters τ and $\overline{S}_k$, one can generate all of the uncountable number of pure securities. Moreover, F, the solution to Eq. 7 used to implement each strategy, will also be the equilibrium price for the corresponding pure Arrow–Debreu security.

Continuous trading, like any other continuous-revision process, is of course an abstraction from physical reality. If, however, the length of time between revisions is very short, then the continuous-trading optimal solutions will be a reasonable approximation to their discrete-time counterparts (see Samuelson 1970 and Merton 1975b, 1982b). From the work of Magill and Constantinides (1976), this conclusion appears to be robust even in the presence of transactions costs, which cause trading to be discrete almost certainly.

Whether the length of time between revisions is short enough for the continuous solution to provide a good approximation must be decided on a case-by-case basis by making a relative comparison with other time scales in the problem. The continuous-trading assumption appears to be especially appropriate for the analysis of security markets where the aggregate trading volume is large, the minimum unit-size for a transaction is relatively small, and the length of calendar time between successive transactions is quite short.

The continuous analysis may also provide a valid approximation in problems where the calendar length of time between revisions is not short. For example, Bourguignon (1974), Bismut (1975), and Merton (1975a) use this mode of analysis to extend the Solow model of economic growth to an uncertain environment and to analyse the stochastic Ramsey problem. It is the practice in such models to neglect 'short-run' business cycle fluctuations and to assume full employment. Moreover, the exogenous factors usually assumed to affect the time path of the economy in these models are either demographic or technological changes. Since major changes in either factor typically take rather long periods of time, the

length of time between revisions in the capital stock, although hardly instantaneous, may well be quite short, relative to the time scale of the exogenous processes.

Continuous-Time Stochastic Processes

Chi-Fu Huang

Applications of continuous-time stochastic processes to economic modelling are largely focused on the areas of capital theory and financial markets. In these applications as in mathematics generally, the most widely studied continuous time process is a Brownian motion – so named for its early application as a model of the seemingly random movements of particles which were first observed by the English botanist Robert Brown in the 19th century. Einstein (1905), in the context of statistical mechanics, is generally given credit for the first mathematical formulation of a Brownian motion process. However, an earlier development of an equivalent continuous-time process is provided by Louis Bachelier (1900) in his theory of stock option pricing. Framed as an abstract mathematical process, a Brownian motion {B(t); t ∈ R+} is described by the following properties: (1) for $0 : (s \leq t < \infty, B(t) - B(s)$ is a normally distributed random variable with mean zero and variance $t - s$; (2) for $0 \leq t_0 < t_1 < \cdots < t_1 < \infty$,

$$\{B(t_0); B(t_k) - B(t_{k-1}), k = 1, \ldots, l\}$$

is a set of independent random variables.

From this construction, Doob, Feller, Itô, Wiener, among others went on to develop the general theory of continuous-time stochastic processes.

During the half century of this development of the theory, its application in economics was confined primarily to the formulation and testing of hypotheses concerning time series properties of economic variables. It was not until the 1950s and early 1960s that the theory of continuous-time stochastic processes found its way into economic theory. Motivated by the rediscovery of Bachelier's work on options by L.J. Savage, Samuelson (1965) presents a theory of rational warrant pricing. Unlike Bachelier's assumption of a Brownian motion for a stock price process, Samuelson posits that the *logarithm* of a stock price follows a Brownian motion, and thereby, ensures that model stock prices exhibit non-negativity as required by limited liability. This process, called a *geometric Brownian motion* by Samuelson, remains to this day the prototypical process used by economists to describe stock price behaviour. Working with Samuelson, McKean (1965) uses the theory of optimal stopping to provide a rigorous derivation of the warrant price in Samuelson's theory.

Although it is the standard mode of analysis for warrant and option pricing theory today, the celebrated work on the stochastic integration by K. Itô (1944, 1951) was not introduced into economic analysis until the late 1960s. Merton (1969, 1971) was the first to use Itô's stochastic calculus in economics. He analysed an agent's optimal consumption and portfolio policies in a continuous time economy where asset prices are Itô processes.

Itô's contribution to the theory of stochastic processes lies in a definition of an integral with desired properties when the integrator is a Brownian motion. A pathwise definition in the Stieltjes sense may fail since a Brownian motion has sample paths that are nowhere differentiable with probability one. For a classical treatment of the Itô integral, see also Itô and McKean (1965) and McKean (1969). A good reference for modern treatments can be found in Chung and Williams (1983).

Itô's definition of a stochastic integral, in contrast to that of Stratonovich (1966), is much better suited for analysing intertemporal economic decision making. The *non-anticipating* integrand in Itô's definition captures the economic constraint that agents cannot anticipate future speculative price movements.

The most useful result of Itô's stochastic calculus is the so-called Itô's lemma: any twice continuously-differentiable function of an Itô process is itself an Itô process. This implies that the agent's wealth process is an Itô process and therefore the Bellman equation in the stochastic dynamic programming problem becomes a second-order partial differential equation. The latter allows one to analyse the portfolio problem by looking at just the first two moments of price processes and to achieve sharp characterizations. Merton (1973a) applied this technique further to study equilibrium relations among risky asset prices and arrived at the *Intertemporal Capital Asset Pricing Model*.

The introduction of Itô's stochastic calculus opened a whole new world for economists. With it, most of the static utility maximization models are readily extended to a dynamic setting with uncertainty. The continuous time set-up allows one to work with differential equations rather than with difference equations. For applications to capital theory and economic growth, see Bismut (1975), Brock and Magill (1979), and Merton (1975); to asset pricing models, see Cox et al. (1985a, b).

Itô's work was later extended by Kunita and Watanabe (1967) to the case where integrators are square-integrable martingales. They also proved a *martingale representation theorem* for a Brownian motion: any square-integrable martingale adapted to a Brownian motion filtration (see below) is representable as an Itô integral.

The most general notions of a stochastic process and a stochastic integral to date are in the terrain of the so-called *French School Probability Theory*, or the *General Theory of Processes*. Very abstract, and surely developed for intrinsic intellectual reasons, it nevertheless seems to have been

invented for the study of financial markets; for references, see Dellacherie and Meyer (1978, 1982), Jacod (1979), and Meyer (1966, 1976).

Although making no explicit use of French probability theory, the seminal paper of Black and Scholes (1973) in the pricing of stock options nevertheless opens up the possibility of its application in financial economics. This work was subsequently generalized and formalized by Merton (1973b, 1977). The idea is that the payoff of a stock option can be *replicated* by continuous trading in its underlying stock and a riskless asset. The replicating strategy is *self-financing* in that after the beginning of this strategy there are neither additional funds invested into it nor funds withdrawn out of it. Thus, to rule out arbitrage opportunities, the stock option must sell for the exact value of the replicating portfolio at any point in time.

Black and Scholes's theory provided a strong incentive for financial economists to study continuous time stochastic processes. The key observation in this literature was made by Cox and Ross (1976). They noted that since the expected rate of return of the stock does not enter the Black and Scholes pricing formula for a stock option, the price of an option must be determined as if investors were risk neutral and had probability beliefs such that the stock earns an expected rate of return equal to the riskless rate. Harrison and Kreps (1979) formalized this observation in showing that *any* arbitrage-free price system can be converted into a martingale through a change of an equivalent probability after a suitable normalization. Note that this martingale connection of an arbitrage-free price system was vaguely foreshadowed in Samuelson and Merton (1969).

Harrison and Kreps (1979) and Harrison and Pliska (1981) make clear that the answer to whether a contingent claim can be replicated by dynamic trading is intimately related to the martingale representation theorem. A sketch of their arguments will be given.

Taken as primitive is a complete separable probability space $(\Omega, \mathcal{F}, P)$ and a *filtration* $\mathbf{F} = \{\mathcal{F}_t; t \in [0, 1]\}$. A filtration is an increasing family of sub-sigma-algebras of $\mathcal{F}$ representing information revelation over time. For simplicity, we take the time span of the economy to be [0,1]. We assume that agents are endowed with the same information structure **F**. Readers can think of a filtration to be like an event tree in a discrete time finite state setting. We also assume that agents at time zero knows that the true state of the nature is an element $\omega \in \Omega$, which they will learn at time one.

Agents can only consume at time one. For simplicity again, we take the commodity space to be the space of square-integrable random variables defined on $(\Omega, \mathcal{F}, P)$, denoted by $L^2(P)$.

There are $N + 1$ long-lived securities traded indexed by $n = 0, 1, \ldots, N$. A long-lived security is a security available for trading all the time in [0,1] and is represented by a price process. $\{S_n(t)\}$ It pays a dividend only at time one and is equal to $S_n(1)$ almost surely. Price processes are semimartingales (adapted to **F**) and $S_n(1) \in L^2(P)$. In modelling a dynamic asset trading economy, before anything interesting can be said, one has to formulate a budget constraint. That naturally involves stochastic integrals. Jacod (1979) has shown that for stochastic integrals to have desired properties, it is necessary that integrators be semimartingales. Thus, semimartingale price processes can be assumed without loss of generality.

In a Walrasian economy, only relative prices are determined. Thus we can assume that the price system has been normalized such that $S_0(t) = 1$ $\forall t \in [0, 1]$. We will call the 0th security the riskless security and the rest risky securities.

A trading strategy is an $(N + 1)$-dimensional predictable process $\theta = \{\theta_n(t); n = 0, 1, -N\}$, where we interpret $\theta_n(t)$ to be the number of shares of security n held from $t -$ to t before trading at time t. A process is predictable if its values at time t depend only upon the information available strictly before time t. Given the interpretation of θ, predictability is a natural information constraint.

A trading strategy is said to be *simple* if it is bounded and changes its value at most at a finite number of time points in [0,1].

A trading strategy θ; is said to be *self-financing* if the stochastic integral

$$\int_0^t \theta(s)^T ds(s)$$

is well-defined and if

$$\theta(t)^T\, S(t) = \theta(0)^T S(0) + \int_0^t \theta(s)^T \mathrm{d}S(s) \quad \forall t \in [0,\ 1]\ \text{a.s.}, \tag{1}$$

where ^{T} denotes transpose. That is, the value of the portfolio θ at time t is equal to its initial value plus accumulated capital gains or losses from time zero to time t. There are neither new investments into nor withdrawals of funds out of the portfolio. This is just a natural budget constraint.

Harrison and Kreps (1979) and Kreps (1981) show that if all the simple of self-financing trading strategies are allowed and if arbitrage opportunities are absent, then there exists a probability measure Q equivalent to P such that the Radon-Nikodym derivative $\xi \equiv \mathrm{d}Q/\mathrm{d}P$ is an element of $L^2(P)$ and that S is a martingale under Q, or a Q-martingale. Fix Q and note that since P and Q are equivalent, all the *a.s.* statements to follow apply to both.

Now we can specify the space of admissible strategies $\Theta\ [S]$. A self-financing trading strategy θ is admissible if

$$\int_0^t \theta(s)^T \mathrm{d}S(s) \quad t \in [0, 1]$$

is a Q-martingale and $\theta\ (1)^T\ S(1) \in L^2(P)$. [See Jacod (1979) for sufficient conditions for this to be true.] Then one can show that given $\Theta\ [S]$ indeed there are no arbitrage opportunities.

A contingent claim is an element of $L^2(P)$. A contingent claim x is said to be *marketed* if it can be dynamically manufactured by an admissible trading strategy. Formally, x is marketed if there exists $\theta \in \Theta\ [S]$ such that

$$x = \theta(0)^T\ S(0) + \int_0^1 \theta(t)^T \mathrm{d}S(t) \quad a.s.$$

The value of x at time t is $\theta\ (t)^T\ S(t)$. By the definition of admissibility, we have

$$\int_0^t \theta(s)^T \mathrm{d}S = \sum_{n=1}^{N} \int_0^t \theta_n(s)\ \mathrm{d}S_n\ (s). \tag{2}$$

Now here is the key observation. Let x be a contingent claim. We know from relation (2) that if it is marketed, its value over time is equal to its initial value at time zero plus a stochastic integral with respect to N Q-martingales. Conversely, a contingent claim x marketed if the conditional expectation $E^*\ [x \mid \mathcal{F}_t]$, which is a Q-martingale, can be represented by a stochastic integral with respect to the N Q-martingales $\{S_n(t);\ n = 1, 2, \ldots, N\}$. [Here we should remark that any $x \in L^2(P)$ has a finite expectation under Q by the Cauchy–Schwarz inequality.] This observation turns on the machinery of the martingale representation theorem in the study of market completeness.

The security markets are said to be *dynamically complete* if all contingent claims are marketed. From the above discussion, it follows that markets are dynamically complete if all Q-martingales are representable as stochastic integrals with respect to the N risky Q-martingale prices. In such event, the N Q-martingales are said to have the *martingale representation property*. Readers might be curious by now that the riskless asset seems to disappear from the story. Indeed, whether a contingent claim is generated by a (not necessarily self-financing) trading strategy does not depend upon the riskless asset after time zero. The riskless asset, however, is a vehicle through which the budget is balanced over time.

The contribution made by Harrison, Kreps, and Pliska is methodological. They make available a powerful machinery for the study of financial/capital markets: the theory of martingales. Now we shall present some consequences of their work.

Since Merton's (1969, 1971, 1973a) analyses of optimal intertemporal consumption-portfolio policies and their implications on equilibrium asset prices, the conditions under which a price system is representable is an Itô process had been an open question for more than a decade. A short answer found in Huang (1985a) is as follows: Take the set-up of the economy as above and

C

assume henceforth that there are no arbitrage opportunities. Moreover, assume that the information structure **F** is a Brownian motion filtration. We know S is a Q-martingale, so we can write

$$S_n(t) = E^*\left[S_n(1)\middle|\mathcal{F}_t\right] \quad a.s.$$
$$= \frac{E\left[S_n(1)\xi\middle|\mathcal{F}_t\right]}{E\left[\xi\middle|\mathcal{F}_t\right]} \quad a.s.,$$

where the second equality follows from the Bayes' rule, and where we recall that $\xi = \mathrm{d}Q/\mathrm{d}P$, which is strictly positive by the fact that Q and P are equivalent. The numerator and the denominator of the above relation are both P-square integrable martingales. By the martingale representation theorem of Kunita and Watanabe (1967), we know that any P-square integrable martingale is representable as an Itô integral. Then S_n is an Itô process by Itô lemma. Hence any arbitrage-free price system is an Itô process when the information structure is a Brownian filtration.

We can also study the sample path properties of a price system, which relates to examining empirically the so-called *efficient market hypothesis*. Much of the empirical work in financial economics and accounting concerns the response of capital/financial asset prices to information. The null hypothesis in this work is typically that the capital/financial markets are *efficient* in the sense that prices rapidly adjust to *new* information. But is it true that prices only make large adjustments at surprises and what exactly is a *surprise*, mathematically? Here we turn to the classification of stopping times in the general theory of processes. In this context, a surprise is a non-predictable stopping time. We also know that a martingale must be continuous at predictable stopping times (provided that a minor technical condition is satisfied). Thus, S can make discrete changes only at nonpredictable stopping times or at surprises. This and other related issues can be found in Huang (1985a, b). A reference for the classification of stopping times is Dellacherie and Meyer (1978).

So we discover that a price system must be Itô process when the information is a Brownian motion filtration and when there are no arbitrage opportunities. There still remain further questions: does there exist an equilibrium where equilibrium price processes are Itô processes? More importantly, does there exist an equilibrium where although there are only a finite number of long-lived securities traded, the markets are dynamically complete and thus the equilibrium allocation is Pareto optimal? Note that in the Arrow–Debreu equilibrium theory, markets for all contingent claims are available at time zero. Agents trade to a Pareto optimal allocation. There is no need and no incentive for the markets to reopen after time zero. Of course, this does not conform with actual market structures. We do not have a complete set of contingent markets. What we do have are constantly-open financial markets where a finite number of long-lived assets are traded. Thus it is important to know whether there exists an equilibrium in such a world and to know the efficiency of the resulting allocation.

It follows from the earlier discussion on the martingale representation property of risky price processes that what is needed for an affirmative answer to the above questions: is that there be a riskless security with unit price throughout and a finite number of risky long-lived securities that have the martingale representation property. What complicates the story, however, is that the demand and supply of the long-lived securities must be equal in equilibrium. Thus those securities must be picked carefully. Moreover, it is not true that a finite number of martingales having the martingale representation property can always be found. Duffie and Huang (1985, 1986b) and Duffie (1986a), in exchange as well as production economies, demonstrated a procedure to select long-lived securities having the desired properties and conditions under which the number is finite.

The martingale connection of an arbitrage-free system has been generalized to economies where securities can pay dividends and agents can consume at any time in [0,1]. After a suitable normalization, a price system plus the accumulated dividends form a martingale under an equivalent probability measure. This is done in Huang (1985b). Similar theory is also valid in economies where agents have differential information. Interested readers are referred to Duffie and Huang (1986b) for details.

Although the focus of research has been on capital theory and financial markets, applications of the theory of continuous time stochastic processes to economic problems outside these areas can be found. For example, Duffie (1986b) applies classical potential theory as in the context of Markov processes to valuation of securities, and Li (1984) examines the stochastic theory of the firm in continuous time. He uses point processes to model stochastic demands for commodities and endogenizes a firm's demand for inventories, among other things. For applications of the theory of optimal stopping to game theory, see Hugues (1974) for zero-sum stopping games, and Huang and Li (1986) for nonzero-sum stopping games.

Contract Theory

David Martimort

Abstract

This article offers a brief overview of contract. It focuses on the theory of complete contracts and the three associated paradigms of adverse selection, moral hazard and non-verifiability. By showing difficulties in allocating resources between asymmetrically informed partners, contract theory has deeply changed our view of the functioning of organizations and markets.

As with so many major concepts in economics, contract theory was introduced by Adam Smith who, in his monumental *Wealth of Nations* (1776, book III, ch. 2), considered the relationship between peasants and farmers through this lens. For instance, he pointed out the perverse incentives provided by sharecropping contracts, widespread in 18th-century Europe. However, it is fair to say that the issues of incentives and contract theory were largely ignored by economists until the end of the 20th century. By then, the focus of economic theory was on the working of markets and price formation. Firms were viewed only as production technologies, and the issue of the separation between ownership and control was most often put aside. This black-box approach was, of course, quite unsatisfactory. At the turn of the 1970s, with the methodological revolution of game theory, more emphasis was placed on strategic interactions between a small number of players in a world where informational problems matter. From this new perspective, the allocation of resources is no longer ruled by the price system but by *contracts* between asymmetrically informed partners. Contract theory has deeply changed our view of the functioning of organizations and markets.

This article aims to provide a brief overview of contract theory, stressing a few major insights and illustrating them with useful applications. Due to space constraints, it does not do justice to several aspects of contract theory, and will mostly reflect my own tastes in the field. In particular, I focus on the so-called *theory of complete contracts*, leaving

aside the burgeoning theory of incomplete contracts which is covered elsewhere in this dictionary. Successive sections deal respectively, with adverse selection, moral hazard and non-verifiability: the three different paradigms which have been used in the field of complete contract theory. Since the distinction between complete and incomplete contracts is easier to draw once these notions have already been explained, I will postpone such discussion to the end of the article.

Adverse Selection

Consider the following buyer–seller relationship as the archetypical example of contractual relationship between a principal (the buyer) and his agent (the seller) who produces some good or service on his behalf. The mere delegation of this task to the agent gives the agent access to private information about the technology. This *adverse selection* environment is captured by assuming that a technological parameter θ is known only by the agent. It is drawn from a distribution in an exogenous type space Θ which is common knowledge. Neither the principal nor a court of law observes this parameter. Contracts cannot specify outputs and prices as a function of the realized state of nature.

The buyer enjoys a net benefit $S(\theta, q) - t$ when buying q units of output at a price t. The seller enjoys a profit $t - C(\theta, q)$ from producing that good. We will assume that these functions are concave in q. Notice that the state of nature θ might affect both the agent's and the principal's utility functions. This can, for instance, be the case if this parameter also determines the quality of the good to be traded.

Under complete information, efficiency requires that the buyer and the seller trade the first-best quantity $q^*(\theta)$ such that the buyer's marginal benefit from consumption equals the seller's marginal cost of production:

$$\frac{\partial S}{\partial q}(\theta, q^*(\theta)) = \frac{\partial C}{\partial q}(\theta, q^*(\theta)). \tag{1}$$

Many mechanisms or institutions lead to this outcome. Both the price mechanism and a take-it-or-leave-it offer by one party to the other would achieve the same allocation, although with different distributions of the surplus between the traders. If the principal retains all bargaining power (for instance, because there is a competitive fringe of potential sellers), he could offer a forcing contract stipulating an output $q^*(\theta)$ and a transfer $t^*(\theta)$ which just covers the seller's cost. This forcing contract maximizes the buyer's net gains from trade and leaves the seller just indifferent between participating or not.

In what follows, we mostly focus on the case where the uninformed principal has full bargaining power in contracting. In this framework, the *contract* between the buyer and the seller does not only have the allocative and distributive roles it has under complete information. It also has the role of *communicating information* from the informed party to the uninformed party. This communication role suggests that the informed party should be given a choice among different options and that this choice should reveal information about the adverse selection parameter.

A first step in the analysis consists of describing the set of allocations which are feasible under asymmetric information. The basic tool for doing so is the revelation principle (see Gibbard 1973; Green and Laffont 1977; Dasgupta et al. 1979; Myerson 1979, among others), which states that there is no loss of generality in restricting the analysis to *revelation mechanisms* that are *direct*, that is, of the form $\left\{t\left(\hat{\theta}\right); q\left(\hat{\theta}\right)\right\}_{\hat{\theta} \in \Theta}$ with $\hat{\theta}$ a message ('report') sent by the informed seller to the uninformed buyer, and *truthful*, that is, such that the agent finds it optimal to report his true type.

Therefore, incentive feasible contracts satisfy the following *incentive* constraints

$$\begin{aligned} &t(\theta) - C(\theta, q(\theta)) \geq t\left(\hat{\theta}\right) \\ &- C\left(\theta, q\left(\hat{\theta}\right)\right) \forall \left(\theta, \hat{\theta}\right) \in \Theta^2. \end{aligned} \tag{2}$$

To be acceptable, a contract must also satisfy the seller's participation constraints

$$t(\theta) - C(\theta, q(\theta)) \geq 0 \quad \forall \theta \in \Theta \tag{3}$$

which ensure that, irrespective of his type, the agent by contracting gets at least his reservation payoff (exogenously normalized to zero).

Once the set of incentive feasible allocations is described, the analysis may proceed further. Keeping in mind that the uninformed buyer designs his offer under asymmetric information, we might characterize an *optimal contract*. Such a contract maximizes the uninformed buyer's expected net surplus subject to the feasibility constraints (2) and (3).

Much of the theoretical literature developed over the 1980s and early 1990s has investigated the structure of the set of incentive feasible allocations and its consequences for optimal contracting. A key property is the so-called Spence–Mirrlees condition (see Spence 1973, 1974; Mirrlees 1971) for early contributions which put forward that condition). This condition is satisfied when the slope of the agent's indifference curves can be ranked with respect to his type. In our example, this condition holds when $\frac{\partial^2 C}{\partial \theta \partial q} > 0$, that is, when higher types also have higher marginal costs and should thus produce less. Therefore, the monotonicity condition

$$q(\theta) \geq q(\theta') \quad \text{for } \theta \leq \theta' \tag{4}$$

is a direct consequence of the incentive constraints. The Spence–Mirrlees condition can be viewed as a regularity assumption making the incentive problem well-behaved. It ensures that only incentive constraints between 'nearby' types matter in the optimization. Intuitively, this means that the seller with a given marginal cost may be tempted to overstate slightly its costs, receiving the higher transfer targeted to less efficient types but producing at a lower marginal cost. By so doing, this more efficient type receives an information rent. Once these local constraints are taken into account and when the Spence–Mirrlees condition holds, the incentives to mimic more distant types are no longer relevant. With this reduction of the set of relevant incentive constraints, the principal's optimization problem is significantly simplified.

The result of this optimization is straightforward. Inducing information revelation by the most efficient types requires giving up an *information rent* to those types. The basic intuition of most adverse-selection models is that reducing this rent requires production to be distorted. For instance, when efficient types want to mimic less efficient ones, the latter's allocation should be made less attractive. This is obtained by distorting their production downward and modifying transfers accordingly.

To see more formally the nature of the output distortion, consider the case where types are distributed over a compact set $\left[\underline{\theta}, \overline{\theta}\right]$ according to the cumulative distribution function $F(\cdot)$ (with a positive density $f(\cdot)$). The second-best optimal output $q^{SB}(\theta)$ under adverse selection is the solution to:

$$\frac{\partial S}{\partial q}\left(\theta, q^{SB}(\theta)\right) = \frac{\partial C}{\partial q}\left(\theta, q^{SB}(\theta)\right) + \frac{F(\theta)\partial^2 C}{f(\theta)\partial q \partial \theta}\left(\theta, q^{SB}(\theta)\right). \tag{5}$$

Condition (5) states that, for any type θ, the buyer's marginal benefit must equal the seller's *marginal virtual cost* (see Laffont and Martimort 2002, chs 2 and 3, for details). The virtual cost of a given type takes into account not only its cost of production but also the cost of deterring other types (here more efficient types) from mimicking that type. The allocation is no longer efficient, as under complete information, but *interim efficient* in the sense of Holmström and Myerson (1983).

Condition (5) is crucial, and is found in various forms in any adverse-selection model. It states that, under asymmetric information, there is a fundamental trade-off between implementing allocations close to efficiency and giving information rents to the most efficient types to induce information revelation. This trade-off calls for distortions away from efficiency.

Provided that the output schedule defined by (5) satisfies the monotonicity condition (4), this is the exact solution of our problem. To guarantee monotonicity, on top of assumptions on the concavity of $S(\cdot)$ and $\frac{\partial S}{\partial \theta}(\cdot)$, convexity of $C(\cdot)$ and $\frac{\partial C}{\partial \theta}(\cdot)$, $\frac{\partial^2 C}{\partial \theta \partial q}(\cdot) > 0$, $\frac{\partial^3 C}{\partial \theta^2 \partial q}(\cdot) > 0$ and $\frac{\partial^2 S}{\partial \theta \partial q}(\cdot) < 0$,

one needs also to impose a property on the type distribution, the so-called *monotonicity of the hazard rate* $\frac{F(\theta)}{f(\theta)}$ (see Bagnoli and Bergstrom 2005). Otherwise, the optimal contract may entail some area of pooling such that all types belonging to a set with positive measure produce the same amount and are paid the same price. The optimal solution may then be obtained using 'ironing techniques' (see for instance Guesnerie and Laffont 1984).

Direct Extensions

Adverse-selection methodology has been successfully extended in various directions allowing for multidimensional types (Armstrong and Rochet 1999), and/or multiple outputs (Laffont and Tirole 1993, ch. 3), and type-dependent reservation utilities (Lewis and Sappington 1989; Jullien 2000). There, the analysis is substantially more complex as types can no longer be ranked as easily as in the model sketched above. The Spence–Mirrlees condition might fail to hold and global incentive constraints may bind, leading to pooling allocations being optimal. Another interesting extension is the case of hidden knowledge, in which contracting takes place before the agent becomes informed. The logic of such models is very close to that we discuss below in the section on moral hazard. In a nutshell, the trade-off between allocative efficiency and rent extraction is now replaced by the trade-off between insuring the agent against shocks on costs and inducing him to reveal his cost once it is known. Output distortions still arise (see Laffont and Martimort 2002, ch. 2, for details). Others have endogenized the asymmetric information structure and examined the incentives to learn about the unknown parameter (see, for instance, Crémer et al. 1998). Finally, there exists a literature that considers the case where the principal is the informed party (Maskin and Tirole 1990, 1992). New difficulties arise from the fact that the mere offer of the contract may signal information.

Multi-agent Organizations

The most important extensions of the adverse selection paradigm certainly concern multi-agent organizations. Such complex organizations emerge because of the need to share common resources, produce public goods, internalize production externalities or enjoy information economies of scale. Although any such reason calls for a specific analysis, a few common themes of the literature can be highlighted by remaining at a rather general level.

Regarding the implementation concept, different notions of incentive compatibility may be used depending on the context. First, agents may know each other's types and play a Nash equilibrium of the direct revelation mechanism offered by the principal (see Maskin 1999, and the discussion of the non-verifiability paradigm below). Second, agents may only know their own type, form beliefs on each others' types and play a Bayesian–Nash equilibrium (see D'Aspremont and Gérard-Varet 1979). Third, one may also insist on dominant strategy implementation because it does not depend on the specification of beliefs (see Gibbard 1973; Groves 1973; Green and Laffont 1977). To each implementation concept corresponds a notion of incentive feasibility. Once the set of incentive feasible contracts is defined, one can proceed to optimization. It is a trivial observation that, the more restrictive the implementation concept, the lower is the principal's payoff at the optimum.

In some cases, such as the provision of public goods within a society of privately informed agents or in bargaining models between a buyer and a seller with equal bargaining power, the goal is no longer to design a multilateral contract which would extract the rents of all agents but, instead, to maximize some *ex ante* efficiency criterion under incentive constraints. Groves (1973) showed that dominant strategy mechanisms suffice to implement the first-best decision in a public good context. One caveat is that the budget generally fails to be balanced. D'Aspremont and Gérard-Varet (1979) proposed a Bayesian incentive-compatible mechanism which implements the first-best and still satisfies budget balance. As argued by Laffont and Maskin (1979), such a mechanism may conflict with the agents' participation constraint. In a bargaining environment, Myerson and Satterthwaite (1983) showed in a similar vein

that there exists no Bayesian bargaining mechanism that is efficient, budget-balance and individually rational.

The optimal multilateral contract can be very sensitive to the information structure. In environments where risk-neutral agents have correlated types but know only their own type, the principal can condition one agent's compensation on another's report. By doing so, the principal can fully extract the rent from both agents in a Bayesian-Nash equilibrium. One may view this result as a strong rationale for relative performance evaluation, yardstick competition, benchmarking and internalization of similar activities within the same organization. This puzzling insight of Crémer and McLean (1988) no longer holds when one introduces risk-aversion, *ex post* participation constraints or limited liability constraints. These assumptions reintroduce information rents in the multi-agent organization, and the standard trade-off between efficiency and rent extraction reappears.

When the agents' types are independently distributed, yardstick competition is ineffective and the agents derive information rents. However, the externality that one agent's task may exert on another can shape the distribution of these rents. In competitive environments, such as procurement auctions among sellers, it is no longer the distribution of the agents' marginal costs but the distribution of their virtual marginal costs (see Myerson 1981) which determines who should produce and how much. Because virtual costs may be ranked differently from true costs, inefficiencies arise under asymmetric information. Moreover, competition may help reduce rents by putting each agent under the threat of being excluded from production if he overstates his cost too much. There is then a positive externality among competing agents.

Instead, more cooperative environments, such as public good problems or procurement of complementary inputs by several suppliers, involve negative externalities between agents. Given that each agent has a limited impact on the organization's overall production, the incentives to overstate costs and thereby receive greater transfers are exacerbated. 'Free riding' arises in such organizations (see Mailath and Postlewaite 1990).

When competition between agents or between agents and the supervisors supposed to monitor them would benefit the principal, one must consider the possibility of collusion aimed at securing more rent. Reducing the scope for collusion requires using mechanisms that are less sensitive to information and reducing supervisory discretion. Incentive contracts look more like inflexible bureaucratic rules (see Tirole 1986; Laffont and Martimort 2000). The optimal response to collusion may also entail more delegation to lower levels of the hierarchy, as in Laffont and Martimort (1998) and Faure-Grimaud et al. (2003).

Dynamics

Different extensions of the static framework correspond to different abilities of the contractual partners to commit themselves inter-temporally and/or different ways for the cost parameters to vary over time. Under full commitment, the lessons of the static rent-efficiency trade-off can be easily extended, although the precise features of the optimal contract depend on how types evolve over time (see, for instance, Baron and Besanko 1984, for the case of persistent types). The case of limited commitment is more interesting. Long-term contracts may either be renegotiated (Dewatripont 1989; Hart and Tirole 1988; Laffont and Tirole 1990) or even are not feasible, in which cases the parties resort to spot contracts (Laffont and Tirole 1988). The rent-efficiency trade-off must be adapted to take into account how information is revealed progressively over time. However, the basic idea still holds. As past performances reveal information about the agent's type, the optimal contract trades off *ex post* efficiency gains in contracting against the agent's desire to hide information in the earlier periods of the relationship so as to secure more rent in the later periods.

Applications

Since the mid-1980s, models of optimal contracting under adverse selection have spanned the economic literature. Let us quote only a few major applications. Mirrlees (1971) analysed optimal taxation schemes when the agent's productivity is privately observed. He introduced the Spence–Mirrlees

condition and derived the implementability conditions. He also used optimal control techniques (Pontryagyn Principle) to compute the optimal taxation scheme. (The taxation problem differs from our buyer–seller example because participation in the mechanism is mandatory and the state's budget constraint must be added to the characterization of feasible allocations.)

Mussa and Rosen (1978) studied the problem of a monopolist selling one unit of a good to a continuum of consumers vertically differentiated with respect to their willingness to pay for the quality of this good. This was the first model using adverse selection techniques in a framework without income effect. Maskin and Riley (1984) were interested in characterizing the optimal nonlinear price used by a monopolist in a second-degree price discrimination context.

Baron and Myerson (1982) applied the methodology to the regulation of natural monopolies privately informed about their marginal costs of production. Laffont and Tirole (1986) extended this analysis to allow for cost observability but also introduced moral hazard elements (the possibility for the regulated firm to reduce its costs by undertaking some non-observable effort). They derived cost-reimbursement rules and pricing policies. They showed that menus of linear contracts might implement the optimal contract.

Green and Kahn (1983) and Hart (1983) studied labour market contracts and discussed distortions towards overemployment or underemployment that may arise depending on the contractual environment considered.

Finally, Townsend (1979) and Gale and Hellwig (1985) analysed optimal financial contracts in a framework where the borrower's income is observable only *ex post* and at a cost. Optimal contracts may look like debt in such environments.

Moral Hazard

To return to our buyer–seller example, we now assume that there is only one unit of a good to be traded whose quality q is random and which yields a surplus $S(q)$ to the buyer. The distribution of quality is affected by an effort e undertaken by the agent at a cost $\psi(e)$ (where $\psi' > 0$ and $\psi'' > 0$). The cumulative distribution is $F(q|e)$ (with density $f(q|e)$) on a support $Q\ [\underline{q}, \overline{q}]$ independent of the agent's effort. To simplify, the agent's preferences are separable in money and effort: $U = u(t) - \psi(e)$ where $u(\cdot)$ is increasing and concave ($u' > 0$, $u'' \leq 0$). The agent's outside option is not to produce, which gives him a payoff normalized to zero.

The agent's effort is observable neither by the principal nor by a court of law. This is a *moral hazard* setting. Contracts stipulate the agent's payment as a function of the realized quality assumed to be observable and verifiable (contractible) by a court of law. Therefore, contracts are of the form $\{t(\tilde{q})\}_{\tilde{q} \in Q}$.

If the effort were observable, its value could also be specified by contract. Therefore, the seller can at the same time be forced to exert the first-best level of effort and be fully insured against uncertainty on realized quality with a flat payment independent of his performance:

$$u(t^*) = \psi(e^*).$$

This is no longer the case when the agent's effort is non-verifiable. The first step of the analysis is to describe the set of feasible incentive contracts implementing a given level of effort e.

In a moral hazard setting, incentive constraints write as:

$$\int_{\underline{q}}^{\overline{q}} u(t(q)) f(q|e) dq - \psi(e) \geq \int_{\underline{q}}^{\overline{q}} u(t(q)) f(q|e') dq - \psi(e') \quad \forall (e, e'). \quad (6)$$

The agent's participation constraint is:

$$\int_{\underline{q}}^{\overline{q}} u(t(q)) f(q|e) dq - \psi(e) \geq 0. \quad (7)$$

Risk Neutrality

A first case of interest is when the agent is risk-neutral ($u(t) \equiv t$). The simple 'sell-out' contract, $t(q) = S(q) - C$ where C is a constant, implements

the first-best level of effort e^*. Provided that $\int_{\underline{q}}^{\overline{q}} S(q) f(q|e^*) - \psi(e^*)$, this scheme also extracts all the surplus from the agent who is just indifferent between producing or not.

Intuitively, with such a 'sell-out' contract, the agent's private incentives to exert effort are aligned with the social incentives. This efficient outcome is obtained by, first, having the agent pay a bond worth C for the right to serve the principal, and second, having the principal pay an amount $S(q)$ contingent on the quality realized.

Such a 'sell-out' contract requires that the agent bears the full consequences of a bad performance. It might not be feasible when the agent has limited liability and cannot be punished for bad performances. (For details, see Laffont and Martimort 2002, ch. 4). The conjunction of moral hazard and limited liability allows the agent to derive a limited liability rent. Intuitively, only rewards, not punishments, can be used to provide incentives, and this restriction on instruments is costly for the principal. This rent creates a trade-off between efficiency and rent extraction, as in the adverse selection framework. Effort is distorted below the first-best level.

Risk Aversion

Let us turn to the more complex case of risk aversion. A first concern of the literature has been to 'simplify' the set of incentive constraints (2) by replacing it with a first-order condition:

$$\int_{\underline{q}}^{\overline{q}} u(t(q)) f_e(q|e) dq = \psi'(e). \tag{8}$$

Denoting by λ (resp. μ) the positive multiplier of the incentive (resp. participation) constraint (8) (resp. (7)), the optimal second-best schedule $t^{SB}(q)$ satisfies

$$\frac{1}{u'(t^{SB}(q))} = \mu + \lambda \frac{f_e(q|e)}{f(q|e)}. \tag{9}$$

This condition yields two important insights. First, the contract must simultaneously provide the risk-averse agent with insurance, which requires a fixed payment, and with incentives to exert effort, which requires that payments be linked to performance. There is now a trade-off between *insurance* and *incentives*.

Second, the monotonicity of the agent's compensation with respect to the quality level (a priori a quite intuitive property) is obtained only when the *monotone likelihood ratio property* holds, namely, when $\frac{\partial}{\partial q}\left(\frac{f_e(q|e)}{f(q|e)}\right) > 0$. This property means that higher levels of performance are more informative about the agent's effort.

Finally, the optimal contract must use all signals which are informative about the agent's effort but no uninformative signals. Using them would only let the agent bear more risk without any beneficial impact on incentives. This is the so-called informativeness principle of Holmström (1979).

Extensions

In a model with a finite number of quality and effort levels, Grossman and Hart (1983) offered a careful study of the set of incentive constraints and its consequences for the shape of optimal contracts. There is no general result on the ranking between the first-best and the second-best effort levels in such environments. The discrete version of the first-order approach requires that only nearby constraints matter in the agent's problem. This concavity of the agent's problem is ensured when $F(q|e)$ is itself convex in q. In models with a continuum of effort levels and outcomes, this first-order approach was suggested in Mirrlees (1999), more rigorously justified in Rogerson (1985) and Jewitt (1988) and applied in Holmström (1979) and Shavell (1979).

The moral hazard methodology has been used to justify the optimality of linear incentive schemes in well-structured environments (Holmström and Milgrom 1987); an often found feature of real world contracts. Equipped with this tool, Holmström and Milgrom (1991, 1994) investigated how multiple tasks and jobs should be arranged in an organization.

To avoid the complexity of models with a continuum of effort levels, modellers have found it useful to focus on simplified environments with two levels of effort. This approach was

instrumental in the work on corporate finance of Holmström and Tirole (1997).

Multi-agent Organizations

When applied to multi-agent organizations, the 'informativeness principle' suggests that an agent's compensation should be linked to another's performance if it is informative about his own effort (see Mookherjee 1984). Relative performance evaluation and benchmarking can help eliminate common shocks affecting all agents' performances. Of particular importance in this respect are tournaments which use only the ranking of the agents' performances to determinate their compensations. Tournaments provide agents with insurance against common shocks, which has a positive incentive effect. More generally, the properties of tournaments and how they compare with (a priori suboptimal) linear schemes have been investigated in Nalebuff and Stiglitz (1983) and Green and Stokey (1983).

In more cooperative environments where different agents contribute to a joint project, the fundamental difficulty is how to share the proceeds of production among agents of the team and still provide some incentives. Since each agent enjoys only a fraction of those proceeds but bears the full cost of his effort, he reduces his effort supply. This leads to a free-rider problem within teams, which is analysed in Holmström (1982).

If we remain in cooperative environments but allow now for a principal acting as a budget breaker, this principal may find it worthwhile to reduce the agency cost of implementing a given effort profile by having agents behave cooperatively (Itoh 1993). Even when agents do not cooperate, mutual observability of effort levels can also help to eliminate agency cost, as in Ma (1988). This last argument relies on the logic of non-verifiability models, developed below.

Dynamics

The basic issue investigated by dynamic models of moral hazard is the extent to which repeated relationships alleviate the moral hazard problem. The intuition is that the principal should filter out the agent's effort by looking at the whole history of his performances. This may eliminate any agency problem, at least when parties do not discount too much the future (see Laffont and Martimort 2002, ch. 8, for an example). More generally, the insurance–incentives trade-off may be relaxed when the risk-averse agent's rewards and punishments can be smoothed over the whole relationship, as shown in Spear and Srivastava (1987). A direct consequence of inter-temporal smoothing is that the optimal dynamic contract exhibits *memory*; good (resp. bad) performance today will also affect positively (resp. negatively) future compensations. This insight has been used to formalize a theory of the wage dynamics inside the firm (Harris and Holmström 1982).

Fama (1980) argued that reputation in the labour market exerts enough discipline on managers to alleviate moral hazard even in the absence of explicit contracts. Holmström (1999) built a model of career concerns where the manager's interest in influencing the labour market's beliefs concerning his or her quality provides incentives to exert effort. Career concerns are nevertheless in general not enough to induce first-best effort levels, and some inefficiencies remain.

Non-verifiability

Let us return to the buyer–seller model above. Although we now assume that it is observable by both the principal and the agent, the state of nature θ may still not be verifiable by a court of law, in which case it cannot be part of the contract. This shared knowledge stands in sharp contrast with the asymmetric information structures examined in previous sections.

The first difficulty consists of building a mechanism based only on verifiable variables (namely, the quantities traded and corresponding payments) which implements the first-best quantity $q^*(\theta)$ and transfers $t^*(\theta)$. This problem was addressed by Maskin (1999). He demonstrated that the first-best quantities and transfers can easily be implemented with a direct revelation mechanism $\left\{t\left(\hat{\theta}_a, \hat{\theta}_b\right), q\left(\hat{\theta}_a, \hat{\theta}_b\right)\right\}_{\left(\hat{\theta}_a, \hat{\theta}_b\right) \in \Theta^2}$ where both the buyer and the seller report

simultaneously the state of nature they commonly know. Truth-telling is obviously a Nash equilibrium of this mechanism provided that both traders are severely punished when making different reports, since such cases would be inconsistent with the underlying information structure.

A more subtle issue is how to design a mechanism such that this truthful Nash equilibrium is unique. Maskin (1999) proposed a condition for players' preferences such that this is the case. Moore and Repullo (1988) significantly extended the domain of preferences by hardening the implementation concept, replacing Nash behaviour by subgame-perfection in a sequential moves mechanism (see Laffont and Martimort 2002, ch. 6, for an example, and Moore 1992, for an exhaustive survey of the literature).

The basic thrust of the non-verifiability paradigm is that a court of law can get around non-verifiability by building such revelation mechanisms, at least as long as the non-verifiable state is payoff-relevant. If one sticks to that interpretation, non-verifiability does not present a significant limit on contracting.

A second issue of the literature is the impact of non-verifiability on the incentives of traders to perform specific and non-verifiable investments. Given our previous claim that non-verifiability is generally not a constraint, the model resembles the standard moral hazard model. Providing incentives for investments meets the same difficulties as in the previous section.

Extensions

In practice, revelation mechanisms have been criticized as overly complex, as relying on threats which may either be non-credible or violate limited liability constraints. The so-called incomplete contracts literature has thus focused on cases where such revelation mechanisms are not feasible. In such environments, either no contract at all or only a very rough one can be written *ex ante*. For instance, parties can agree *ex ante* on a simple fixed-price/fixed quantity contract which serves as a threat point for the bargaining which takes place *ex post* when the state of nature is realized (see Edlin and Reichelstein 1996, among others).

Alternatively, this threat point may be determined by the allocation of ownership rights where such a right gives the owner the opportunity to use assets as he prefers in case bargaining fails (see Grossman and Hart 1986; Hart and Moore 1988). The issue is then to derive from those exogenous constraints distortions of investments and optimal organizations which may mitigate those distortions.

The incomplete contracts paradigm is similar to the complete contracts one (adverse selection, moral hazard and non-verifiability) in the sense that it also imposes limits on what a court may verify. It differs from it because it also imposes exogenous restrictions on the set of mechanisms available to the parties. The justification for these restrictions is found either in the bounded rationality of players or the difficulties in describing or foreseeing contingencies, all theoretical issues which remain high on the agenda of economic theorists and are still unsettled. The relevant literature on incomplete contracts is too large to be summarized in this short article. The interested reader may refer to Tirole (1999) for an overview or to the entry for this term in this Dictionary.

Contracting in Firms

Canice Prendergast

Abstract

This article provides an overview of recent advances in theoretical and empirical work on incentive contracting in firms. The specific focus is on a variety of reasons why the prediction of the early literature on contracting –suggesting a strong relationship between performance and pay – has not been borne out.

In many realms of economic life, the actions of individuals affect the welfare of others. Nowhere is this more relevant than in firms, where employees act on behalf of owners or shareholders to provide services for customers and clients. This separation of the interests of employees from those whose actions they benefit has generated a large literature on incentive contracting, where the overarching objective is the alignment of such interests. The early literature on agency theory, described in the first edition

of this volume by Lazear (1987), conceptually mimics that on externalities – the other area of economics that deals with welfare consequences of actions on others – by showing a variety of ways in which the compensation of agents can be constructed to internalize the effects on one's actions on others. There are two ways of doing this. First, one could simply tell employees what to do and to penalize them if they fail to do so. In the literature, this is referred to as input monitoring. While this can sometimes help, it is often hard to monitor either what workers do, or the intensity with which they do so – a salesman on the road would be a good example. Similarly, while overseers can sometimes identify what it is that agents are doing, they may not know what they *should* be doing – a board of directors monitoring a CEO would be apposite here. Accordingly, the second solution to misaligned incentives is to design compensation plans such that the agent's pay depends on her contribution – 'output' – so that the concerns of other parties are internalized.

A simple model can illustrate this point, and is useful to describe other complications that can arise. The agent is assumed to take some action ('effort') $e \geq 0$, which is unobserved by the principal. She is averse to exerting effort. Consider a simple parameterization of the agent's utility function, where the agent cares about wages w and effort; assume that the agent has exponential utility $V = -\exp[-r(w - C(e))]$, where w is the worker's wage, $r \geq 0$ is the constant rate of absolute risk aversion, the worker's cost of supplying effort is $C(e) = \frac{ce^2}{2}$, and her reservation utility is U^*. To focus attention on the role of output contacting, assume that the principal cannot observe effort e (so monitoring of inputs is not possible), but instead only observes a signal on effort $y = e + \varepsilon$, where $\varepsilon \sim N(0, \sigma^2)$, with σ^2 representing measurement error. Assume also that the principal chooses to reward the agent in a linear fashion on output – a piece rate: $w = \beta_0 + \beta_{yy}$ (There is a large literature on the optimal shape of compensation contracts – see Prendergast 1999; Gibbons 1996, for an overview). Then there is a simple solution to attaining efficient effort: choose the contact to internalize the benefit to others by setting $\beta_y = 1$. In words, efficiency arises when the agent is residual claimant on the benefit of others.

This solution, providing a simple prescription for how compensation contacts should be designed, is both simple and intuitive. And empirically false. There are, of course, some occupations where one can find evidence of such 'high-powered incentives', where agents are essentially residual claimants on output. Indeed, the literature on agency theory is replete with references to such occupations – taxi cab drivers, franchisees, sharecropper farmers and the self-employed. Yet these are exceptions; instead, 'low-powered incentives' in firms are more the norm (see Prendergast 1999, for details). Consequently, one of the quandaries of the literature has become why so few workers seem to have contracts where their pay is strongly linked to their performance, and much of the subsequent literature to that outlined in the first edition of the *New Palgrave* has identified relevant constraints on incentive contracting.

The earliest candidate to explain why high-powered incentives are rare is that high-powered contracts impose *risk* on workers (Holmstrom 1979). Consider the contract that induces efficient effort above: $\beta_y = 1$. The objective of the firm is to maximize profits subject to the worker's willingness to take the position. This implies that the fixed component, β_0, is changed to guarantee that agents earn their reservation utility, so the principal's objective becomes a surplus maximization exercise. When the worker is risk neutral, the fixed component is reduced sufficiently such that the total compensation cost is $U* + \frac{c}{2}$. In words, the only cost that the employer incurs in addition to U^* is the effort cost. This is not true when the worker is risk averse. In the context of the preferences V above, compensation costs increase when incentive contracts are used for two reasons – the cost of increased effort as above, but also a risk cost imposed on workers. Both costs are increasing in β_y. With exponential preferences and linear contracts, this trade-off results in the optimal contract being $\beta_y^* = \frac{1}{1+rc\sigma_y^2}$. This approach to studying incentive contracting has become knows as the 'trade-off of risk and

incentives', where firms trade off the benefits of great effort with higher compensation costs induced by a risk premium, such that the chosen level of effort falls below the level that internalizes benefits to others. Only in the case where there is either no measurement error ($\sigma_y^2 = 0$) or risk neutrality ($r = 0$) does efficient effort arise.

At its most general, this costliness of exposing a worker to large degrees of risk (or its analogue, liquidity constraints) surely explains some part of the absence of high-powered incentives. In much the same way as financial assets with higher undiversifiable risk require higher expected returns, so also are risky jobs likely to demand higher compensation. Despite this, the empirical literature on how compensation contracts trade off such risk issues against higher effort has shown little evidence in its favour. There are two principal empirical implications of the theory. First, riskier environments should have lower incentives $-\beta_y$* declines with σ_y^2. There have been many studies of the relationship between risk and the strength of incentives in a variety of occupations. If anything, this literature suggests that the relationship between risk and the provision of incentives is positive rather than the negative relationship posited by this theory. See Prendergast (2002) for details and an explanation as to why this may be. Second, the trade-off of risk and incentives implies that compensation should not depend on measures that workers cannot control. Again, this has found little support in the data. For example, Bertrand and Mullainathan (2001), have examined executive contracts in the United States, and found little evidence that contracts reward executives any less for measures that they cannot control (say, where an oil company's profits change simply because the price of crude changed) than for those that they can (such as a merger). More evidence on this failure to filter out uncontrollable factors concerns the infrequency of relative performance evaluation. Consider two sales-force workers (or executives) who carry out a similar job. If demand for the products that they sell varies for common reasons beyond their control, an efficient way of limiting risk exposure is to (at least partially) reward the workers on how well they do relative to each other. Yet empirically there is relatively little evidence of such benchmarking (for example, see Janakiraman et al. 1992).

A second limitation on incentive contracting arises when measures do not reflect the objectives of the principal. Workers often carry out a host of activities in their jobs, yet measures of performance may not reflect all these aspects. A good example of this would be measuring the performance of a teacher. While measures may be available on some component of what they do – such as test scores for a teacher – many important aspects may remain unmeasured. When contracts are designed on the subset of things that can be measured, there is a danger that they ignore the unmeasured aspects. For instance, there is evidence of teachers 'teaching for the test' or cheating to achieve higher test scores (Jacob and Levitt 2003). This phenomenon has become known as *multitasking* (Holmstrom and Milgrom 1992), which becomes potentially important when there is no single measure that reflects the contribution of an agent. Accordingly, it is not surprising that a consistent empirical finding is that jobs which are described by firms as complex tend not to offer significant incentive pay (see Prendergast 1999, for details).

Another limitation on the ability of firms to provide incentives to workers comes from team production. Measures of performance for most workers reflect not only what they do but also the contributions of others. In itself, this does not change the calculus above in any conceptual sense, other than that the measurement error now includes the actions of others. As an example, assume that two agents (1 and 2) work on a team and that output measures the true contributions of both plus an error term $y = e_1 + e_2 + \varepsilon$. Efficient effort arises as before by setting $\beta_y = 1$ for each worker. However, there is now a potential problem of budget breaking, where marginal payments exceed marginal output. In this example, when total output rises by one dollar, compensation costs increase by two dollars. In many firms – for instance, partnerships – such budget breaking is not possible. If instead the principal

can pay out no more than one dollar for every dollar extra on output, this naturally places an upper bound of $\beta_y = \frac{1}{2}$ on average for the agents. Hence, budget balancing places a natural limitation on firm incentives. This also leads to a free rider problem in teams, where maximum incentive compensation in an N member team mechanically declines as N increases (This is known as the '$\frac{1}{N}$problem'). There is also considerable empirical evidence (such as Gaynor and Pauly 1990) on such free riding – mostly from legal and medical partnerships – illustrating how various measures of performance disimprove as the size of the team being rewarded increases.

Many measures of output are not denominated in dollar terms, but instead come in the form of evaluations by others. For instance, it would be difficult to measure the contribution of a social worker or a customer service representative without using feedback from supervisors or clients. Another limitation on contracts arises when such subjective measures can be corrupted by evaluators with vested interests. Two particular sources of such vested interests have been considered in the literature. First, information on performance often originates with clients as they are the only ones with first-hand experience of the agent's efforts. For instance, compensation for many customer service representatives depends on client evaluations. When clients have relatively similar preferences to the principal – such as that the agent should be courteous and efficient – contracts based on evaluations can mimic the objective contracts above. Yet in other instances, the vested interest of clients can render incentives difficult to implement. A good example of this arises in occupations such as police or immigration control, whose objective is not necessarily to make their clients happy. Making pay depend on evaluations in these instances can be harmful as it gives agents incentives to keep clients happy when they should not, such as a police officer not arresting a suspect. In these cases, incentive contracting on evaluations typically needs to be curtailed to avoid such incentives (see Prendergast 2003, for details).

The second example of vested interests with subjective evaluations is where the principal has an incentive not to implement the *(ex ante)* efficient contract by reneging on a promised payment to save costs. Thus, even though an agent exerts effort and performs well, the supervisor claims otherwise to keep costs down. This can arise either by outright lying or perhaps by manipulating whatever measures are available. A relevant example here is the movie industry, where actors are sometimes paid on the 'net profits' of a film. As a result, there have been numerous court cases regarding firms using creative transfer pricing arrangements to reduce profits for very successful movies. See Cheatham et al. (1996) for more details on this. Such incentives to renege are likely even worse when there are no objective measures of performance. Because the desire to renege is greater when discretionary incentive payments are higher, it follows that the only credible contracts often involve few incentives (Clive Bull 1987, considers a role for repeated interaction between the principal and agent as a means of reducing incentives to renege. While repeating the relationship can result in sufficient incentives for complete honesty by the principal, it remains the case that, if the relationship's value is not sufficiently great, incentives must be muted to reduce incentives for cheating).

It is incorrect to assume that the ability to manipulate measures of performance always mute incentives – sometimes it can result in incentive pay being inefficiently high. Consider again two occupations where agents are typically residual claimants – taxi drivers and sharecroppers. At first blush, it would seem odd that they have such extreme incentives. Aren't these as likely candidates for trading off risk against incentives as any? However, one characteristic of each of these occupations is that they have opportunities for hiding output, either by taking fares without using the metre (in the case of cab drivers) or selling crops privately (in the case of farmers). In both cases, the only outcome that makes this incentive irrelevant is to render them residual claimants, even if risk considerations would suggest otherwise.

Another issue which can constrain efficient incentives, yet which has received almost no attention in the empirical literature, is where

agents hold *private information.* Take a specific instance – real estate agents. In Chicago, real estate contracts take a simple form – agents make three per cent of the sales price of the house. Assume that my home is worth $500. This linear contract not only offers only three per cent on the relevant margin for improving the selling price of the house, but predominantly rewards the agent for selling the house for say $450. Yet anyone could sell the house for $450 and it seems highly inefficient to reward in this way. So why not renegotiate to something better? An example of such an improvement (subject to risk issues) would be to offer nothing on the first $450, but to pay a piece rate of 30 per cent on anything over $450. In this way, the agent has more incentives on margin, yet breaks even relative to the original contract if the house sells for its original price.

One reason why such renegotiation does not arise is that the agent may privately know the true value of the home, while the owner believes it to be worth $500 on average. Consider a homeowner who offers the new contract above to the agent. It is clear that the agent rejects the new contract if it is truly worth less than expected, and accepts it if worth more. But this implies that the agent earns *information rents* on average. As a result, on average the homeowner loses money from the renegotiation unless effort increases enough. This option available to the agent limits the ability of contracts to attain efficiency. Instead, in the usual monopoly fashion, the homeowner would offer a contract to trade off the efficiency gains of increased effort with infra-marginal losses of the type described above, resulting in lower-powered incentives (There is a large mechanism design literature on this topic that has largely been ignored by the empirical literature on incentives; see Laffont and Tirole 1986, for example. This is surely partly because of the empirical conundrum as to why mechanisms are so rare in reality).

Much of the recent literature has been focused on how incentive contracts can cause adverse behavioural responses. Another possible mechanism for such responses is where *intrinsic motivation* can be crowded out by the use of incentive contracts. The premise of this literature has been that in many occupations agents enjoy carrying out the activity or care about the outcomes of their actions. As a result, they will exert effort beyond that which they can get away with even in the absence of incentive contracts. This, in itself, is not enough to limit incentive contracting. However, there is some psychological evidence that agents enjoy their jobs less when incentive contracting is used. In effect, they feel that they are only doing it 'for the money' and hence lose interest. A commonly cited example is the willingness of people to donate blood, where the warm feeling from donating declines when payments are made. In some instances, this can imply that incentive contracting can *reduce* effort if these crowding out effects are strong enough. As a result, it can be optimal to provide no incentives even when effort is one-dimensional. This area of research, whose empirical testing has largely been restricted to the laboratory, is still in its early stages and is likely to see much refining over the coming years. See Frey and Jegen (2001) for a survey.

Another likely fruitful area of future research concerns non-monetary ways of motivating workers. This literature largely began as an exercise in how workers could be motivated to internalize the benefits of others, yet has almost exclusively become an exercise in how to motivate through monetary contracting. Yet it is clear that there are a myriad of means of motivating workers – sense of achievement, 'doing good', status, and so on – that firms tap into. How such mechanisms operate, and the way in which they interact with monetary contracts, remain an unstudied topic of research, though see Besley and Ghatak (2005), for some theoretical work on this issue.

It is worthwhile to note a caveat before concluding. The discussion above concerns the absence of *observed* incentive contracts. Yet workers often have unobserved carrots and sticks that can motivate them. For instance, many workers exert effort in the hope of attaining a promotion (Lazear and Rosen 1981), or a better job offer (Holmstrom 1999). Many of these mechanisms for inducing desired behaviour are dynamic, where good performance today results

in a greater likelihood of promotion, or better job offers in future. Such incentives are clearly important for workers. However, it remains the case that explicit incentive payments remain limited even in those cases where the above types of career concern are negligible (For example, it is well known that promotion prospects become very limited for workers who remain in a job grade for a long period. Yet explicit incentives are no more common for those workers than for any other). The interaction of unobserved (typically career) incentives with the more explicit set of piece rates and bonuses that have been considered above is surely of first-order importance to firms, though it remains surprisingly unexplored in the literature (see Baker et al. 1994, for an exception).

To conclude, perhaps the central foundation of modern economics is the idea that appropriate prices guide behaviour in efficient ways. Despite this, one of the defining characteristics of the employment relationship in many firms is the absence of the kind of explicit prices whereby wages depend in a clear way on observed outcomes. The early incarnations of agency theory were concerned with designing prices in a way that could serve to fully internalize the effects of agents' actions on the welfare of their employers. Yet this initial optimism has now been tempered with a somewhat more nuanced view that shows trade-offs that will ultimately help in defining more precisely the nature of labour market relationships.

Contradiction

Michael Dummett

The fundamental form of a contradiction is a pair of propositions, 'A' and 'Not A', one the negation of the other. If such an explicit contradiction is

part of a body of propositions asserted by some individual or group at a given time, it follows that not all those propositions can be true: by thus impairing the reliability of the proponent, the occurrence of the contradiction throws doubt upon the truth of all the other propositions asserted.

Far more frequent than an overt or explicit contradiction is a hidden contradiction. A hidden contradiction is contained in a body of propositions when, by logically valid deductive reasoning, an explicit contradiction can be derived from them. Two quite different cases arise, according to the status of the original propositions from which the contradiction was derived. The first is that in which, as before, those propositions were all asserted by an individual or body of people. In this case, the hidden contradiction is as fatal to the joint correctness of those assertions as is the explicit one, although, of course, considerable work may have had to be expended in bringing it to light.

The second case is that in which at least some of the original propositions were not asserted, but merely advanced as suppositions to be considered. The formal conclusion now remains exactly the same: given that the contradiction was validly derived, not all the original propositions can be true. The effect, of course, is very different. Suppose that the original propositions – the premisses from which the contradictory pair 'A' and 'Not A' have been derived – were four in number: 'B_1', 'B_2', 'C_1', and 'C_2'; and suppose that 'B_1' and 'B_2' were asserted outright, but that 'C_1' and 'C_2' were merely advanced for consideration. The contradiction shows that not all four can be true: without having to withdraw anything that he asserted, the proponent, still maintaining 'B_1' and 'B_2', is now in a position to assert 'If C_1, then not C_2' (or its equivalent, 'If C_2, then not C_1').

For this reason, derivation of a contradiction can be employed, not merely as a means of refuting the assertions of another, but as a method of demonstrating negative propositions: this is the celebrated mode of argument *reductio ad absurdum*. In conjunction with premisses, 'B_1' and 'B2', say asserted outright, a proposition 'C' is presented as a hypothesis: not as a conjecture or supposition to be seriously entertained, but with an eye to proving its negation 'Not C'. From the premisses 'B_1' and 'B_2' and the hypothesis 'C', two contradictory propositions 'A' and 'Not A' are then derived: on the basis of the two premisses, the hypothesis now being dropped, its negation 'Not C' can now be definitely asserted. Two special cases fall under this general description. One is that under which 'A' is actually one of the two premisses, say 'B_1'. If from premisses 'B2' and the hypothesis 'C', the conclusion 'Not B', can be derived, one may assert 'Not C' on the strength of the two premisses. The other special case is that in which 'A' is the hypothesis 'C', itself. If from premisses 'B_1' and 'B_2' and the hypothesis 'C', the negation 'Not C' of the hypothesis can be derived, 'Not C' may be asserted outright on the strength of the two premisses.

As is well known, *reductio ad absurdum* arguments are frequent in mathematics. One of the simplest, as well as historically most important, is the proof that 2 has no rational square root. We may take as the premisses: (B_1) any rational number may be represented as a fraction whose numerator and denominator have no common factor; and (B_2) the square of an odd number is odd. As the hypothesis we may take: (C) 2 has a rational square root. From (B_1) and (C) it follows that, for some integers m and n, m and n have no common factor and $(m/n)_2 = 2$; hence $m^2 = 2n^2$. Hence, by the definition of 'even', m_2 is even, and from (B_2) it can be inferred that m is not odd, and hence is even. Thus $m = 2k$ for some k, and we have: $m_2 = 4k^2 = 2n^2$, and so $2k^2 = n^2$. Applying (B_2) once more, we infer that n is also even. Since m and n are both even, they have 2 as a common factor, which contradicts the earlier stipulation that they have no common factor. By arriving at this contradiction, we have achieved a demonstration that 2 has no rational square root, that is, a proof of the negation of our hypothesis (C).

The derivation of a hidden contradiction from premisses all definitely asserted may also be illustrated from mathematics. The most celebrated examples are the set-theoretic paradoxes which provoked the first 'crisis in the foundations' of mathematics in the early years of this century. Some of these, such as Burali-Forti's paradox and Cantor's paradox, demand some technical background; but Russell's paradox has the advantage of being statable in very simple terms. The propositions leading to this contradiction appear at first sight entirely harmless. They are: (1) to every property there corresponds a class, the class of things having that property; (2) the class of things having a given property F contains as members all and only those things that have the property F. Russell's contradiction arises from considering the property G of being a class that does not contain itself as a member. By assumption (1), there exists a class, which we may call W, of things having the property G. We now ask whether W contains itself as a member. It may then be argued by *reductio ad absurdum* that it does not: we have first to suppose, as a hypothesis, that it does. By assumption (2), it therefore has property G. But properly G is the properly of being a class that does not contain itself: it follows, contrary to the hypothesis, that W does not contain itself. We may thus discard the hypothesis, and assert outright that W does not contain itself. Applying assumption (2) once more, we may then conclude that W lacks property G. It therefore is either not a class or does contain itself as a member; since it is by definition a class, it contains itself as a member. This now contradicts our earlier conclusion that it does not contain itself as a member: the two intuitively reasonable assumptions (1) and (2) have led to a contradiction.

Russell's contradiction is so simple to state and so easy to derive that those who are unaware of the importance in mathematics of the notion of a class or set are liable to think it no more than a trivial verbal puzzle. It is very far from trivial. It overthrew the life's work of the great logician Gottlob Frege, namely to provide unquestionably firm foundations for the theories of natural numbers and of real and complex numbers, just when he believed that he had accomplished it; and it cast the foundations of mathematics into confusion for some years. By showing that assumptions (1) and (2) cannot both be consistently made, it challenged mathematicians and logicians to find weaker assumptions that would be consistent: for which properties F do assumptions (1) and (2) hold good? This question proved exceedingly difficult to answer: hence the 'crisis in the foundations'.

Why is the discovery of a hidden contradiction so devastating? One answer is that, if a pair of contradictory propositions are both consequences of a given set of assumptions, then *every* proposition is a consequence of them. This holds good in virtue of the logical law, known to the medievals as *ex falso quodlibet*, that, from a pair of premisses 'A' and 'Not A', any proposition 'B' may be inferred. This law appears at first glance both useless and implausible; a natural first reaction is therefore to suggest repudiating it. That, however, is not easily done, since it is a consequence of two other, seemingly inescapable, laws concerning the logical constant 'or'. The first is the law now usually known as 'or'-introduction or disjunction-introduction, that, for any propositions 'A' and 'B', 'A or B' follows from 'A'. The second is that known in the traditional logic as *modus tollendo ponens*, that 'B' follows from the premisses 'A or B' and 'Not A'. It is quite obvious that, from the premisses 'A' and 'Not A' of the *ex falso quodlibet*, its conclusion 'B' can be reached by first applying 'or'-introduction and then *modus tollendo ponens*: but it is very hard to see how we could possibly reject either of the two latter laws, for they appear absolutely constitutive of the meaning of the connective 'or'. The best possible way to establish the truth of a disjunction – a statement of the form 'A or B' – is to establish the truth of one or other of the disjuncts 'A' and 'B': if the truth of 'A' does not guarantee the truth of 'A or B', what does 'or' mean? Conversely, the truth of a disjunction appears to *demand* that at least one of the disjuncts be true: so, if 'A or B' is

true and 'A' is not true, 'B' must be true. If 'Not A' is true, 'A' cannot be true: so the validity of *modus tollendo ponens* appears likewise unquestionable.

Faced with the difficulty of rendering contradictions harmless by modifying our logic, some have proposed extruding the sign of negation altogether from the language. What use are merely negative propositions, they enquire: when we are tempted to assert one, we usually have to hand a more informative affirmative statement to take its place, and, when we do not, it will be a good thing to search for one. But the proposed remedy, drastic as it sounds, does not work: for, in place of the derivation of a contradiction, it is usually possible to exhibit a more direct method of deriving any proposition whatever. This may be illustrated by converting the Russell paradox into this form. Take any random proposition, say 'The Earth is flat': and consider the property H of being a class such that, if it contains itself as a member, the Earth is flat. By assumption (1), there exists a class, say Y, of things having the property H: let us ask, as before, whether Y contains itself as a member. Suppose, as a hypothesis, that it does. Then, by assumption (2), it possesses property H: that is, it is a class such that, if it contains itself as a member, the Earth is flat. Now, by hypothesis, it *does* contain itself as a member; hence, on this hypothesis, the Earth must be flat. We have now shown, on the hypothesis that Y contains itself as a member, that the Earth is flat: we may therefore assert outright, independently of the hypothesis, that, *if* Y contains itself as a member, the Earth is flat. From this we see that, since Y is by definition a class, it has property H. Hence, by assumption (2), Y contains it as a member: that is, Y really does contain itself as a member (and not just by hypothesis). We have now shown two things: first, that if Y contains itself as a member, the Earth is flat; and, secondly, that Y *does* contain itself as a member. It follows inescapably that the Earth is flat.

This version of the paradox lies in wait for any who would seek to escape it by tampering with the logical operation of negation. The idea, that some have had, that escape lies in rejecting the principle of bivalence (that every proposition is either true or false) or the closely related law of excluded middle (that, for any proposition 'A', 'A or not A' is a logical truth), does not even avoid the original paradox. It is tempting to open the argument by which the contradiction is derived with the declaration, 'Either W contains itself as a member or it does not': but it is quite unnecessary, and the foregoing statement of the argument neither began in this way, nor invoked the law of excluded middle at any other point. It turned principally on an application of *reductio ad absurdum*, in order to infer 'W does not contain itself as a member' from the fact that a contradiction followed from the hypothesis 'W contains itself as a member'. There are, indeed, logical systems in which the law of excluded middle does not hold. But, in the principal logical system of this kind, that known as intuitionistic logic, *reductio ad absurdum*, in the above form, is perfectly valid: indeed, all arguments and forms of argument hitherto considered are intuitionistically valid. It is true, indeed, that there is another, frequently used, version of *reductio ad absurdum* that is *not* intuitionistically valid. As *reductio ad absurdum* was characterized above, it always leads to a *negative* conclusion: the derivation of a contradiction from a hypothesis shows that hypothesis is *not* true. In the intuitionistically invalid version, a proposition is deduced to be true from the fact that the hypothesis that its negation is true leads to a contradiction. Certain propositions, say 'B_1' and 'B_2', are asserted as premisses, and 'Not C' is assumed as hypothesis. A contradiction 'A' and 'Not A' is derived, and, on the strength of this, 'C' is asserted as following from the premisses 'B_1' and 'B_2' alone. *This* form of argument does depend, for its validity, on the principle of bivalence. If we equate the falsity of 'C' with the truth of 'Not C', then the contradiction shows that 'C' cannot be false: to infer that it is actually true requires the presupposition that it is either true or false. Intuitionistic logic sanctions our treating large classes of propositions as satisfying bivalence, so that many

applications of this extended form a *reductio ad absurdum* will be legitimate: but it objects to considering it generally valid, since not all propositions can be regarded as necessarily being either true or false.

The devastating effect of the appearance of a hidden contradiction in a set of propositions asserted as true, or hitherto accepted as true, is not, of course, due to the fear that anyone will use the *ex falso quodlibet* law to deduce arbitrary conclusions: the utility of the *ex falso quodlibet* turns on its use in subordinate deductions (deductions under a hypothesis subsequently to be abandoned). The point is, rather, that we no longer have *any* reason to believe a proposition on the strength of its being a logical consequence of the given set, since every proposition is such a consequence: until we have discovered what gave rise to the contradiction, and have corrected it, no conclusion we derived from that set has any claim to be believed. The great philosopher Ludwig Wittgenstein scoffed at mathematicians for their 'superstitious awe and dread in face of a contradiction', and asked why they did not simply go round it: but, until it has been resolved, no one can be sure that the path he has taken does go round it. Analysis may show that the use of one particular notion is responsible for the contradiction, and we may then trust those conclusions, previously drawn, the argument to which in no way involved that notion: but, once the contradiction has appeared, only strong measures will supply us with any rational ground for believing any proposition that does involve it, directly or in the argument it is based on. It is not enough merely to find a way to weaken those of our former assumptions that involved the suspect notion so as to block the derivation of the contradiction. That was precisely what Frege did when Russell showed that his contradiction could be derived in Frege's logical theory: but it proved that another contradiction, similar though more complex, was lurking in the modified theory. We have, therefore, in such a case, not merely to weaken our assumptions, but to supply some argument that at least makes it plausible that the weakened assumptions are now consistent. When no hidden contradiction has been revealed, intuitive acceptability may be sufficient basis on which to treat our assumptions as true, even though it does not amount to proof. Once a contradiction has appeared, however, intuition is no longer to be trusted. The contradiction is evidence that the theory is diseased. It is no more enough to root out that particular contradiction than it is to eliminate a particular patch of dry rot: a thorough decontamination of the whole is called for.

The reason why the appearance of a contradiction is so dire a symptom lies not so much in any laws of inference as in the semantic notions of truth and falsity. A proposition and its negation cannot both be true, whereas it is inherent in the definition of 'follows (logically) from' that what follows from a set of true propositions must itself be true: hence, if 'A' and 'Not A' both follow from a set of assumptions, not every assumption in that set can be true. Appeal to semantic notions is in fact needed to explain the concept of the negation of a proposition. Logicians are accustomed to employ a negation operator, with the sense 'It is not the case that . . .', which acts on whole propositions (sentences) to form their negations; and that has hitherto been tacitly done in this article. But natural language hardly possesses such an operator. Apart from the clumsy expedient of sticking the phrase 'It is not the case that . . . in front of a sentence, natural language has no uniform way of forming negations. Admittedly, the negations of many sentences can be found by negating the main verb (in English, replacing 'is' by 'is not', 'resembles' by 'does not resemble', etc.), but this does not work for all. The negation of 'Someone is snoring' is not 'Someone is not snoring', but 'No-one is snoring', the negation of 'You must attend' is not 'You must not attend', but 'You need not attend'; the negation of 'Whenever I look up, I see you yawning' is not 'Whenever I look up, I do not see you yawning', but 'I do not see you yawning whenever I look up'; and the negation of 'If taxes are cut, the government will be re-elected' is not 'If taxes are cut, the government will not be re-elected', but 'The government

will not necessarily be re-elected if taxes are cut'. There is no uniform syntactic rule for determining the negation of any given proposition: to identify the negation of a proposition 'A', we have to advert to its characterization as that proposition which (in any given context) is true just in case 'A' is false.

This means that the notion of falsity is essential for an explanation of 'not' as used to qualify whole sentences: it does not mean that the notion is more fundamental than the uses of 'not' that occur in natural language. On the contrary, to identify the negations of most propositions, it is necessary to understand the word 'not' as it occurs in a variety of positions in a sentence, as illustrated in the above examples. It is therefore in no way inconsistent with the general characterization of the negation of a proposition in terms of truth and falsity to explain a proposition as being false just in case it is not true. It is, in fact, a mistake to think of truth and falsity as equally fundamental notions: the application to a proposition of only one of them is sufficient to determine its content. If this were not so, there could be one pair of propositions 'A' and 'B' differing only in that 'B' was neither true nor false in certain of the cases in which 'A' was false, and another pair 'C' and 'D' differing only in that 'D' was neither true nor false in certain of the cases in which 'C' was true, and these differences would entail that the two propositions in each pair diverged in content. But that is impossible, if 'content' is understood as here intended, namely as what is conveyed by the assertion of the proposition on its own. What was not laid down, in the foregoing stipulation, was whether, in asserting a proposition, a speaker is to be understood as excluding or as allowing for the case in which that proposition is neither true nor false. If he is to be understood as excluding it, what he conveys by his assertion is that the case in which the proposition is true obtains: the content of 'A' and of 'B' will therefore coincide. If, on the other hand, the speaker is to be understood as allowing for the case in which the proposition is neither true nor false, what he conveys by asserting it is that one of the cases in which it is not false obtains: if so, the content of 'C' and 'D' will coincide. To fix the content of a proposition, in the sense explained, we need to know, of any state of affairs specified in sufficient detail, whether an assertion of the proposition would rule it out or allow for it: and this does not provide for the introduction of two notions, those of truth and falsity, whose application is partially independent of one another.

The principle of bivalence rests on the conception that, to grasp the content of a proposition, one must know just what circumstances must obtain for it to be true, independently of whether or not these are circumstances which we are capable of recognizing as obtaining when they do. Given this conception, we may understand 'Not A' as being true in all circumstances save those in which 'A' is true: and so 'A' will be determinately either true or false. Likewise, the connective 'or' is so understood that 'A' or 'B' is true in those circumstances in which 'A' is true, and in those in which 'B' is true, but in no others. Intuitionistic logic, on the other hand, is founded on the idea that the content of a proposition must be determined by our capacity to recognize it as true or as false. To grasp its content, we must know which recognizable circumstances render it demonstrably true: to assert it is to claim that such circumstances obtain. The meaning of 'or' must be explained by a rule determining the content of 'A or B', as given in this way, from the content of 'A' and of 'B', also so given: namely that those recognizable circumstances which render 'A' demonstrably true, and those which render 'B' demonstrably true, also count as rendering 'A or B' demonstrably true, but that no other recognizable circumstances do so. Since there is plainly no general guarantee, for any proposition 'A', that any recognizable circumstances will obtain that either render 'A', or render 'Not A' demonstrably true, the law of excluded middle 'A or not A' is not, in this logic, a valid law. (Some have seen in the requirement that a proof of 'A or B' constitute a proof either of 'A' or of 'B' an analogy with the legal conception of proof.)

How, then, is the operator 'not' to be understood in this logic? The usual explanation is to pick some patently absurd proposition, say 'Black is white', and explain 'Not A' as equivalent to 'If A, then black is white'. This throws us back on the intuitionistic explanation of 'if', which is that 'If A, then B' is demonstrably true in recognizable circumstances which would render 'B' demonstrably true, given that 'A' were demonstrably true. On the assumption that the absurd proposition 'Black is white' can never be demonstrably true, this amounts to counting 'Not A' as demonstrably true in circumstances which can be recognized as excluding the possibility that 'A' can become recognizably true. The assumption is not built into the logic, however. The fundamental laws governing negation are *reductio ad absurdum*, in the restricted form leading to a negative conclusion, and *ex falso quodlibet*. On the explanation of 'not' in terms of 'if', *reductio ad absurdum* is derivable from the laws governing 'if'. If from the hypothesis 'C' we can infer both 'A' and 'If A, then black is white', only one more step is needed to infer 'Black is white' from 'C': hence, dropping the hypothesis 'C', we may assert, 'If C, then black is white', which is 'Not C'. The *ex falso quodlibet*, however, is not derivable without a further assumption. We need to show that, from the premisses 'A' and 'Not A', we can infer any proposition. Since 'Not A' is 'If A, then black is white', the ordinary laws governing 'if' allow us to infer 'Black is white': so we need to assume that, from the absurd proposition 'Black is white', we can infer any proposition. The stronger assumption, that we shall never be able to assert 'Black is white', here plays no role. If we had a very restricted language, for which there was no absurdity in supposing that every proposition expressible in it might prove to be demonstrably true, it would be sufficient to understand what we have been calling the 'absurd' proposition as the conjunction of all other propositions expressible in the language: all the laws of intuitionistic logic would then hold good. In this sense, then, the intuitionistic meaning of negation – unlike those of the other propositional operators such as 'and' and 'or' – is relative to the language: the weaker the expressive power of the language: the weaker the meaning which logic requires us to impose on the word 'not'.

The word 'contradiction' is often used in a looser sense than the strict one so far discussed. When it is said that there is a contradiction in capitalist economies, it is not meant that the very notion of a capitalist economy involves a contradiction in the strict sense, or otherwise no such thing as a capitalist economy could exist. One of several things may be meant instead. (1) There is a formal contradiction, not in a *description* of a capitalist economy, but in the *justification* normally offered for it, or, perhaps, in any that could be offered. (2) A capitalist economy has a necessary tendency to evolve in each of two incompatible ways, and the resulting social and economic tensions will inevitably destroy it. (3) The term 'capitalist' applies to an economic system as the term 'smooth' applies to a surface, in virtue of its approximation to an unattainable limit: there really is a formal contradiction in the notion of a *pure* capitalist system – one that occupies the limiting position – but not in that of one that approximates to that limit and is hence ordinarily called 'capitalist'. It is in one of these senses, or a similar one, that the word 'contradiction', as customarily employed by Marxists and Hegelians, must be understood; but such a stretched use of it is best avoided. An explicit contradiction, in argument or testimony, is comparatively rare, although of course it does occur: but nothing deserves to be called a contradiction unless it genuinely implies an explicit one.

Contradictions of Capitalism

Andrew Glyn

Writers in the Marxist tradition frequently make use of the term 'contradiction of capitalism'. It is sometimes used, in a very loose sense, to describe virtually any malfunction or indeed objectionable feature of the capitalist system. But in Marx's theory of historical materialism the notion of contradiction played a more fundamental role. One of the central tenets of the theory is that there can be a contradiction between a society's system of economic organization and its capacity to develop its productive potential. Indeed it is precisely such a contradiction between the relations of production (relations of ownership, control etc.) and the forces of production (productive potential), which necessitates through some mechanism or other, a transformation of the economic system. Thus, argued Marx, at a certain stage the rigidities of the feudal system hampered economic growth, which required for its promotion the full and unfettered development of production for the market. The development of productive potential under capitalism formed the basis on which socialism *could* be constructed. The contradictions of capitalism, its inability in turn to take society forward beyond a certain stage, ensured that it *would* be superseded by socialism (see Elster 1985, especially chapter 5).

Labour Power and the Labour Process

For Marx the defining feature of capitalism is that *labour power*, workers' capacity to work, becomes a commodity, which has to be sold by workers who do not have the means of production necessary to work on their own account. The capitalist class pays for this labour power at its value, that is, at a wage determined by social and historical circumstances. But labour power has the capacity to create more value than is contained in it – more precisely, the working class is forced to work longer than is required to produce the goods required to sustain it, leaving a surplus value to be appropriated by the capitalist.

This analysis of the source and nature of profit focuses attention on the factory floor as the locus of the exploitative relation between capital and labour. Labour power is a special commodity in that it cannot be detached from the worker. They do not literally leave their labour power at the factory gate each morning and pick it up in the evening in order to reconstitute it with food and sleep. While this is obvious, it has to be emphasized, since the conventional treatment of production as a matter of technically combining 'labour services' and 'capital services' pays no attention to the active participation of workers in the process of production (see Rowthorn 1980). In fact discipline, supervision, *control* over work are integral to the capitalist system. In turn this means that conflict between workers and employers over all aspects of the labour process is endemic.

Control over labour, and the conflict involved, is clearly a problem for the functioning of capitalism ignored by theories which describe it in terms of the harmonious cooperation between the classes (or owners of factors of production). But does it constitute a contradiction in the sense that it is unresolvable on the basis of private ownership of the means of production, and will lead to increasing malfunctioning of the system as a whole?

It is quite possible to conceive of situations in which inability to control labour in the labour process would become chronic. If it were the case that the development of capitalist production necessarily crowded workers into larger and larger factories, with deteriorating working conditions, but increasing opportunities for organization and resistance, then the question of control over labour could become critical. In fact trends have been more complex. In the advanced capitalist countries, firms have grown enormously in terms of numbers employed, but average plant size has grown much less. Whilst Ford-type production lines may have represented the ultimate in the imposition of capitalist control over the labour process by mechanical means, the continued

requirement for skilled work, demanding judgement, has prevented such systems of work organization being instituted in all industries. Indeed in some industries, worker opposition, or a trend towards more sophisticated products, has led to a reversion to smaller-scale, more integrated methods of production where work is more varied, skilled and responsible.

What is striking, however, is that such trends have in part derived precisely from the resistance engendered by large-scale production. To take the case only of the motor industry, the development of worker resistance in US car plants in the 1960s led to widespread attempts to 'humanize' work by introducing team methods of production and payment. In Italy, conflict in Fiat car factories led to a deliberate policy of decentralizing the less skilled processes of production in order to overcome the problem of controlling 'mass work' in the factories. The production system of Japanese car companies is widely admired, whereby the most important and technically sophisticated stages of production are carried out in large factories, by trained workers, with high wages, paternalistic welfare provisions, tight labour discipline and a modicum of consultation, leaving many components to be produced in much smaller plants by subcontractors, paying lower wages and with less security of employment.

The most important point is a more general one. The shape of development of the capitalist system is determined by the problems and difficulties it encounters. It does not evolve out of some inexorable pattern of technical development; indeed, technology is consciously shaped to overcome social problems (like control over workers) as well as technical ones. A contradiction does not have to spell increasing malfunctioning, let alone capitalism's destruction, to heavily influence the way the system develops.

Labour Shortage

If the first special characteristic of the commodity labour power is that its 'consumption' in the labour process involves the seller (the worker), the second is that its 'production' does not involve the capitalists. For workers are of course 'reproduced' in the home, not produced in factories. The supply of labour power, therefore, cannot like other commodities be increased by a simple redistribution of resources to the sector producing it. The supply of labour, while by no means independent of economic conditions, is not regulated by them as simply as other commodities. Availability of consumer goods does not spell availability of workers. This feature of labour power, together with the issue of control of work already discussed, explains why in analysing production workers cannot be represented by the consumer goods they live on.

The supply of labour is not entirely fixed, of course. Higher wages may increase population growth (as child mortality declines for example), but the social development which accompanies increased living standards may lead to smaller families. This in turn may permit greater participation by women in the labour force. But increased educational standards may delay entry into the labour force, welfare provisions may enable earlier retirement, and part of increased living standards may be taken in reduced hours of work. As pre-capitalist forms of production decline, the possibility for recruiting wage labour from their ranks is diminished; immigration from countries with a labour surplus may meet social and political barriers.

While the supply of labour depends on a host of these factors, not very amenable to short-term manipulation, the demand for labour depends on the rate at which capital is accumulated and its form. Rapid capital accumulation leads to increased demand for labour as workers are required for the new factories. But the new investment may be of a labour-saving variety, requiring fewer workers per machine as compared to earlier vintages. The rise in labour demand depends on the balance between these two forces. If accumulation is sufficiently rapid (as in the advanced capitalist countries in the 1950s and 1960s for example), so that demand for labour rises faster than the supply, then the reserve army of labour (the unemployed and underemployed) shrinks. This improves workers' bargaining position, with consequent difficulties for the employers in

controlling work and wages. A crisis of 'over-accumulation' results.

Increased wages and difficulties in keeping up productivity levels both tend to reduce profits. This leads to reduced investment, insufficient demand for commodities and labour, and stagnation. The 'law of value' does not apply to labour power, so that shortage of supply does not lead to increased profitability in its production and thus increased supply. This can be seen as a fundamental 'contradiction' of capitalism, in the sense that the functioning of capitalism requires labour power to be fully a commodity, and yet this is impossible (see Itoh 1980). Of course this does not establish that the contradiction is irresolvable. If the unemployment which results has the expected effect of reducing workers' bargaining power, then wages can be forced down and productivity up, profits and investment recover and a cyclical upturn results.

Individual and Class Interests

The development of such a crisis of 'over-accumulation' is an example of a more general category of problems. Each individual capitalist is attempting to maximize his profits through securing more labour; yet this leads to lower profits for the capitalist class as a whole as they bid up wages and find increasing problems in work organization. So the rationality of the individual economic agents conflicts with what is rational for the system as a whole. It seems very reasonable to describe this as a 'contradiction' in the functioning of capitalism (Elster 1985). It would require a degree of coordination, which is actually impossible under normal circumstances in a competitive decentralized economy, for the individual employers to hold back from accumulating at a rate which in aggregate is unsustainable. There is no mechanism to tailor the rate of accumulation to what, given the pattern of technical progress, is compatible with the growth of the labour supply, or adjust the pattern of technical progress to what is compatible with the other two variables. What has to 'give' is the rate of profit, and there is no guarantee that the response to a profit squeeze will be a smooth reduction in accumulation to the appropriate level.

There are other examples of 'contradictions' between the interests of individual capitalists and their class interest. Suppose an economic crisis has developed with unused capacity and unemployed labour. Each capitalist may try to improve his competitive position by cutting his employees' wages. But in aggregate the effect of such a strategy would be to reduce consumer demand, which could make the crisis worse. Exactly the same argument applies to the policies of individual capitalist countries trying to solve their problems by increasing their competitiveness. For the context may be a 'negative sum game', whereby cutting wages actually worsens the overall situation. Attempting to cut workers wages, whilst exhorting other capitalists' workers through advertisements to consume more, is a profoundly contradictory situation.

The famous example of this type of contradiction described by Marx was his Law of the Tendency of the Rate of Profit to Fall (LTRPF). He argued that the individual attempts of capitalists to maximize their profits led them to introduce techniques of production which reduced the profit rate for the class as a whole. As described elsewhere (*see* ▶ "Marxist Economics"), Marx's argument is not satisfactory. But this weakness may not seem of great importance, since we have seen in the discussion of overaccumulation that it is perfectly possible to describe a situation where capitalists do act in such a way as to lead to lower profits for them all. The LTRPF leads to a prediction of a continuous decline in the profit rate, and a declining rate of accumulation, leading, if the process developed that far, to absolute stagnation. The actions of capitalists would, in the long run, destroy the very motor of the system, capital accumulation. Crises of overaccumulation, however, are less fundamental in the sense that they are contingent on a particular pattern of accumulation, technical progress and labour supply. Moreover, while they might be repeated there is no basis for asserting an inevitable tendency that they should become deeper and deeper. They can hardly be said therefore to amount to an absolute contradiction in the capitalist process of accumulation, which is the way Marx himself interpreted the LTRPF.

Competition and Concentration

The driving force of capitalism, according to Marx, is competition. This forces the individual capitalist to accumulate capital in the form of new factories, embodying the latest technology. If he fails to do this he will be defeated by his rivals in the battle for markets since his costs will be greater. In modern conditions, where investment is so necessary to generate new products, and where economies of scale in marketing are important alongside those in production, this pressure is stronger than ever. According to Marx the advantages of large-scale production lead to its concentration (he uses the term centralization) in the hands of fewer and fewer firms. As the most dynamic firms knock out, or take over, those that invest less effectively the degree of competition is reduced. At a certain stage this could weaken the pressure to accumulate and generate stagnation in the economy.

Such a contradiction was particularly emphasized by writers basing their ideas on the postwar dominance of giant US firms (see Baran and Sweezy 1966). The development of Japanese and European industry, however, challenged this dominance and, during the 1960s, ushered in a great increase in competition on world markets. While monopolization has increased within each country, there has been a tremendous rise in competition through trade and foreign investment. Some of the Newly Industrialized Countries of South East Asia have begun to break into world markets as well.

The process of competition is, therefore, a complex one. The notion that increased concentration would both reduce the pressure to invest and increase the resources for investment (through higher prices and profits) does not stand as a convincing general trend. That is not to say however that, should a new era of protectionism develop, the high degree of industrial concentration within countries would not exacerbate a tendency to stagnation.

Wasted Resources and Unused Potential

Capitalist production is guided by profit, not social need, or to put it more abstractly, by exchange value rather than use value. The existence of unemployment is the most obvious example of such a contradiction. Unemployed workers could produce the very commodities which they, and the rest of society, need. But since production is for profit, they will only be taken on if the employers foresee a profit. In a situation of unemployment and unused capacity, capital accumulation and thus the introduction of new technology will be held back. The development of technology itself will be reduced if lower profits lead to cuts in research and development spending. For these reasons, society's capacity to produce will be reduced below what is feasible, as well as actual production being reduced below capacity.

These then are some of the senses in which capitalism has been deemed by Marxists to be a 'contradictory' system. The idea, prevalent in the 1950s and 1960s, that these contradictions had been overcome by the expansion of state activities or the advent of the managerial corporation, has disappeared with the collapse of the great postwar boom. Whether capitalism will find a way out of its problems, and lay the basis for rapid growth and full employment, depends of course on how fundamental these contradictions actually are. Even if less binding than some in the Marxist tradition have tended to assert, the idea that such contradictions generate powerful pressures for changes in the economic system remains a powerful and important one.

Control and Coordination of Economic Activity

Béla Martos

The particular point of view of the present paper is that it looks upon the economy as a *control system*. This approach was pioneered in the 1950s by Simon (1952), Tustin (1953), Phillips (1954) and Geyer and Oppelt (1957). Lange (1965) attempted an early synthesis. In the 1970s the idea became widespread and developed in two directions. The first and more popular one applied control theoretical models to *economic policy-making*. In this case the structure of the controller is considered to be given and the problem is to find values (time-paths) of the control variables such that the functioning of the economic system be acceptable (most often, stable and/or optimal) according to certain criteria. The second direction is related to the theory of economic systems, and this is where the present paper also belongs. A descriptive and explanatory *theory of economic mechanisms* is aimed at, which might be useful in the choice, change or construction of controllers. Although this research was certainly motivated by, and the findings often applied to, problems emerging in centrally planned economies, with particular reference to mechanism reform in East European countries, the theoretical framework is conceived in a more general setting. This research was initiated by Kornai (1971) and pursued further in Kornai (1980), and Kornai and Martos (1981).

In the first section I present the basic concepts and classifications, followed in the second section by the characterization of the elementary control processes, with the generation and transmission of information and decisions. The final section illustrates the usefulness of this framework by a microeconomic analysis of a non-Walrasian control model.

The Economic Control System

At any point of time (t) an abstract economic system consists of the following ingredients:

A set $\mathcal{A}$ of *agents* (e.g. households, productive firms, banks, government agencies); they are the subjects of the economic activities.

A set $\mathcal{O}$ of *objects* upon which the economic agents act.

The natural, historical, social and economic environment $\mathcal{E}$, which is not a part of, but interacts with, the system.

A set $\ddot{\mathcal{Y}}$ of processes which connect elements of sets $\mathcal{A}$, $\mathcal{O}$ and $\mathcal{E}$ and changes their state.

When speaking about an economic system the first thing we have in mind is a national economy. However, most of the qualifications and methods we use can be applied to systems which are smaller or larger than that (e.g. an industry, a corporation, a region.)

For a consistent control-theory approach two kinds of economic processes (elements of $\ddot{\mathcal{Y}}$) must be distinguished:

Real processes ($\ddot{\mathcal{Y}}_{\mathbf{r}} \subset \ddot{\mathcal{Y}}$), which change the state of physical objects. The most important real processes are production, storage, transfer of physical objects among agents, consumption (whether for productive or for final use). The objects of real processes form the set of *commodities*. ($\mathcal{O}_{\mathbf{r}} \subset \mathcal{O}$), The set of real processes consists of the real activities of the agents and the external effects of the environment. The former ones depend also on the control processes; the external effects cannot be controlled. The rules which connect the real processes are mostly the laws of nature (or more to the point, technology).

Control processes ($\ddot{\mathcal{Y}}_{\mathbf{c}} \subset \ddot{\mathcal{Y}}$), which change the state of knowledge of the agents and regulate their behaviour. The objects of these processes ($\mathcal{O}_{\mathbf{c}} \subset \mathcal{O}$) are called *signals*. The most important control processes are observation of real processes, signal generation and transmission among agents, and decision-making (the final signal generation) on real activities. A part of the signals may come directly from the environment as far as it is observable.

Since each agent $\boldsymbol{a} \in \mathcal{A}$ performs both real and control activities, it is convenient not only to split the set of activities and objects into two (real vs

control) subsets but also to consider each agent as consisting of two units: the *real unit* and the *control unit*, which perform real activities and control, respectively. Needless to say, this splitting of an agent into two units is only a conceptual separation of the functions may correspond with some kind of agents (e.g. large firms), but need not in any organized form exist with other kinds (e.g. households).

Finally, to make the dichotomy of the economic system complete, we can divide even the set $\mathscr{A}$ of agents into two subsets: that of *real agents* (or real organizations), $\mathscr{A}_{\mathbf{r}} \in \mathscr{A}$, whose *main* activities belong to the real processes (like households or productive firms) and that of *control agents* (or control organizations), $\mathscr{A}_{\mathbf{c}} \in \mathscr{A}$, whose *main* activity lies in information-processing and decision-making (like legislative bodies, local authorities, government agencies).

This classification of the agents requires some further comments. Firstly, there might be borderline agents (e.g. schools) whose classification is ambiguous and will be dependent on the role which they play in a given context. Secondly, the real units (real activities) of the control organizations are often negligible in theoretical considerations (just as the energy input of an electric control device might be negligible compared to the energy input of the physical process it controls). We also will make use of this simplification in the sequel and disregard the real activities of the control agents.

Finally, a few words are in order about the place of *fiduciary goods* (banknotes, accounting money, stocks and bonds), *monetary processes* (emission, exchange, income generation, credit) and *financial organizations* (banks, stockbrokers, tax offices) in the above dichotomy. Since it is not the physical transformation of fiduciary goods which is of economic interest (and hence they cannot belong to the real commodities), they belong to the control sphere by exclusion (in contrast with many other theoretical approaches where money is simply taken as one of the commodities). However, it must be kept in mind that the monetary sphere plays not only a particularly important part in the control of economic activities, but is in many aspects different from the rest of the control processes and obeys laws which are partly similar to the ones valid in the real sphere. A thorough discussion of the consequences of this reasoning would require a separate entry.

The economic control system can also be interpreted in the language of mathematical control theory. In a standard state-space representation of a continuously operating, multivariate, deterministic, externally commanded system, it consists of three equations:

Controlled subsystem:

$$\dot{\boldsymbol{x}} = \Phi(\boldsymbol{t}, \boldsymbol{x}, \boldsymbol{u}, \boldsymbol{z}) \tag{1}$$

Measurement:

$$\boldsymbol{y} = \psi(\boldsymbol{x}) \tag{2}$$

Controller:

$$\boldsymbol{u} = \Theta(\boldsymbol{t}, \boldsymbol{y} - \boldsymbol{y}^*), \tag{3}$$

where $t \geq 0$ denotes time and the dot above a variable differentiation with respect to time, $x(t)$ is the state vector, $u(t)$ is the control vector, $y(t)$ is the output vector, $y^*(t)$ is the command vector (the normal value of y), $z(t)$ is the vector of external effects on the state and Φ, Ψ and Θ are functions of their arguments as indicated.

The above system is said to be (globally) *viable* with respect to a closed convex subset $\mathscr{K}$ (the viability set) of the state space (the space of xs) if $\boldsymbol{x} \in \mathscr{K}$ for all $t \geq 0$ and any given initial state $\boldsymbol{x}(\mathbf{0}) = \boldsymbol{x}_{\mathbf{0}} \in \mathscr{K}$. If there is a state $\bar{x} \in \text{Int}\,\mathscr{K}$ and a number $\delta > 0$ such that $\boldsymbol{x} \in \mathscr{K}$ for all $t \geq 0$ and any given initial state $x_o \in \mathscr{K} \cap \{x \mid \|x - \bar{x}\| < \delta\}$, that is in the neighbourhood of $\bar{x}$, then the system is said to be *locally viable* at $\bar{x}$ with respect to $\mathscr{K}$.

It was proved by Aubin and Cellina (1983, theorem 5.4.1) that under some continuity, convexity and compactness assumptions there is a feedback rule Θ such that the system (1) to (3) is globally viable. It is to be noted, however, that this is an existence theorem from which no conclusion

can be drawn, in this generality, as to how the appropriate feedback rule Θ can be constructed.

The form (1) to (3) is, of course, not the only mathematical form in which a control system can be represented, but it is general enough to cover many important cases and special forms, which are too numerous to list here even partially. I would rather mention systems which are not explicitly represented by the above formulation.

(a) *Intermittently operating systems*. It is frequently the case that, especially in economic applications, the measurement of the state is not done continuously but only at discrete points of time. In this case the value of the control variable remains constant in between. If the observation times are equidistant, the above formulation can easily be transformed to cover this case simply by replacing the differential operator of the left-hand side by a time shift operator $Ex(t) = x(t+1)$

(b) *Stochastic systems* arise if x and/or y and/or u represent stochastic processes, and consequently some of the operators, Φ, Ψ Θ have stochastic values. In the case of a stochastic Φ, the controlled system works erratically; a stochastic ψ indicates measurement errors; and a stochastic Θ indicates uncertain control behaviour. These are frequent cases in economic systems. (It is to be noted that any random disturbance on z and y^*, i.e. on variables representing the environment, does not make the system stochastic, they are the realizations which enter the functions.)

(c) *Optimum control*, in which case the control rule is not given in the form (3) but is rather a solution to the problem of maximizing a given functional

$$\mathrm{I} = \int_0^T \mu(t, x, u)\mathrm{d}t$$

subject to (1) and some other constraints which require the control variable u to belong to a given set $\mathscr{U}$, and where μ is a scalar function of the arguments.

(d) *Higher-order systems* (as contrasted to externally commanded systems) take different forms:

Self-command (or target modifying) systems produce the command signals y^* themselves.

Learning systems modify the form or parameter values characterizing the operator Θ ; a learning mechanism improves the controller.

Self-organizing systems are capable of changing the control structures, the organizations and the interrelations among them both in the controlled subsystem and the controller.

Although it is clear that most economic systems perform such higher-order functioning, their mathematical analysis is difficult and mostly reduced to narrowly specified cases.

The Structure of the Controller

The controller was typified in equation (3) in a very rough-and-ready way. In actual economic systems the controller has a rather complicated structure, consisting of many different elements which interact in various ways. Some of the elements make simple observations, routine calculations, bookkeeping, and so on; others collect, generate and disseminate important information or make crucial decisions and plans relying on a vast amount of preprocessed information. Some of them work in parallel on different sets of data, and some form interactive or hierarchically ordered groups.

The study of such a structure must begin with the functioning of its constituent elements which are called *transfer elements*. A transfer element is an elementary part of a complex controller which cannot be divided further or has not been in a particular analysis.

There are three subsequent actions in the functioning of a transfer element:

Signal reception. The transfer element receives signals (information) from the observation of real processes, from the environment or from another transfer element. These are the *input signals* of the element.

Signal transformation or signal generation. The transfer element transforms, stores and combines the received signals and hereby generates new ones. The rules by which signals are generated form the *transfer function* of the element.

Signal emission. The transfer element transmits the generated signal (*output signal*) to one or more other transfer elements or to an agent which acts directly on real processes.

In the classification of the elementary control process we apply two criteria both with respect to the kinds of agents who participate in the process: – What kind of agent generates the signal? – Among what kind of agents is the signal transmitted?

With respect to *signal generation* we distinguish three kinds of processes:

Uncoordinated. The signal is generated by the control unit of a single real organization.

Interactive. The signal is generated jointly by the control units of several real organizations.

Centralized. The signal is generated by a control organization or jointly by several control and perhaps real organizations.

With respect to *signal transmission* we also distinguish three kinds of process:

Non-communicative. The signal does not leave the organization where it was generated.

Transactional. The sender and the addressee are two different real organizations, and the signal refers to an (actual or potential) real transaction (usually transfer of a commodity) between the two real organizations (e.g. dispatch of an order, a price quotation, a bill).

Communicative (non-transactional). Any other signal transmission; for example, among more than two real organizations, or whenever a control organization is the sender or the addressee or both.

This dual classification of the transfer elements can be summarized in below table. The two empty boxes represent signal generation–transmission combinations which cannot occur. (An interactive signal generation implies some kind of communication, since to generate signals jointly by several real organizations, they must communicate somehow. In the centralized signal generation a control organization takes part, hence it cannot be transactional.)

This simple classification scheme can be applied to elementary transfer units of the controller only. In a complex control process several transfer units are combined which differ with respect to their signal generation and transmission patterns.

	Signal generation		
	Uncoordinated	Coordinated	
Signal transmission		Interactive	Centralized
Non-communicative	+	Ø	+
Transactional	+	+	Ø
Communicative (non-transactional)	+	+	+

Most of the actually existing economic control systems may be called *partially coordinated systems*, in which a considerable part of the decisions are taken by the real organizations in isolation, another part by their interaction (e.g. on the market) and yet another part by different control agents (e.g. legislative bodies, government agencies, banks, trade unions etc.). The problem of analysing (synthesizing) an economic control system consists of the decision about whether one or the other function of the system is (should be) served by this or that kind of transfer unit and how these units are (can be) integrated into a viable or even efficient entity.

An essential feature of the above conceptualization of the structure of the economic control system is that it does not restrict the issue to 'control and coordination of economic activity' from the outside (done exclusively by specialized control organizations) but includes the control functions which work within the real organizations and interact among them. It is also to be noted that the classical distinction between centralized and decentralized control turned out to be insufficient and has been replaced by a more elaborate classification pattern.

A Non-Walrasian Control Structure

The first economic theory which offered a mathematically rigorous representation of the control mechanism of a national economy is known under the term *General Equilibrium Theory.* Since neither Keynesian macroeconomics in capitalistic systems nor shortage phenomena in socialist economies could have been appropriately studied within the framework of this theory, a new approach emerged under various names: *disequilibrium theory, temporary equilibrium theory, theory of equilibria with rationing, non-Walrasian equilibrium theory.* Without discussing here merits and demerits of these approaches, it is to be noted that – as a rule–they were not based on mathematical control theory.

In what follows I present a non-Walrasian control model differing from the aforementioned approaches in many aspects:

(a) It is not only the (essentially static) equilibrium, its existence and efficiency which is studied, but rather the dynamics of the trajectories leading to an equilibrium state. Real and control processes run in parallel (out of equilibrium); there is no timeless *tâtonnement* process.
(b) No optimizing behaviour of the agents is assumed; adjustment to exogenous normal values of some output variables is the behavioural rule. When applying this 'control by norm' principle I assume that norms are formed by individual experience or social consent in a long-run process (which is not modelled here), and the norms remain constant along the short-and medium-run adjustment process.
(c) Information and decisions are not centralized as in the hands of an auctioning or rationing agent, but the whole control process is carried out by the control units of real organizations among themselves in an uncoordinated but transactionally communicative way. (This refers only to the particular model variant which follows. In other variants control organizations and coordination also appear.)
(d) Only observable variables are used (no fictitious 'effective demand') and hence the underlying assumptions can be, but generally have not been, empirically tested. (For an exception, see Kawasaki et al. 1982.)

Still it is to be admitted that this approach has not yet reached the generality and mathematical refinement of general equilibrium and disequilibrium theory.

The model. The economy consists of n producers (real organizations), each producing a single commodity. The technology is of the Leontief-type, with constant input coefficients. The environment acts upon the real processes by the final use (private and public consumption, investment) and on the control processes by past experiences, which determine the normal level of inventories (output stocks, input stocks) and backlog orders.

Notation: lower case–n-vector; upper case–$n \times n$ matrix; Greek lower case–scalar.

State variables:

q – vector of output stocks
V – matrix of input stocks
K – matrix of backlog orders

An asterisk * as a superscript refers to the exogenous normal values of the state variables.

Control variables:

r – vector of production ($\langle r \rangle$: the diagonal matrix formed from r)
Y – matrix of commodity transfers among producers
W – matrix of the transmission of new orders

Other notations:

$e = [1,1,\ldots 1]'$ – the summation vector
A – the input coefficient matrix
c – the vector of final uses
β, γ – control parameters
$\Gamma(\cdot) = -2\beta\gamma\,[d(\cdot)/\mathrm{dt}] - \gamma^2 \cdot (\cdot)$-differential operator.

Assumptions:

1. The final use is constant and semipositive, $c \geq 0$.

2. The input coefficient matrix A is constant and
   (a) non-negative
   (b) irreducible
   (c) productive, i.e. its spectral radius $\rho(A) < 1$.
3. $\gamma > 0$ (without loss of generality).

The real processes:

$$\dot{q} = r = Ye - c \tag{4}$$

$$\dot{V} = Y - A\langle r \rangle. \tag{5}$$

Equation (4) expresses the change of output stocks as the difference between the amounts produced and that transferred for productive and final use. Equation (5) tells that the change of input stocks equals the material purchases minus the materials used up in production.
The control processes:

$$\dot{K} = W - Y \tag{6}$$

$$\dot{\boldsymbol{r}} = \Gamma(\boldsymbol{q} - \boldsymbol{q}^*) \tag{7}$$

$$\dot{\boldsymbol{W}} = \boldsymbol{\Gamma}(\boldsymbol{V} - \boldsymbol{V}^*) \tag{8}$$

$$\dot{\boldsymbol{Y}} = -\boldsymbol{\Gamma}(\boldsymbol{K} - \boldsymbol{K}^*). \tag{9}$$

Equation (6) describes the bookkeeping (at the supplier) of the backlog of orders; its change equals the difference between the incoming new orders and the deliveries. Equations (7) to (9) are the control equations proper, all of the same (linear) form, describing the assumed behaviour of the agents. The decisions on production level is dependent on the output stocks, the dispatch of orders (by the buyer) on the input stocks, and the deliveries (decided by the supplier) on the backlog of orders, in each case taking the deviation of the actual value from the normal value into account. None of these behavioural rules is at variance with common sense.

It is to be observed, that the transfer elements corresponding to equations (6) to (9) generate all the signals without any coordination; equations (6), (7) and (9) represent non-communicative elements, while there is transactional communication according to equation (8); namely, the orders are transmitted from the buyers to the suppliers.

The viability domain $\mathscr{K}$ for system (4) to (9) may be defined in the following way:

(a) All the variables are uniformly bounded, but the bounds are unspecified.
(b) The variables in q, V, K, r and Y are non-negative, but negative elements of W (withdrawal of orders) are permitted.

Although the theorem of Aubin and Cellina referred to above does not apply here, where was specified the form of the control equations (6) to (9), we can still guarantee local viability in the neighbourhood of the equilibrium state by an appropriate choice of the parameter β.

Theorem. Suppose that the following conditions are met:

(a) Assumptions (4) to (6) hold.
(b) The norms are positive: $q^*>0$, $V^*>0$, $K^*>0$.
(c) $\beta > \max\{|\operatorname{Im}\sigma| / (2|\sigma|)\sqrt{\operatorname{Re}\sigma|} - \sigma^3 + 2\sigma^2 - 2\sigma + 1 \in \text{spectrum of } A\}$ and $\beta > \sqrt{6/4}$.
(d) The initial values at $t = 0$: $(q^0, V^0, K^0, r^0, Y^0, W^0)$ are close enough to the equilibrium state:

$$\overline{q} = q^*, \quad \overline{V} = V^*, \overline{K} = K^*,$$
$$\overline{r} = (E - A)^{-1}c, \quad \overline{Y} = \overline{W} = A\left\langle (E - A)^{-1}c \right\rangle.$$

Then the system (4) to (9) is viable for $t \geq 0$ (local viability).

Remark: under (a) the relation (c) is both a necessary and sufficient condition of asymptotic stability.

A detailed analysis of the model and proof of the theorem (extended to varying c) is to be found in a forthcoming book by Martos. Models in a similar vein are analysed in Kornai and Martos (1981).

Control Functions

Salvador Navarro

Abstract

The control function approach is an econometric method used to correct for biases that arise as a consequence of selection and/or endogeneity. It is the leading approach for dealing with selection bias in the correlated random coefficients model. The basic idea of the method is to model the dependence between the variables not observed by the analyst on the observables in a way that allows us to construct a function K such that, conditional on the function, the endogeneity problem (relative to the object of interest) disappears.

The control function approach is an econometric method used to correct for biases that arise as a consequence of selection and/or endogeneity. It is the leading approach for dealing with selection bias in the correlated random coefficients model (see Heckman and Robb 1985, 1986; Heckman and Vytlacil 1998; Wooldridge 1997, 2003; Heckman and Navarro 2004), but it can be applied in more general semiparametric settings (see Newey et al. 1999; Altonji and Matzkin 2005; Chesher 2003; Imbens and Newey 2006; Florens et al. 2007).

The basic idea behind the control function methodology is to model the dependence between the variables not observed by the analyst on the observables in a way that allows us to construct a function K such that, conditional on the function, the endogeneity problem (relative to the object of interest) disappears.

In this article I deal exclusively with the problem of identification. That is, I assume access to data on an arbitrarily large population. As a consequence, I do not discuss estimation, standard errors or inference. In the examples, I analyse how to recover parameters in a way that, I hope, shows directly how to perform estimation via sample analogues.

The Set-Up

The general set-up I consider is the following two-equation structural model; an outcome equation:

$$Y = g(x, D, \varepsilon), \tag{1}$$

and an equation describing the mechanism assigning values of D to individuals:

$$D = h(X, Z, v), \tag{2}$$

where X and Z are vectors of observed random variables, D is a (possibly vector valued) observed random variable, and ε and v are general disturbance vectors not independent of each other but satisfying some form of independence of X and Z.

The problem of endogeneity arises because D is correlated with ε via the dependence between ε and v. Because Eq. (2) represents an assignment mechanism in many economic models, it is generically called the 'selection' or 'choice' equation. This set-up has been applied to problems like earnings and schooling (Willis and Rosen 1979; Cunha et al. 2005), wages and sectoral choice (Heckman and Sedlacek 1985) and production functions and productivity (Olley and Pakes 1996), among others.

The goal of the analysis is to recover some functional of $g(X, D, \varepsilon)$ of interest

$$a(X, D) \tag{3}$$

that cannot be recovered in a straightforward way because of the endogeneity/ selection problem. As an example, when D is binary interest sometimes centres on the effect of going from $D = 0$ to $D = 1$ for an individual chosen at random from the population, the so-called average treatment effect:

$$a(X, D) = E(g(X, 1, \varepsilon) - g(X, 0, \varepsilon)).$$

The key behind the control function approach is to notice that (conditional on X, Z) the only source of dependence is given by the relation between ε and v. If v was known, we could condition on it and analyse Eq. (1) without having to worry about endogeneity. The main idea behind the control function approach is to recover some function of v via its relationship with the model observables so that we can now condition on it and solve the endogeneity problem.

Definition The control function approach proposes a function K (the control function) that allows us to recover a (X, D) such that K satisfies

A-1. K is a function of X, Z, D.

A-2. ε satisfies some form of independence of D conditional on ρ (X, K), with ρ a knowable function.

A-3. K is identified.

Assumption **A-2** is the key assumption of the approach. It states that, once we condition on K, the dependence between ε and D (that is, the endogeneity) is no longer a problem. To help fix ideas, consider the following example of a simple linear in parameters additively separable version of the model of Eqs. (1 and 2).

Example 1 *Linear regression with constant effects. Write the outcome Eq. (1) as*

$$Y = X\beta + D\alpha + \varepsilon$$

and assume that our object of interest (3) is α. Assume that we can write Eq. (2) as

$$D = X\rho + Z\pi + v \tag{4}$$

with v, $\varepsilon \perp\!\!\!\perp X$, Z where $\perp\!\!\!\perp$ denotes statistical independence. Such a model arises, for example, if Y is logearnings and D is years of schooling as in Heckman et al. (2003). If ability is unobservable since high ability is associated with higher earnings but also with higher schooling, then ε and v would be correlated.

If we let $K = v$ be the residual of the regression in (4), then we can recover a from the following regression

$$Y = X\beta + D\alpha + K\psi + \eta,$$

where it follows that $E(\eta|X, K) = 0$. It is easy to show that in this case the control function estimator and the two-stage least squares estimator are equivalent. (To my knowledge, although in a different context – a SUR model – Telser 1964, was the first to use the residuals from other equations as regressors in the equation of interest.)

The previous case is a simple example of a control function where $K = D - E(D|X, Z)$. In

this case, because of the constant effects assumption (that is, α is not random), standard instrumental variables methods and the control function approach coincide. In general, this is not the case.

In the next section I describe in detail the control function methodology for the binary choice case (Roy 1951). This case is interesting both because it is the workhorse of the policy evaluation literature and because, by virtue of its nonlinearity, it highlights the implications of a nonlinear structure in a relatively simple context. I then briefly describe extensions to more general cases. For simplicity, I focus on the additively separable in unobservables case, but recent research provides generalizations to non-additive functions (see Blundell and Powell 2003; Imbens and Newey 2006, among others).

The Case of a Binary Endogenous Variable

In this section I describe how the control function approach solves the selection/ endogeneity problem when the endogenous variable is binary. This problem has a long tradition in economics going back (at least) to Roy (1951). In Roy's original version of the model (see Roy model) an individual is deciding whether to become a fisherman ($D = 0$) or a hunter ($D = 1$).

Associated with each occupation is a payoff $Y_D = g_D(X) + \varepsilon_D$. Since we can only observe individuals in one sector at a time, the *observed* outcome for an individual is given by Y_1 if he becomes a hunter ($D = 1$) and by Y_0 if he becomes a fisherman ($D = 0$). That is, the observed outcome (Y) can be written as:

$$\begin{aligned} Y &= DY_1 + (1-D)Y_0 \\ &= g_0(X) + D(g_1(X) - g_0(X)) + \varepsilon_0 + D(\varepsilon_1 - \varepsilon_0). \end{aligned} \tag{5}$$

The model is closed by assuming that individuals choose the occupation with the highest payoff. That is,

$$\begin{aligned} D &= 1(Y_1 - Y_0 > 0) \\ &= 1(g_1(X) - g_0(X) + \varepsilon_1 - \varepsilon_0 > 0), \end{aligned} \tag{6}$$

where $\mathbf{1}(a)$ is an indicator function that takes value 1 if a is true and 0 if it is false. Endogeneity arises because the error term in choice Eq. (6) contains the same random variables as the outcome Eq. (5). A generalized version of the model replaces the simple income maximization rule in (6) with a more general decision rule

$$D = 1(h(X,Z) - v > 0). \tag{7}$$

The model described by Eqs. (5 and 7) is general enough to be used in many different cases. Many qsts of interest in economics fit this framework if, instead of thinking of two sectors, fishing and hunting, we think of two generic potential states, the treated state ($D = 1$) and the untreated state ($D = 0$) with their associated potential outcomes. The decision rule in (7) is general enough to capture not only income maximization but also utility maximization and even a deciding actor different from the agent directly affected by the outcomes (parents deciding for their children, for example). The simple income maximization rule in (6) shows why, in *general* if $\varepsilon_1 \neq \varepsilon_0$, then $\varepsilon_1 - \varepsilon_0$ is likely to be correlated with D.

The correlated random coefficients model is a special case of the model described by (5) and (7) when $\varepsilon_1 - \varepsilon_0$ is not independent of D and $g_j(X) = \alpha_j + X\beta$ for $j = 0,1$. (For simplicity I assume $\beta_1 = \beta_0 = \beta$. The case where $\beta_1 \neq \beta_0$ follows directly.) To see why simply rewrite (5) as

$$Y = \alpha_0 + X\beta + D(\alpha_1 - \alpha_0 + \varepsilon_1 - \varepsilon_0) + \varepsilon_0 \tag{8}$$

so that now the coefficient on D is (a) random and (b) correlated with D. In this case we have that the gains from treatment ($\alpha_1 - \alpha_0 + \varepsilon_1 - \varepsilon_0$) are heterogeneous (that is, they are not constant even after controlling for X) and they are correlated with D. I come back to this special linear in parameters case in Example 2.

Though other parameters of interest can be defined, I consider the case in which we are interested in the two particular functionals that receive the most attention in the evaluation literature – the average treatment effect and the average effect of treatment on the treated. I impose that ε_1, ε_0, v are absolutely continuous with finite means, and that

$\varepsilon_1, \varepsilon_0, v \perp\!\!\!\perp X, Z$. (One could weaken the assumption to be $\varepsilon_1, \varepsilon_0 \perp\!\!\!\perp X|Z$ and $v \perp\!\!\!\perp X, Z$.)

Under these assumptions the average treatment effect is given by

$$\begin{aligned} ATE(x) &= E(Y_1 - Y_0 | X = x) = g_1(x) - g_0(x) \\ &= x(\beta_1 - \beta_0) \end{aligned}$$

where the last equality follows if Eq. (8) applies. $ATE(X)$ is of interest to answer qsts like the average effect of a policy that is mandatory, for example. When receipt of treatment is not mandatory or randomly assigned, the average effect of treatment among those individuals who are selected into treatment is commonly the functional of interest (see Heckman 1997; Heckman and Smith 1998). This effect is measured by the average effect of treatment on the treated:

$$\begin{aligned} TT(x) &= E(Y_1 - Y_0 | X = x, D = 1) \\ &= g_1(x) - g_0(x) + E(\varepsilon_1 - \varepsilon_0 | X = x, D = 1) \\ &= \alpha_1 - \alpha_0 + E(\varepsilon_1 - \varepsilon_0 | X = x, D = 1), \end{aligned}$$

where the last equality follows for the linear in parameters case of Eq. (8).

Now, suppose we ignored the endogeneity problem and attempted to recover either of these objects from the data on outcomes at hand. In particular, if we used the (observed) conditional means of the outcome

$$\begin{aligned} E(Y | X = x, D = 1) - E(Y | X = x; D = 0) \\ = g_1(x) - g_0(x) + E(\varepsilon_1 | X = x, D = 1) \\ - E(\varepsilon_0 | X = x, D = 0) \end{aligned}$$

we would not recover either $ATE(X)$ or $TT(x)$. Notice too that, since the endogenous variable D is binary, we cannot directly recover v and use it as a control as we did in the linear case of Example 1 above. Instead, we can recover a function of v that satisfies the definition of a control function.

Let $F_v()$ denote the cumulative distribution function of v. To form the control function in this case, first take Eq. (7) and write the choice probability

$$\begin{aligned} P(x, z) &= \Pr(D = 1 | X = x, Z = z) \\ &= \Pr(v < h(x, z)) = F_v(h(x, z)), \end{aligned}$$

which under our assumptions implies

$$h(x, z) = F_v^{-1}(P(x, z)).$$

Following the analysis in Matzkin (1992), we can recover both $h(x, z)$ and $F_v()$ nonparametrically up to normalization.

Next, take the conditional (on X, Z) expectation of the outcome for the treated group

$$\begin{aligned} E(Y | X = x, Z = z, D = 1) \\ = g_1(x) + E(\varepsilon_1 | X = x, Z = z, D = 1). \end{aligned}$$

We can write the last term as

$$\begin{aligned} E(\varepsilon_1 | X = x, Z = z, D = 1) &= E(\varepsilon_1 | v < h(x, z)) \\ &= E\left(\varepsilon_1 | v < F_v^{-1}(P(x, z))\right). \end{aligned}$$

That is, we can write it as a function of the known h(x, z) or, equivalently, as a function of the probability of selection $P(x, z)$,

$$\begin{aligned} E(Y | X = x, Z = z, D = 1) \\ = g_1(x) + K_1(P(x, z)), \end{aligned}$$

where $K_1(P(X, Z))$ satisfies our definition of a control function. So, provided that we can vary $K_1(P(X, Z))$ independently of $g_1(X)$, we can recover $g_1(X)$ up to a constant. We can identify the constant in a limit set such that P → 1 since $\lim_{P \to 1} K_1(P) = 0$. Provided that we have enough support in the probability of treatment – that is, provided that some people choose treatment with probability arbitrarily close to (1) – we can recover the constant. (See Example 2.) Using the same argument we can form

$$\begin{aligned} E(Y | X = x, Z = z, D = 0) \\ = g_0(x) + K_0(P(x, z)) \end{aligned}$$

and identify $g_0(X)$ (up to a constant) and the control function K_0(P(X, Z)). As before, we can recover the constant in $g_0(X)$ by noting that $\lim_{P \to 0} K_0(P) = 0$.

Intuitively, we need to be able to vary the $K_1(P(X, Z))$ function relative to the $g_1(X)$ function

so that we can identify them from the observed variation in Y_1. One possibility is to impose that g_1 and K_1 are measurably separated functions. (That is, provided that, if $g_1(X) = K_1(P(X, Z))$ almost surely then $g_1(X)$ is a constant almost surely; see Florens et al. 1990.) The simplest way to satisfy this restriction is by exclusion. That is, if $K_1(P(X, Z))$ is a nontrivial function of Z conditional on X and Z shows enough variation, we can vary the K_1 function by varying Z while keeping g_1(X) constant. Another related possibility is to assume that g_1 and K_1 live in different function spaces. For example, g_1 a linear function and K_1 the nonlinear mills ratio term that results from assuming that (ε_0, ε_1, v) are jointly normal as in the original Heckman (1979) selection correction model.

Once we have recovered $g_0(X)$, $g_1(X)$, K_0 ($P(X, Z)$), K_1 ($P(X, Z)$) we can now form our parameters of interest. Given $g_0(X)$ and $g_1(X)$, $ATE(X) = g_1(X) - g_0(X)$ immediately follows. To recover $TT(X)$, first notice that, by the law of iterated expectations

$$\begin{aligned} E(\varepsilon_0|X = X, Z = z) &= E(\varepsilon_0|X = x, Z = z, D = 1)P(x, z) \\ &\quad + E(\varepsilon_0|X = x, Z = z, D = 0)(1 - P(x, z)) \\ &= 0, \end{aligned}$$

where P(X, Z) is known from our analysis above and $E(\varepsilon_0|\ X = x,\ Z = z,\ D = 0) = K_0(P(X, z))$. Rewriting the expression above we get $E(\varepsilon_0|X = x, Z = z, D = 1) = \frac{K_0(P(x,z))(1-P(x,z))}{P(x,z)}$. With this expectation in hand we can recover $TT(X, Z) = g_1(X) - g_0(X) + K_1(P(X, Z)) + \frac{K_0(P(X,Z)(1-P(X,Z))}{P(X,Z)}$. By integrating against the appropriate distribution, we can recover $TT(X) = \int TT(X, z)dF_{Z|X,\ D\ =\ 1}(z)$.

The following example shows how the control function methodology can be applied to recover average effects of treatment in a linear in parameters model with correlated random coefficients. This model arises when there are unobservable gains that vary over individuals and these gains are correlated with the choice of treatment (that is, when there is essential heterogeneity. See Heckman et al. 2006; Basu et al. 2006). The Roy model of Eqs. (5 and 6) in which the unobservable individual gains ($\varepsilon_1 - \varepsilon_0$) are correlated with the choice of sector is an example of this case.

Example 2 *Correlated random coefficients with binary treatment.* Assume we can write the outcome equations in linear in parameters form,

$$Y_j = \alpha_j + X\beta_j + \varepsilon_j j = 0, 1.$$

Let D be an indicator of whether an individual receives treatment ($D = 1$) or not ($D = 0$). We also write a linear in parameters decision rule:

$$D = 1(X\delta + Z\gamma - v > 0).$$

From the analysis in Manski (1988) we can recover δ, γ and F_v (up to scale). With $P(x, z) = \Pr(D = 1|X = x, Z = z)$ in hand, we then form

$$Y_j = \alpha_j + X\beta_j + K_j(P(X, Z)) + \eta_j$$

where $E(\eta_j|\ X = x,\ K_j(P(X, Z)) = k_j) = 0$. To emphasize the problem of identification of the constant α_j we can rewrite the outcome as

$$Y_j = \tau_j + X\beta_j + \tilde{K}_j(P(X, Z)) + \eta_j$$

where $K_j = (P(X, Z)) = \kappa_j + \tilde{K}_j(P(X, Z))$ and $\tau_j = \alpha_j + \kappa_j$.

The elements of the outcome equations can be recovered by various methods. One could, for example, use Robinson (1988) and use residualized nonparametric regressions to recover β_j, τ_j and $K_j(P(X, Z))$. Alternatively, one could approximate $K(P(X,\ Z))$ with a polynomial on $P(X, Z)$. In this case we would have

$$\begin{aligned} Y_j = \tau_j + X\beta_j + \pi_1 P(X, Z) + \pi_2 P(X, Z)^2 + \cdots \\ + \pi_n P(X, Z)^n + \eta_j \end{aligned}$$

where $\tilde{K}_j(P(X, Z)) = \sum_{i=1}^{n} \pi_{j1} P(X,\ Z)^i$. When $j = 0$ then $\lim_{P \to 0} K_0(P) = 0$ and it follows that $\tilde{K}_0(P) = K_0(P)$ and $\tau_0 = \alpha_0$. For the treated case ($j = 1$) we have that $lim_{P \to 1} K_1(P(X, Z)) = 0$. Since $\tilde{K}_1(1) = \sum_{i=1}^{n} \pi_{1i}$ it follows that $\kappa_1 = -\sum_{i=1}^{n} \pi_{1i}$ and $\alpha_1 = \tau_1 - \sum_{i=1}^{n} \pi_{1i}$.

Extensions for a Continuous Endogenous Variable

In this section I briefly review the use of the control function approach for the case in which the endogenous variable D is continuous and we assume that $X, Z \perp\!\!\!\perp \varepsilon, v$. Following Blundell and Powell (2003) I assume that the object of interest is the average structural function

$$a(X,D) = \int g(X,D,\varepsilon) dF_{\varepsilon}(\varepsilon),$$

which, in the additively separable case $g(X, D, \varepsilon) = \mu(X, D) + \varepsilon$ is simply the regression function $\mu(X, D)$.

If we assume that the choice equation

$$D = h(X,Z,v)$$

is strictly monotonic in v (which would follow automatically if it were additively separable in v), we can recover $h()$ and F_v from the analysis of Matzkin (2003) up to normalization. A convenient normalization is to assume that $v \sim$ Uniform (0,1) in which case we can directly recover v from the quantiles of F_v, but other normalizations are possible. From the independence assumption it follows that $E(\varepsilon|X, D, Z) = E(\varepsilon|v)$, so we can write the outcome equation as

$$\begin{aligned} Y &= \mu(X,D) + E(\varepsilon|\, v) \\ &= \mu(X,D) + K(v) \end{aligned}$$

which allows us to recover $\mu(X, D)$ directly (up to normalization). In the additively separable case we analyse, we can relax the full independence assumption and instead assume directly that the weaker mean independence assumption $E(\varepsilon|X, D, Z) = E(\varepsilon|v)$ holds.

Conventionalism

Lawrence A. Boland

Abstract

Conventionalism is the methodological doctrine that asserts that explanatory ideas should not be considered true or false but merely better or worse. The truth status of theories cannot be so easily dismissed. While a choice of language may be conventional, the truth status is not a matter of convenient choice. Among economists the most common practice is to avoid using the words 'true' (or 'false') when discussing models and assumptions and instead to invoke 'best' by using a conventionalist theory-choice truth-likeness criterion. The notion of a conventionalist theory-choice criterion presumes a philosophical necessity to choose one theory among competitors.

Conventionalism is the methodological doctrine that asserts that explanatory ideas should not be considered true or false but merely better or worse. At the beginning of the 20th century the status of the laws of physics was the burning issue. It was the famous philosopher Henri Poincaré who in 1902 asked whether the laws of physics were 'only arbitrary conventions'. He answered 'Conventions, yes; arbitrary, no'. Obviously, languages and measurement units are arbitrary conventions but nobody would seriously claim they were explanatory ideas. In Poincaré's day, the question bothering physicists who were dealing with Albert Einstein's new theory (namely, relativity) was whether the choice between Euclidian and non-Euclidian geometry was a matter of convention – that is, a matter of convenience. For everyday questions Euclidian geometry is convenient but perhaps for Einstein's physics non- Euclidian is the better choice. For some matters, such as the choice of language to express

an idea or of units to measure a distance, most people would allow that such a choice may be completely arbitrary.

Although few of them have ever heard of Poincaré, most economists will say almost the same thing whenever they make a methodological pronouncement concerning the truth status of economic theories, models or assumptions. Rarely, however, have economists been concerned with the questions raised about non- Euclidian geometry (except for John Maynard Keynes's metaphorical suggestion at the beginning of his *General Theory*). Of course, hardly any economist questions language being a matter of convenience; moreover, economists often justify the use of mathematics by claiming that its use is like that of language and thus should be judged by its convenience, not its truth status (Samuelson 1952, 1954). But in the 1940s critics of Marshallian and Walrasian (that is, neoclassical) economics argued that the truth status of a theory's assumptions should matter. In his 1953 response to the critics of the realism of assuming perfect competition when explaining the economy, Milton Friedman advocated an alternative methodology: instrumentalism. Instrumentalism, unlike conventionalism, claims merely that the truth status of assumptions does not matter so long as the theory is useful. For those economists who still think the truth status of their theories matters, but realize that one can never prove a theory's truth status by induction, the most common response is something like Poincaré's conventionalism.

There are many examples of economists making methodological pronouncements that exhibit adherence to conventionalism. Paul Samuelson denied that any economic explanation was true, writing that 'An explanation . . . is a better kind of description' (1965, p. 1165). Obviously, some descriptions are better than others, and thus he claimed that we give the honorific title of 'explanation' to the best description. If one were to agree with Samuelson then one certainly could never claim that one's explanation was true. Herbert Simon chose to express this differently; he said all explanations are approximations. Specifically, he said (1963, p. 231) 'Unreality of premises is not a virtue in scientific theory; it is a necessary evil – a concession to the finite computing capacity of the scientist that is made tolerable by the principle of continuity of approximation'. Robert Lucas agreed with that when he said 'Any model that is well enough articulated to give clear answers to the questions we put to it will necessarily be artificial, abstract, patently "unreal"' (1980, p. 696). Robert Aumann, the game theorist, has advocated an even more limited view for explanatory theories. As he put it 'scientific theories are not to be considered "true" or "false"'. Going further, he said, 'In constructing such a theory, we are not trying to get at the truth, or even to approximate to it: rather, we are trying to organize our thoughts and observations in a useful manner.' In this regard, he argued that a theory is like 'a filing system in an office operation, or to some kind of complex computer program' (1985, pp. 31–2). Lucas and Aumann were merely restating Samuelson's 1965 position on methodology.

The Philosophy of Conventionalism

For followers of philosophers Willard Quine and Karl Popper, the truth status of explanations or theories cannot be so easily dismissed or limited. While any choice of language or units of measurement may be conventional, the truth status of theories is not a matter of choice, convenient or otherwise.

Unfortunately, the methodological doctrine of conventionalism is often confused with instrumentalism. As the philosopher Joseph Agassi (1966a) points out, they are responses to two different questions. One concerns the role of theories and the other the truth status of theories. Specifically, if we ask 'What is the *role* of a theory?', instrumentalism's answer is that theories are tools and should not be judged by epistemological standards of truth status or by conventionalist criteria of approximate truth or relative merit (except, perhaps, by simplicity or economy). Conventionalism's different answer is the one stated by Aumann: theories are filing systems or catalogues of observed data. Of course, every

description is also an appeal to a filing system in that one depicts or locates it within a system by referring to other defined dimensions and concepts. If, instead, we chose the question, 'What is the *status* of a theory?', conventionalism's answer is that, of course, theories are approximations and thus should not be considered true or false but better or worse. Instrumentalism's position is simply that truth status does not matter. With this in mind, it is easy to find economists advocating both methodological positions depending on which question is asked. For example, after saying that a theory is like a filing system, Aumann goes on to say that 'We do not refer to such a system as being "true" or "untrue"; rather, we talk about whether it "works" or not, or, better yet, how well it works' (1985, p. 32).

From the perspective of the philosopher Karl Popper, the main question is: what problem is solved by the doctrine of conventionalism? Since the time when Adam Smith's friend David Hume observed that there was no logical justification for the common belief that much of our empirical knowledge was based on inductive proofs (see Russell 1945), methodologists and philosophers have been plagued with what they call the 'problem of induction'. The paradigmatic instance of the problem of induction is the realization that we cannot provide an inductive proof that 'the sun will rise tomorrow'. This leads many of us to ask, 'So *how* do we know the sun will rise tomorrow?' If it is impossible to provide a proof, then presumably we would have to admit we do not know the answer to this burning question! Several writers have claimed to have solved this famous problem (for a discussion of such claims, see Miller 2002). Such a claim is quite surprising since it is a problem that is impossible to solve. Nevertheless, what it is and how it is either 'solved' or circumvented is fundamental to understanding all contemporary methodological discussions.

Up to the time of Popper's entry into the discussion in the mid-1930s, most philosophers took it for granted that all claims to knowledge must be justified. Inductive arguments were seen to be the obvious method. But Popper acknowledged the problem that as a matter of simple logic an inductive argument is impossible. A logical argument is one in which, whenever all the premises are true, any logically derived statements must also be true. An inductive argument is one in which one would argue logically from the truth of particular statements (for example, observation statements such as 'the sun rose today at 7 a.m.') alone to prove the truth of a general statement (for example, the sun always rises). The 'problem of induction' would be solved if one could demonstrate the existence of such an inductive logic. The importance of this problem arises once one realizes that, without some premise of a general nature (such as we find in physics concerning the movement of the earth around the sun and earth's rotation), no finite set of observations could ever prove the non-existence of a counter-example (a refuting instance that would be denied by the general statement in question) somewhere or sometime in the future. For example, to prove that the statement 'All ravens are black' is true requires a proof that there does not exist anywhere in the universe a 'non-black raven'. Everyone agrees that one cannot provide such a literal negative proof. So, it has been argued (Boland 1982, 2003), most discussions of methodology in economics are concerned with the problem *with* induction rather than the problem *of* induction.

Conventionalism can be seen as a solution to the problem *with* induction. Conventionalism presumes that this problem can be solved even though the problem *of* induction cannot. That is, if there were an inductive logic, then the truth status of a true theory or model could in principle be provable since all assumptions of a universal form could be inductively proven. Without such a logic, many think – still insisting that any claim to knowledge must be justified – that some other means must be found to sort through competing theories. That is, how can we choose the best from a set of competing theories? More specifically, by what criteria do we choose between competing theories? Obvious examples of such criteria are simplicity, generality, robustness, testability, falsifiability, verifiability, confirmability, operational meaningfulness, plausibility, probability, and so on. None of these criteria are considered substitutes for truth status (truth or falsity); they are only

choice criteria (truthlikeness). If a criterion can be quantified, one could even see the choice as a matter of applying economics (see Boland 1971). For example, one might choose the theory that is most confirmed – but it still must be remembered that today's most confirmed theory could be a false theory even today.

For many philosophers, such theory-choice criteria are just short-run solutions to the problem *with* induction. That is, in the short run we might be satisfied with invoking such criteria, so that we can choose between theories and thereby be able to push on, but it is hoped that in the long run someone can come up with a solution to the problem *of* induction.

Conventionalism as Employed by Economists

Among economists who openly practise conventionalism, it is a doctrine with many variants and relatives. The most common practice is the avoidance of using the words 'true' (or 'false') when discussing theories, models and assumptions. Instead, we see 'best' being invoked with the use of some conventionalist theory-choice truthlikeness criterion. Also common is the use of the word 'valid' to avoid saying 'true'. Sometimes it is used to mean that a theory is valid if it is logically consistent with available data or evidence. The difficulty is that 'valid' is a question of the logicality of an argument (do the conclusions necessarily follow from the assumptions made?) A logically valid argument can still be false, so it is not always clear what is meant by a valid statement or a valid theory.

One weak form conventionalism is old-fashioned relativism. Another weak form is what the followers of McCloskey (1983) call modernism. In yet another weak form it can be seen to be the rationale for so-called methodological pluralism. The most common form is stronger in that it involves the notion that theories are to be evaluated or compared by means of some form of probability calculus.

Those adherents to conventionalism who advocate the objective form of probability calculus seem unaware of the logical difficulties involved. One might wish to use probability as the measure of confirmation of a theory so that one could use such a measure as the criterion for theory choice. The difficulty arises when one asks what constitutes positive evidence – namely, evidence to be used to calculate the probability measure that would serve as, say, the 'degree of confirmation'. Of course, if one requires all observational evidence to be exactly true, then to be an actual confirmation the objective probability measure would have to be 1.00. That is, just one true observation that contradicts the theory in question requires the rejection of the theory. So it would seem that objective probability measures are inappropriate. But econometrics-based hypothesis testing is not as strict since it allows for errors in the observations of the variables. Hence, the objective probability measure can be of some value less that 1.00. Theory choice in this case would seem to be a simple matter of choosing the theory with the highest probability, that is, the highest degree of confirmation.

Among those who openly advocate a subjective form of probabilities, the most common view is based on Bayesian probabilities which provide a compromise by allowing for explicit roles for both subjectivism in the form of prior probability assessments and objectivism in the form of adjustments based on new objective evidence. Again, the main question for using probabilities concerns what would count as confirming evidence or evidence that increases the subjective probability. Like all confirmation criteria, even if everyone attaches a high subjective probability to the theory in question being true it could still be false and perhaps refuted by the next observation report.

The common element underlying all probability measures to be used for theory choice is the notion that the number of confirming observations should somehow matter. Of course, such an expectation does not require the questionable use of probabilities as a measure of confirmation. But avoiding any reliance on probability will not circumvent the more well-known logical problems of confirmation. All conceptions of a logical connection between positive evidence and degrees of confirmation suffer from a profound logical

problem called, by some philosophers, the 'paradox of confirmation' or the 'paradox of the ravens' (cf. Sainsbury 1995; Agassi 1966b).

The philosopher's paradox of confirmation merely points out that *any* evidence which does not refute a simple universal statement, say, 'All ravens are black' must increase the degree of confirmation. The paradox is based on the observation that, *in terms of what observable evidence would count,* this example of a simple universal statement is logically equivalent to its 'contra-positive' statement 'All non-black things are non-ravens'. Any true observation that is consistent with one of the statements is consistent with the other (equivalent) statement. But in these terms it must be recognized that positive evidence consistent with the contra-positive statement includes red shoes as well as white swans – since in both cases we have non-black things which are not ravens. That is, the set of all confirming instances must include all things which are not non-black ravens. In other words, the more red shoes we observe, the more evidence there is in favour of the contra-positive statement – that is, a red shoe increases the universal statement's degree of confirmation – and, since the contra-positive statement is logically equivalent to the universal statement in question, the latter's degree of confirmation also increases. Obviously, this consideration merely divides the contents of the universe into non-black ravens and everything else (Hempel 1966). This consideration calls into question all claims of confirmation.

Few economists who make pronouncements concerning the appropriate methodology to use in economics are aware of the philosophical problems involved. Almost all think we must have some criterion to choose between competing theories or models. All of them take for granted the necessity of justifying their choice. No recognition seems to be given to the simple fact that one's favourite theory can be true even though it cannot be proven true. That is, whether one's theory is true is a separate question from how one knows it to be true.

The notion of a conventionalist theory-choice criterion presumes that there is a philosophical necessity to choose one theory from among its competitors. But there is no such necessity, even though it will always be difficult to convince economists of this whenever they are naive concerning the philosophy of science. But, given that there are so many different criteria to use, one would think any theory that is best by all criteria should be the chosen theory. But it is doubtful that any theory could satisfy all criteria; so the question is begged as to which criterion is the best criterion. This question seems to put us on the road of an infinite regress: by what criterion do we choose the best criterion to choose between theories? Not a promising journey.

Convergence

Steven N. Durlauf and Paul A. Johnson

Abstract

One of the most widely studied empirical questions in the new growth economics concerns the role of initial conditions in affecting long-run outcomes. The statistical formulation of this dependence is known as convergence. This article surveys empirical work on convergence, with emphasis on the relationships between conventional definitions of convergence, the main statistical frameworks of evaluating convergence, and various economic models.

The general question of convergence, understood as the tendency of differences between countries to disappear over time, is of long-standing interest to social scientists. In the 1950s and early 1960s, many analysts discussed whether capitalist and socialist economies would converge over time, in the sense that market institutions would begin to shape socialist economies just as government regulation and a range of social welfare policies grew in capitalist ones.

In modern economic parlance, convergence usually refers specifically to issues related to the persistence or transience of differences in per capita output between economic units, be they countries, regions or states. Most research has focused on convergence across countries, since the large contemporaneous differences between countries generally dwarf intra-country differences. In the context of economic growth, the convergence hypothesis arguably represents the most commonly studied aspect of growth, although the effort to identify growth determinants is arguably the main area of contemporary growth research.

In this overview of convergence, our primary emphasis will be on the development of precise statistical definitions of convergence. This reflects an important virtue of the current literature, namely, the introduction of statistical methods to adjudicate whether convergence is present. At the same time, there is no single definition of convergence in the literature, which is one reason why empirical evidence on convergence is indecisive. Our discussion focuses on convergence across countries, which has dominated empirical studies, although there is reference to studies that focus on other units.

β-Convergence

The primary definition of convergence used in the modern growth literature is based on the relationship between initial income and subsequent growth. The basic idea is that two countries exhibit convergence if the one with lower initial income grows faster than the other. The local (relative to steady state) dynamics of the

neoclassical growth model in both its Solow and Cass–Koopmans variants imply that lower-income economies will grow faster than higher-income ones.

As a statistical question, this notion of convergence can be operationalized in the context of a cross-country regression. Let g_i denote real per capita growth of country i across some fixed time interval and $y_{i,0}$ denote the initial per capita income for country i. Then, unconditional β-convergence is said to hold if, in the regression

$$g_i = k + \log y_{i,0}\beta + \varepsilon_i, \beta < 0. \quad (1)$$

For cross-country regression analysis, one typically does not find unconditional β-convergence unless the sample is restricted to very similar countries, for example, members of the OECD. This finding is in some ways not surprising, since unconditional β-convergence is typically not a prediction of the existing body of growth theories. The reason for this is that growth theories universally imply that growth is determined by factors other than initial income. While different theories may propose different factors, they collectively imply that (1) is misspecified. As a result, most empirical work focuses on conditional β-convergence. Conditional β-convergence holds if $\beta < 0$ for the regression

$$g_i = k + \log y_{i,0}\beta + Z_i\gamma + \varepsilon_i \quad (2)$$

where Z_i is a set of those growth determinants that are assumed to affect growth in addition to a country's initial income. While many differences exist in the choice of controls, it is nearly universal to include those determinants predicted by the Solow growth model, that is, population growth and human and physical capital accumulation rates.

Unlike unconditional β-convergence, evidence of conditional β-convergence has been found in many contexts. For the cross-country case, the basic finding is generally attributed to Barro (1991), Barro and Sala-i-Martin (1992) and Mankiw et al. (1992). The Mankiw, Romer and Weil analysis is of particular interest as it is based on a regression suggested by the dynamics of the Solow growth model. Hence, their findings have been widely interpreted as evidence in favour of decreasing returns to scale in capital (the source of $\beta < 0$ in the Solow model), and therefore as evidence against the Lucas–Romer endogenous growth approach, which emphasizes increasing returns in capital accumulation (either human or physical) as a source of perpetual growth.

From the perspective of the neoclassical growth model, the term $-\beta$ also measures the rate at which an economy's convergence towards its steady-state growth rate, that is, the growth rate determined exclusively by the exogenous rate of technical change. The many findings in the cross-country literature are often summarized by the claim countries converge towards their steady-state growth rates at a rate of about two per cent per year, although individual studies produce different results. The convergence rate has received inadequate attention in the sense that a finding of convergence may have little consequence for questions such as policy interventions if it is sufficiently slow.

As is clear from (2), any claims about conditional convergence necessarily depend on the choice of control variables Z_i. This is a serious concern given the lack of consensus in growth economics on which growth determinants are empirically important. Doppelhofer et al. (2004) and Fernandez et al. (2001) use model averaging methods to show that the cross-country findings that have appeared for conditional β-convergence are robust to the choice of controls. A number of additional statistical issues such as the role of measurement error and endogeneity of regressors are surveyed and evaluated in Durlauf et al. (2005).

The assumption in cross-section growth regressions that the unobserved growth terms ε_i are uncorrelated with log $y_{i,0}$ rules out the possibility that there are country-specific differences in output levels; if such effects were present, they would imply a link between the two. For this reason, a number of researchers have investigated convergence using panel data. This leads to models of the form

$$g_{i,t} = c_i + \log y_{i,t-1}\beta + Z_{i,t}\gamma + \varepsilon_{i,t} \quad (3)$$

where growth is now measured between $t-1$ and t. This approach not only can handle fixed effects, but can allow for instrumental variables to be used

to address endogeneity issues. Panel analyses have been conducted by Caselli et al. (1996), Islam (1995) and Lee et al. (1997). These studies have generally found convergence with rather higher rates than appear in the cross-section studies; for example, Caselli et al. (1996) report annual convergence rate estimates of ten per cent.

As discussed in Durlauf and Quah (1999) and Durlauf et al. (2005), panel data approaches to convergence suffer from the problem that, once country specific effects are allowed, it becomes more difficult to interpret results in terms of the underlying economics. The problem is that, once one allows for fixed effects, then the question of convergence is changed, at least if the goal is to understand whether initial conditions matter; simply put, the country-specific effects are themselves a form of initial conditions. When studies such as Lee et al. (1997) allow for rich forms of parameter heterogeneity across countries, β-convergence become equivalent to the question of whether there is some mean reversion in a country's output process, not whether certain types of contemporaneous inequalities diminish. This does not diminish the interest of these studies as statistical analyses, but means their economic import can be unclear.

σ-Convergence and the Cross-Section Distribution of Income

A second common statistical measure of convergence focuses on the whether or not the cross-section variance of per capita output across countries is or is not shrinking. A reduction in this variance is interpreted as convergence. Letting $\sigma^2_{\log y,t}$ denote the variance across i of $\log y_{it}$, σ-convergence occurs between t and $t+T$ if

$$\sigma^2_{\log y,t} - \sigma^2_{\log y,t+T} > 0. \tag{4}$$

There is no necessary relationship between β- and σ-convergence. For example, if the first difference of output in each country obey $\log y_{i,t} - \log y_{i,t-1} = \beta \log y_{i,t-1} + \varepsilon_{i,t}$, then $\beta < 0$ is compatible with a constant cross-sectional variance (which in this example will equal the variance of $\log y_{i,t}$). The incorrect idea that mean reversion in time series implies that its variance is declining is known as Galton's fallacy; its relevance to understanding the relationship between convergence concepts in the growth literature was identified by Friedman (1992) and Quah (1993a). While it is possible to construct a cross-section regression to test for σ-convergence (cf. Cannon and Duck 2000), they do not test β-convergence per se.

Work on β-convergence has led to general interest in the evolution of the crosscountry income distribution. Quah (1993b, 1996) has been very influential in his modelling of a stochastic process for the distribution itself, with the conclusion that it is converging towards a bimodal steady-state distribution. Other studies of the evolution of the cross-section distribution include Anderson (2004) who uses nonparametric density methods to identify increasing polarization between rich and poor economies across time. Increasing divergence between OECD and non-OECD economies is shown in Maasoumi et al. (2007), working with residuals from linear growth regressions.

One difficulty with convergence approaches that emphasize changes in the shape of the cross-section distribution is that they may fail to address the original question of the persistence of contemporaneous inequality. The reason for this is that it is possible, because of movements in relative position within the distribution, for the cross-section distribution to flatten out while at the same time differences at one point in time are reversed; similarly, the cross-section distribution can become less diffuse while gaps between rich and poor widen. That being said, an examination of the locations of individual countries in various distribution studies typically indicates that the increasing polarization of the world income distribution is mirrored by increasing gaps between rich and poor. A useful extension of this type of research would be to employ the dynamics of individual countries to provide additional information on how the cross-section distribution evolves.

Time Series Approaches to Convergence

An alternative approach to convergence is focused on direct evaluation of the persistence of transitivity of per capita output differences between economies. This approach originates in Bernard and Durlauf (1995), who equate convergence with the statement that

$$\lim_{T\Rightarrow\infty} E\left(\log y_{i,t+T} - \log y_{j,t+T} | F_t\right) = 0 \quad (5)$$

where F_t denotes the history of the two output series up to time t. They find that convergence does not hold for OECD economies, although there is some cointegration in the individual output series. Hobijn and Franses (2000) find similar results for a large international data-set. Evans (1996) employs a clever analysis of the evolution of the cross-section variance to evaluate the presence of a common trend in OECD output, and finds one is present; his analysis allows for different deterministic trends in output and so in this sense is compatible with Bernard and Durlauf (1995).

The relationship between cross-section and time series convergence tests is complicated. Bernard and Durlauf (1996) argue that the two classes of tests are based on different assumptions about the data under study. Cross-section tests assume that countries are in transition to a steady state, so that the data for a given country at time t is drawn from a different stochastic process from the data at some future $t + T$. In contrast, time series tests assume that the underlying stochastic processes are time-invariant parameters, that is, that countries have transited to an invariant output process. They further indicate how convergence under a cross-section test can in fact imply a failure of convergence under a time series test, because of these different assumptions. For these reasons, time series tests of convergence seem appropriate for economies that are at similar stages and advanced stages of development.

From Statistics to Economics

The various concepts of convergence we have described are all purely statistical definitions. The economic questions that motivated these definitions are not, however, equivalent to these questions, so it is important to consider convergence as an economic concept in order to assess what is learned in the statistical studies. As argued in Durlauf et al. (2005), the economic questions that underlie convergence study revolve around the respective roles of initial conditions versus structural heterogeneity in explaining differences in per capita output levels or growth rates. It is the permanent effect of initial conditions, not structural features that matters for convergence. If we define initial conditions as ρ_{i0} and the structural characteristics as $\theta_{i,0}$, convergence can be defined via

$$\lim_{t\to\infty} E\left(\log y_{i,t} - \log y_{j,t} | \rho_{i,0}, \theta_{i,0}, \theta_{j,0}\right) = 0 \text{ if } \theta_{i,0} = \theta_{j,0}. \quad (6)$$

The gap between the definition (6) and the statistical tests that have been employed is evident when one considers whether the statistical tests can differentiate between economically interesting growth models, some of which fulfil (6) and others of which do not. One such contrast is between the Solow growth model and the Azariadis and Drazen (1990) model of threshold externalities, in which countries will converge to one of several possible steady states, with initial conditions determining which one emerges. By definition (6), the Solow model produces convergence whereas the Azariadis–Drazen model does not. However, as shown by Bernard and Durlauf (1996) it is possible for data from the Azariadis–Drazen model to produce estimates that are consistent with a finding of β-convergence.

There is in fact a range of empirical findings of growth nonlinearities that are inconsistent with convergence in the sense of (6). Durlauf and Johnson (1995) is an early study of this type, which explicitly estimated a version of the Azariadis–Drazen model in which the Solow model, under the assumption of a Cobb–Douglas aggregate production function, is a special case. Durlauf and Johnson rejected the Solow model specification and found multiple growth regimes

indexed by initial conditions. Their findings are consistent with the presence of convergence clubs in which different groups of countries are associated with one of several possible steady states. These results are confirmed by Papageorgiou and Masanjala (2004) using a CES production function specification.

The Durlauf and Johnson analysis uses a particular classification procedure, known as a regression tree, to identify groups of countries obeying a common linear model. Other statistical approaches have also identified convergence clubs. For example, Bloom et al. (2003) use mixture distribution methods to model countries as associated with one of two possible output processes, and conclude that individual countries may be classified into high-output manufacturing- and service-based economies and low-output agriculture-based economies. Canova (2004) uses Bayesian methods to identify convergence clubs for European regions.

As discussed in Durlauf and Johnson (1995) and Durlauf et al. (2005), studies of nonlinearity also suffer from identification problems with respect to questions of convergence. One problem is that a given data-set cannot fully uncover the full nature of growth nonlinearities without strong additional assumptions. As a result, it becomes difficult to extrapolate those relationships between predetermined variables and growth to infer steady-state behaviour. Durlauf and Johnson give an example of a data pattern that is compatible with both a single steady and multiple steady states. A second problem concerns the interpretation of the conditioning variables in these exercises. Suppose one finds, as do Durlauf and Johnson, that high- and low-literacy economies are associated with different aggregate production functions. One interpretation of this finding is that the literacy rate proxies for unobserved fixed factors, for example culture, so that these two sets of economies will never obey a common production function, and so will never exhibit convergence in the sense of (6). Alternatively, the aggregate production function could structurally depend on the literacy rate, so that, as literacy increases, the aggregate production functions of currently low-literacy economies will converge to those of the high-literacy ones. Data analyses of the type that have appeared cannot distinguish between these possibilities.

Conclusions

While the empirical convergence literature contains many interesting findings and has helped identify a number of important generalizations about cross-country growth behaviour, it has yet to reach any sort of consensus on the deep economic questions for which the statistical analyses were designed. The fundamentally nonlinear nature of endogenous growth theories renders the conventional crosssection convergence tests inadequate as ways to discriminate between the main classes of theories. Evidence of convergence clubs may simply be evidence of deep nonlinearities in the transitional dynamics towards a unique steady state. Crosssection and time series approaches to convergence not only yield different results but are predicated on different views of the nature of transitory versus steady-state behaviour of economies, differences that themselves have yet to be tested.

None of this is to say that convergence is an empirically meaningless question. Rather, progress requires continued attention to the appropriate statistical definition of convergence and the use of statistical procedures consistent with the definition. Further, it seems important to move beyond current ways of assessing convergence both in terms of better use of economic theory and by a broader view of appropriate data sources. Graham and Temple (2006) illustrate the potential for empirical analyses of convergence that employ well-delineated structural models. The research programme developed in Acemoglu, Johnson and Robinson (2001, 2002) provides a perspective on the micro-foundations of country-specific heterogeneity that speaks directly to the convergence question and which shows the power of empirical analysis based on careful attention to economic history. For these reasons, research on convergence should continue to be productive and important.

Convergence Hypothesis

P. J. D. Wiles

This is the doctrine that the Soviet Union and 'similar countries' are becoming and will further become socially and economically similar to the United States and other advanced capitalist countries; or the other way round – so that eventually in

either case political differences, and thus foreign policy tensions, will also disappear.

The doctrine takes many detailed forms, but is most often very unspecific. For instance does it mean: that Texan agriculture will be collectivized (each family farm is larger in area than a Soviet *Kolkhoz*); that there will be a stock exchange again in Moscow, where equity shares in Soviet businesses are freely traded; that the *zloty* will be made convertible; that Switzerland will introduce controls over all retail and wholesale prices; that British trade unions will be reduced to the status of Bulgarian trade unions, or vice versa; that Albania will allow a good deal of minor private enterprise; or even that both sides will converge upon self management in a market, *á la Yougoslave*?

The proponents of the doctrine seldom do it the courtesy of bringing it so close to brass tacks. Above all they fail to recognize just how numerous and diverse those brass tacks are. But the core of the doctrine is clear: advanced capitalism is (said to be) moving, through the large corporation (often public) and its intimacy with certain government departments, irreparably away from share-holder dominance, free enterprise and free markets, in respect of all sectors where small enterprise does not dominate; and a new socio-political type is coming to power, nearly indistinguishable in government and business, and very liable to swap jobs (corruptly, let us add). Meanwhile the advanced Communist states are admitting more and more the role of enterprise independence and markets for everyday small decisions; even the quasi-independence of associations of enterprises in larger decisions – the association would correspond to the corporation and the Communist enterprises to its separate, decentralized 'establishments'.

Hungary and France are of course very much further forward in convergence. A major problem, too for Convergence theorists and for sceptics alike, is China. Here, right at the bottom of the Communist income scale and without even having first introduced any central planning worthy of the name, 20 per cent of the human race is 'converging' very rapidly indeed. As partly too in Hungary, even private property in the means of production is making a comeback. It is not easy to fit this fact into the ordinary framework of debate.

As to a new socio-political type in power in government and 'business', in the USSR ideology is dying and the typical Party apparatchik is more and more obliged to have had some serious professional training and responsibility within the State machine. Meanwhile the obligatory Party membership of the senior technocrat continues to lie lightly on his shoulders. What then is this type, on both sides? It is above all a professional type: technically educated, pragmatic but accepting the particular value system of the given profession, believing in the rule of reason but unphilosophically confusing it with what was judged reasonable at professional school, striving for a higher 'earned' income as the right of competence in his chosen profession, and naive as to what constitutes the rule of reason in unprofessional matters (which are of course the very great majority of matters). One may think in 1986, as the fathers of Convergence certainly did not think, of the American term Yuppie (Young Upwardly Mobile Professionals). However, in the USSR Yuppies are much more idealistic and critical.

It is clear that every prophecy made about Communism in the previous paragraphs is coming true, and the Convergence theorists deserve praise for this – although it took much longer than they expected. The rule of reason is taking over, and the notion that the Soviet system is a frozen monolith, condemned to remain for ever its unpleasant and highly suboptimal (but rapidly growing!) self, is unfounded. But capitalism by no means shows the predicted unilinear change. Japan in one way ('industrial policy', unnaturally accommodating unions) and France in another (mild planning) used to be the showpieces of convergence from the other side. But recent Japanese financial reforms have tended to open up the country to free trade in money, and French planning is at present being down-graded. Monetarist and supply-sider attacks on the public sector and on taxes in the USA and the UK constitute divergence. So does the new tolerance for very heavy unemployment; even if Communist economic experts talk about the necessity for a little

unemployment to discipline labour and create flexibility, the 'target' of Western levels is rapidly receding!

It is, then, capitalism that has 'misbehaved'. And if the rule of reason is eventually restored to economic affairs in the Western world, exactly how far, in so unreasonable a universe, will present divergent trends be reversed? We can at least be sure that protectionism – if that is reason – having flourished even under monetarism, will bloom yet taller under what succeeds it. Indeed under this or that institutional guise, protectionism is common to all systems except capitalist laissez faire in the 19th century. Then too why should not the rule of reason be 'relaxed' again in the East? Besides, 'reason is and ought to be the slave of the passions': if the value systems of Communism and democratic Capitalism continue to diverge only half as much as now, this is cause enough for the reasonable choice of radically divergent policies and substantially divergent institutions.

These considerations alone give us pause before we can accept the basic optimism of Convergence theory. We pause to note that the seven questions of our second paragraph have not been answered at all. But there is worse – though outside of economics – to follow. Since when did resemblance make for peace? Since when was dissimilarity a cause of war? Especially in this ideological age, is not *minor* dissimilarity, or heresy, a major cause of war? For that matter, do not Third World capitalist countries make war on each other, quite unabashedly, over mere boundary disputes and ethnic irredentas in quite the old style? It is very long way from convergence in respect of planning and the market, to international peace.

The alleged *aetiology* of convergence could, as set out above, be the existence of an optimal system somewhere in the middle, to which all existing systems gravitate simply because it is better. If, as is often reasonably claimed, the Yugoslav industrial system represents a third pole of equal theoretical importance, then moderate elements of self-management must be added to that optimal goal. But this is all mere wishful thinking: the judgements of politicians and (where they are counted) voters do not coincide all over the world with each other, let alone with the opinions of centre-left economists. An economic system good for some purposes (e.g. full employment, equality) is bad for others (e.g. rational resource allocation, stable prices, labour discipline). As we have seen, people *value* different sets of outcomes differently, and are also confused as to how in practice to obtain them.

But convergence through contact and competition is another matter. Since nearly all people are unthinking materialists, contact (say as an importer and an exporter) will sway them to imitate the at present more prosperous system: capitalism, to which may or may not be attached, in the perception of observers, parliamentary democracy. And this is truer of people living under Communism than of people in the Third World: for the latter are apt to attribute capitalist prosperity to the exploitation of themselves. Sheer economic contact undoubtedly influences Communist leaders in a capitalist direction, if only because of the overwhelmingly unfavourable balance of technological exchange.

Competition is the almost inevitable result of contact: both commercial and military. It goes without saying that competitors in an export market imitate each other, and not only in quality and technology embodied; but even the administrative systems of the enterprises producing the exports will converge on the one that is seen to be superior. Exporting is a sure and genuine source of convergence, that the most hard-nosed Sovietologist must accept. Military rivalry has much the same effects; for a country's forces also 'export' – a threat. But if the convergence of military technology and its maintenance and auxiliary equipment is of obvious relevance to economic systems, that of military doctrine and organization is not our subject. Still less is the convergence of para-military 'exports': training for guerrillas and terrorists, security systems for underdeveloped countries, espionage.

It can be seen that while high convergence theory is largely (but not altogether) hot air and wishful thinking, there exists a great deal of low-level convergence in fact, all of it easily explicable and much of it very regrettable.

Convex Programming

Lawrence E. Blume

Abstract

This article summarizes the basic ideas of convex optimization in finite-dimensional vector spaces. Duality, the Fenchel transforms and the subdifferential are introduced and used to discuss Lagrangean duality and the Kuhn–Tucker theorem. Applications of these ideas can be found in duality.

Introduction

Firms maximize profits and consumers maximize preferences. This is the core of microeconomics, and under conventional assumptions about decreasing returns it is an application of convex programming. The paradigm of convex optimization, however, runs even deeper through economic analysis. The idea that competitive markets perform well, which dates back at least to Adam Smith, has been interpreted since the neoclassical revolution as a variety of conjugate duality for the primal optimization problem of finding Pareto-optimal allocations. The purpose of this article and the companion article duality is (in part) to explain this sentence. This article surveys without proof the basic mathematics of convex sets and convex optimization with an eye towards their application to microeconomic and general equilibrium theory, some of which can be found under duality.

Unfortunately there is no accessible discussion of concave and convex optimization outside textbooks and monographs of convex analysis such as Rockafellar (1970, 1974). Rather than just listing theorems, then, this article attempts to provide a sketch of the main ideas. It is certainly no substitute for the sources. This article covers only convex optimization in finite-dimensional vector spaces. While many of these ideas carry over to infinite-dimensional vector spaces and to important applications in infinite horizon economies and economies with nontrivial uncertainty, the mathematical subtleties of infinite-dimensional topological vector spaces raise issues which cannot reasonably be treated here. The reader looking only for a statement of the Kuhn–Tucker theorem is advised to read backwards from the end, to find the theorem and notation.

A word of warning. This article is written from the perspective of constrained maximization of concave functions because this is the canonical problem in microeconomics. Mathematics texts typically discuss the constrained minimization of convex functions, so textbook treatments will look slightly different.

Convex Sets

A subset C of a Euclidean vector space V is convex if it contains the line segment connecting any two of its members. That is, if x and y are vectors in C and t is a number between 0 and 1, the vector $tx + (1 - t)\,y$ is also in C. A linear combination with non-negative weights which sum to 1 is a *convex combination* of elements of C; a set C is

convex if it contains all convex combinations of its elements.

The key fact about convex sets is the famous *separation th*. A linear function p from the vector space V to $\mathbf{R}$ and a real number a define a *hyperplane*, the solutions to the equation $p \cdot x = a$. Every hyperplane divides V into two *half-spaces*; the upper (closed) half-space, containing those vectors x for which $p \cdot x \geq a$, and the lower (closed) half-space, containing those vectors x for which $p \cdot x \leq a$. The separation theorem uses linear functionals to describe closed convex sets. If a given vector is not in a closed convex set, then there is a hyperplane such that the set lies strictly inside the upper half-space while the vector lies strictly inside the lower half-space:

Separation Theorem If C is a closed convex set and x is not in C, then there is a linear functional p and a real number a such that $p \cdot y > a$ for all $y \in C$, and $p \cdot x < a$.

This theorem implies that every closed convex set is the intersection of the half-spaces containing it. This half-space description is a *dual* description of closed convex sets, since it describes them with linear functionals. From the separation theorem the existence of a *supporting hyperplane* can also be deduced. If x is on the boundary of a closed convex set C, then there is a (non-zero) linear functional p such that $p \cdot y \geq p\, x$ for all $y \in C$; p is the hyperplane that supports C at x.

The origin of the term 'duality' lies in the mathematical construct of the dual to a vector space. The *dual space* of a vector space V is the collection of all *linear functionals*, that is, real-valued linear functions, defined on V. The distinction between vector spaces and their duals is obscured in finite dimensional spaces because each such space is its own dual. If an n-dimensional Euclidean vector space is represented by column vectors of length n, the linear functionals are $1 \times n$ matrices; that is the dual to $\mathbf{R^n}$ is $\mathbf{R^n}$. (This justifies the notation used above.) Self-duality (called reflexivity in the literature) is not generally true in infinite-dimensional spaces, which is reason enough to avoid discussing them here. Nonetheless, although V will be $\mathbf{R^n}$ throughout this article, the usual notation V^* will be used to refer to the dual space of V simply because it is important to know when we are discussing a vector in V and when we are discussing a member of its dual, a linear functional on V.

If the weights in a linear combination sum to 1 but are not constrained to be non-negative, then the linear combination is called an *affine combination*. Just as a convex set is a set which contains all convex combinations of its elements, an affine set in a vector space V is a set which contains all affine combinations of its elements. The set containing all affine combinations of elements in a given set C is an affine set, $A(C)$. The purpose of all this is to define the *relative interior* of a convex set C, ri C. The relative interior of a convex set C is the interior of C relative to $A(C)$. A line segment in $\mathbf{R^2}$ has no interior, but its relative interior is everything on the segment but its endpoints.

Concave Functions

The neoclassical assumptions of producer theory imply that production functions are concave and cost functions are convex. The quasi-concave functions which arise in consumer theory share much in common with concave functions, and quasi-concave programming has a rich duality theory.

In convex programming it is convenient to allow concave functions to take on the value $-\infty$ and convex functions to take on the value $+\infty$. A function f defined on $\mathbf{R^n}$ with range $[-\infty,\infty)$ is concave if the set $\{(x, a) : a \in , a \leq f(x)\}$ is convex. This set, a subset of $\mathbf{R^{n+1}}$, is called the *hypograph* of f and is denoted hypo f. Geometrically, it is the set of points in $\mathbf{R^{n+1}}$ that lie on or below the graph of f. Similarly, the *epigraph* of f is the set of points in $\mathbf{R^{n+1}}$ that lie on or above the graph of f: epi $f = \{(x, a): a \in , a \geq f(x)\}$. A function f with range $(-\infty,\infty]$ is convex $-f$ is concave, and convexity of f is equivalent to convexity of the set epi f. Finally, the *effective domain* of a concave function is the set dom $f = \{x \in \mathbf{R^n} : f(x) > -\infty\}$, and similarly for a convex function. Those familiar with the literature will note that attention here is restricted

to *proper* concave and convex functions. Functions that are everywhere $+\infty$ will also be considered concave, and those everywhere $-\infty$ will be assumed convex when Lagrangeans are discussed below.

Convex optimization does not require that functions be differentiable or even continuous. Our main tool is the separation theorem, and for that closed convex sets are needed. A concave function f is *upper semi-continuous* (usc) if its hypograph is closed; a convex function is *lower semi-continuous* (lsc) if its epigraph is closed. Upper and lower semi-continuity apply to any functions, but these concepts interact nicely conveniently with convex and concave functions. In particular, usc concave and lsc convex functions are continuous on the relative interiors of their domain. A famous example of a usc concave function that fails to be continuous is $f(x, y) = -y^2/2x$ for $x > 0$, 0 at the origin and $-\infty$ otherwise. Along the curve $y = \sqrt{\alpha x},\ y \to 0$ as $x \to 0$, but f is constant at $-\alpha/2$, so f is not continuous at (0,0), but it is usc because the supremum of the limits at the origin is 0.

It is useful to know that, if f is concave and usc, then $f(x) = \inf q(x) = a \cdot x + b$ where the infimum is taken over all a and b such that $a \cdot x + b$ is everywhere at least as big as f. This is another way of saying that, since hypo f is closed, it is the intersection of all half-spaces containing it.

The Fenchel Transform

The concave Fenchel transform associates with each usc function on a Euclidean space V, not necessarily concave, a usc concave function on its dual space V^* (which, we recall, happens to be V since its dimension is finite). The adjective 'concave' is applied because a similar transform is defined slightly differently for convex functions. The concave Fenchel transform of f is

$$f^*(p) = \inf_{x \in V} \{p \cdot x - f(x)\},$$

which is often called the *conjugate* of f. (From here on out we will drop the braces.) The conjugate f^* of f is concave because, for fixed x, $p \cdot x - f(x)$ is linear, hence concave, in p, and the pointwise infimum of concave functions is concave. The textbooks all prove that, if hypo f is closed, so is hypo f^*, that is, upper semi-continuity is preserved by conjugation. So what is this transformation doing, and why is it interesting?

The conjugate f^* of a concave function f describes all the non-vertical half-spaces containing hypo f. This should be checked. A half-space in $\mathbf{R^{n+1}}$ can be represented by the inequality $(p, q)\,(x, y) \geq a$ where q is a real number (as is a) and $p \in V^*$. The half-space is non-vertical if $p^* \neq 0$. In $\mathbf{R^2}$ this means geometrically that the line defining the boundary of the half-space is not vertical. So choose a linear functional $p \neq 0$ in V^*. For any $(x, z) \in$ hypo f, and any $p \in V^*$,

$$p \cdot x - z \geq p \cdot x - f(x) \geq \inf_{x \in V} p \cdot x - f(x) = f^*(p).$$

In other words, the upper half-space $(p, -1) \cdot (x, z) \geq f^*(p)$ contains hypo f. It actually supports hypo f because of the infimum operation: If $a > f^*(p)$, there is an $(x, z) \in$ hypo f such that $px - z < a$, so the upper half-space fails to contain hypo f.

Before seeing what the Fenchel transform is good for, we must answer an obvious qst. If it is good to transform once, why not do it again? Define

$$f^{**}(x) = \inf_{p \in V^*} p \cdot x - f^*(p),$$

the *double dual* of f. The fundamental fact about the Fenchel transform is the following theorem, which is the function version of the dual descriptions of closed convex sets.

Conjugate Duality Theorem If f is usc and concave, then $f^{**} = f$.

This is important enough to explain. Notice that just as p is a linear functional acting on x, so x is a linear functional acting on p. Suppose that f is concave and usc. For all x and p, $p \cdot x - f(x) \geq f^*(p)$,

and so $p \cdot x - f^*(p) \geq f(x)$. Taking the infimum on the left, $f^{**}(x) \geq f(x)$.

On the other hand, take a $p \in V^*$ and a real number b such that the half-space $(p, -1) \cdot (x, z) \geq b$ in $\mathbf{R}^{n+1}$ contains the hypograph of f. This is true if and only if $p \cdot x - b \geq f(x)$ for all x and because f is usc, $f(x)$ is the infimum of $p \cdot x - b$ over all such p and b. Since $p \cdot x - f(x) \geq b$ for all x, take the infimum on the left to conclude that $f^*(p) \geq b$. Thus $p \cdot x - b \geq p \cdot x - f^*(p)$, and taking the infimum now on the right, $p \cdot x - b \geq f^{**}(x)$. Taking the infimum on the left over all the p and b such that the half-space contains hypo f, $f(x) \geq f^{**}(x)$.

It is worthwhile to compute an example to get the feel of the concave Fenchel transform. If C is a closed convex set, the *concave indicator function* of C is $\varphi(x)$ which is 0 for x in C, and $-\infty$ otherwise. This is a good example to see the value of allowing infinite values. The Fenchel transform of φ is $\varphi^*(p) = \inf_{x \in \mathbf{R}^n} p \cdot x - \varphi(x)$. Clearly the infimum cannot be reached at any $x \notin C$, for the value of φ at such an x is $-\infty$, and so the value of $p \cdot x - \varphi(x)$ is $+\infty$. Consequently $\varphi^*(p) = \inf_{x \in C} p \cdot x$. This function has the enticing property of positive homogeneity: If t is a positive scalar, then $\varphi^*(tp) = t\varphi^*(p)$.

Compute the double dual, first for $x \notin C$. The separating hyperplane theorem claims the existence of some p in V^* and a real number a such that $p \cdot x < a \leq p \cdot y$ for all $y \in C$. Take the infimum on the right to conclude that $p \cdot x < \varphi^*(p)$, which is to say $p \cdot x - \varphi^*(p) < 0$. Then, multiply both sides by an arbitrary positive scalar t to conclude that $tp \cdot x - \varphi^*(tp)$ can be made arbitrarily negative. Hence $\varphi^{**}(x) = -\infty$ if $x \notin C$. And if x is in C? Then $p \cdot x - 0 \geq \varphi^*(p)$ for all p (recall $\varphi(x) = 0$). So $p \cdot x - \varphi^*(p) \geq 0$. But $\varphi^*(0) = 0$, so $\varphi^{**}(x)$, the infimum of the left-hand side over all possible p functionals, is 0. Thus the Fenchel transform of φ^* recovers φ.

A particularly interesting version of this problem is to suppose that C is an 'at least as good as' set for level u of some upper semi-continuous and quasi-concave utility function (or, more generally, a convex preference relation with closed weak upper contour sets). Then $\varphi^*(p)$ is just the minimum expenditure necessary to achieve utility u at price p. See duality for more discussion. Another interesting exercise is to apply the Fenchel transform to concave functions which are not usc, and to non-concave functions. These constructions have important applications in optimization theory which we will not pursue.

The theory of convex functions is exactly the same if, rather than the *concave Fenchel transform*, the *convex Fenchel transform* is employed: $\sup_{x \in \mathbf{R}^n} p \cdot x - f(x)$. This transform maps convex lsc functions on V into convex lsc functions on V^*. Both the concave and convex Fenchel transforms will be important in what follows.

The Subdifferential

The separation theorem applied to hypo f implies that usc concave functions have tangent lines: For every $x \in$ ri dom f there is a linear functional p_x such that $f(y) \leq f(x) + p_x(y - x)$. This inequality is called the *subgradient inequality*, and p_x is a *subgradient* of f; p_x defines a tangent line for the graph of f, and the graph lies on or underneath it. The set of subgradients of f at $x \in$ dom f is denoted $\partial f(x)$, and is called the *subdifferential* of f at x. Subdifferentials share many of the derivative's properties. For instance, if $0 \in \partial f(x)$, then x is a global maximum of f. In fact, if $\partial f(x)$ contains only one subgradient p_x, then f is differentiable at x and $Df(x) = p_x$. The set $\partial f(x)$ need not be single-value, however, because f may have kinks. The graph of the function f defined on the real line such that $f(x) = -\infty$ for $x < 0$ and $f(x) = \sqrt{x}$ for $x \geq 0$ illustrates why the subdifferential may be empty at the boundary of the effective domain. At 0, a subgradient would be infinitely steep.

There is a corresponding *subgradient inequality* for convex f: $f(y) \geq f(x) + p_x \cdot (y - x)$. With these definitions, $\partial(-f)(x) = -\partial f(x)$. Note that some texts refer to superdifferentials for concave functions and subdifferentials for convex functions. Others do not multiply the required terminology, and we follow them.

The multivalued map $x \mapsto \partial f(x)$, is called the *subdifferential correspondence* of f. An important property of subdifferential correspondences is

monotonicity. From the subgradient inequality, if $p \in \partial f(x)$ and $q \in \partial f(y)$, then $f(y) \leq f(x) + p \cdot (y - x)$ and $f(x) \leq f(y) + q \cdot (x - y)$, and it follows that $(p - q) \cdot (x - y) \leq 0$. For convex f the inequality is reversed.

The Fenchel transforms establish a clear relationship between the subdifferential correspondences of concave functions and their duals. If f is concave, then the subdifferential inequality says that $p \in \partial f(x)$ if and only if for all $z \in X$, $p \cdot x - f(x) \leq p \cdot z - f(z)$. The map $z \mapsto p \cdot z - f(z)$ is minimized at $z = x$, and so p is in $\partial f(x)$ if and only if $f^*(p) = p \cdot x - f(x)$. If f is usc, then $f^{**} \equiv f$, and so $f^{**}(x) = f(x) = p \cdot x - f^*(x)$. That is, $p \in \partial f(x)$ if and only if $x \in \partial f^*(p)$.

Optimization and Duality

Economics most often presents us with constrained maximization problems. Within the class of problems with concave objective functions, there is no formal difference between constrained and unconstrained maximization. The constrained problem of maximizing concave and usc f on a closed convex set C is the same as the unconstrained problem of maximizing $f(x) + I_C(x)$ on $\mathbf{R^n}$, where $I_C(x)$ is the concave indicator function of C.

The general idea of duality schemes in optimization theory is to represent maximization (or minimization) problems as half of a minimax problem which has a saddle value. There are several reasons why such a seemingly odd construction can be useful. In economics it often turns out that the other half of the minimax problem, the dual problem, sheds additional light on properties and inpts of the primal problem. This is the source of the 'shadow price' concept: The shadow price is the value of relaxing a constraint. Perhaps the most famous example of this is the Second Theorem of Welfare Economics.

Lagrangeans

The *primal problem* (problem P) is to maximize $f(x)$ on a Euclidean space V. Suppose there is a function $L : V \times V^* \to \mathbf{R}$ such that $f(x) = \inf_{p \in V^*} L(x, P)$. Define $g(p) = \sup_{x \in V} L(x, p)$, and consider the problems of maximizing $f(x)$ on V and minimizing $g(p)$ on V^*. The first problem is the primal problem, and the second is called the *dual problem*. For all x and p it is clear that $f(x) \leq L(x, p) \leq g(p)$, and thus that

$$\sup_x \inf_p L(x,p) = \sup_x f(x) \leq \inf_p g(p) = \inf_p \sup_x L(x,p).$$

If the inequality is tight, that is, it holds with equality, then the common value is called a *saddle value* of L. In particular, a saddle value exists if there is a *saddle point* of L, a pair (x^*, p^*) such that for all $x \in V$ and $p \in V^*$, $L(x, p^*) \leq L(x^*, p^*) \leq L(x^*, p)$. A pair (x^*, p^*) is a saddlepoint if and only if x^* solves the primal, p^* solves the dual, and a saddle value exists. The function L is the *Lagrangean*, which is familiar from the analysis of smooth constrained optimization problems. Here it receives a different foundation.

The art of duality schemes is to identify an interesting L, and here is where the Fenchel transforms come in. Interesting Lagrangeans can be generated by embedding the problem max f in a parametric class of concave maximization problems. Suppose that there is a (Euclidean) parameter space P, and a usc and concave function F: $V \times Y \to$ such that $f(x) = F(x, 0)$, and consider all the problems $\max_{x \in V} F(x, y)$. A particularly interesting object of study is the *value function* $\varphi(y) = \sup_x F(x, y)$, which is the indirect utility function in consumer theory, and the cost function in the theory of the firm (with concave replaced by convex and max by min). The map $y \mapsto -F(x, y)$ is closed and convex for each x, so define on $V \times V^*$

$$L(x,p) = \sup_y p \cdot y + F(x,y),$$

its (convex) Fenchel transform. The map $p \mapsto L(x, p)$ is closed and convex on V^*. Transform again to see that $F(x, y) = \inf_{p \in V^*} L(x, p) - p \cdot y$. In particular, $f(x) = \inf_p L(x, p)$.

An example of this scheme is provided by the usual concave optimization problem given by a

concave objective function f, K concave constraints $g_k(x) \geq 0$, and an implicit constraint $x \in C$: $\max_x f(x)$ subject to the constraints $g_k(x) \geq 0$ for all k and $x \in C$. Introduce parameters y so that $g_k(x) \geq y_k$, and define $F(x, y)$ to be $f(x)$ if all the constraints are satisfied and $-\infty$ otherwise. The supremum defining the Lagrangean cannot be realized for y such that x is infeasible, and so

$$L(x,p) = \begin{cases} f(x) + \sum_k p_k g_k(x) & \text{if } x \in C \text{ and } p \in \mathbf{R}^{\mathbf{K}}_+, \\ +\infty & x \in C \text{ and } p \notin \mathbf{R}^{\mathbf{K}}_+ \\ -\infty & \text{if } x \notin C \end{cases} \tag{1}$$

if there are feasible x, then $F(x,y)$ is everywhere $-\infty$, and so $L(x, p) \equiv -\infty$.

Here, in summary, are the properties of the Lagrangean for the problems discussed here:

Lagrangean Theorem If $F(x, y)$ is lsc and concave then (1) the Lagrangean L is lsc and convex in p for each $x \in V$, (2) L is concave in x for each $p \in V^*$, and (3) $f(x) = \inf_p L(x, p)$.

Following the original scheme, the objective for the dual problem is $g(p) = \sup_x L(x, p)$, and the *dual problem* (problem D) is to maximize g on V^*. Perhaps the central fact of this dual scheme is the relationship between the dual objective function g and the value function φ. The function φ is easily seen to be concave, and simply by writing out the definitions, one sees that $g(p) = \sup_y \cdot p \cdot y + \varphi(y)$, the convex Fenchel transform of the convex function $-\varphi$. So $g(p)$ is lsc and convex, $g(p) = (-\varphi)^*(p)$ and whenever φ is usc, $\inf_p g(p) = \varphi(0)$.

To make the duality scheme complete, the min problem should be embedded in a parametric class of problems in a complementary way. Take $G(p, q) = \sup_{x \in V} L(x, p) - q \cdot x$, so that $g(p) = G(p, 0)$. With this definition, $-G(p, q) = \inf_{x \in V} q \cdot x - L(x, p)$, the concave Fenchel transform of $x \mapsto L(x, p)$. The value function for the parametric class of minimization problems is $\gamma(q) = \inf_p G(p, q)$. The relationship between F and G is computed by combining the definitions:

$$\begin{aligned} \mathrm{G}(p,\mathrm{q}) &= \sup_{x,y} F(x,y) - q \cdot x + p \cdot y \\ &= -\inf_{x,y} q \cdot x - p \cdot y - F(x,y) \\ &= -F^*(q, -y) \end{aligned}$$

and so

$$F(x,y) = \inf_{x,y} G(p,q) + q \cdot x - p \cdot y$$

where the F^* is the concave Fenchel transform of the map $(x, y) \mapsto F(x, y)$. Computing from the definitions, $f(x) = \inf_{p,q} q \cdot x + G(p, q) = \inf_q q \cdot x + \gamma(q)$, so $f = (-\gamma)^*$, and whenever γ is lsc, $\sup_x f(x) = \gamma(0)$.

In summary, if $F(x, y)$ is concave in its arguments, and usc, then we have constructed a Lagrangean and a dual problem of minimizing a concave and lsc $G(p, q)$ over p. If the value functions $\varphi(y)$ and $\gamma(q)$ are usc and lsc, respectively, then $\sup_x F(x, 0) = \gamma(0)$ and $\inf_p G(p, 0) = \varphi(0)$, so a saddle value exists. Upper and lower semi-continuity of the value functions can be an issue. The hypograph of φ is the set of all pairs (y, a) such that $\sup_x F(x, y) \geq a$, and this is the projection onto y and a of the set of all triples (x, y, a) such that $F(x, y) \geq a$, that is, hypo F. Unfortunately, even if hypo F is closed, its projection may not be, so upper semi-continuity of φ does not follow from the upper semi-continuity of F.

In the constrained optimization problem with Lagrangean (1), the parametric class of dual minimization problems is to minimize $G(p, q) = \sup_{x \in C} f(x) + \sum_k p_k g_k(x) - q \cdot x$ if $y \in \mathbf{R}^{\mathbf{K}}_+$ and $+\infty$ otherwise. Specialize this still further by considering linear programming. The canonical linear program is to *max* $a \cdot x$ subject to the explicit constraints $b_k \cdot x \leq c_k$ and the implicit constraint $x \geq 0$. Rewrite the constraints as $-b_k \cdot x + c_k \geq 0$ to be consistent with the formulation of (1). Then

$$\begin{aligned} G(p,q) &= \sup_{x \geq 0} \; a \cdot x - \sum_k p_k (\mathrm{b}_k \cdot x - c_k) - q \cdot x \\ &= \sum_k c_k p_k + \sup_{x \geq 0} \left(a - \sum_k p_k b_k - q \right) \cdot x \end{aligned}$$

for $p \in \mathbf{R}^{\mathbf{K}}_{+}$ and $+\infty$ otherwise. The dual problem is to minimize this over p. The sup term in G will be $+\infty$ unless the vector in parentheses is non-positive, in which case the sup will be 0. So the dual problem, taking $q = 0$, is to minimize $\sum_k c_k p_k$ over p subject to the constraints that $\sum_k p_k b_k \geq a$ and $p \in \mathbf{R}^{\mathbf{K}}_{+}$. If the prima constraints are infeasible, $\varphi(0) = -\infty$. If the dual is infeasible, $\gamma(0) = +\infty$, and this serves as an example of how the dual scheme can fail over lack of continuity. For linear programs there is no problem with the hypographs of φ and γ, because these are *polyhedral convex sets*, the intersection of a finite number of closed half-spaces, and projections of closed polyhedral convex sets are closed.

Solutions

Subdifferentials act like partial derivatives, particularly with respect to identifying maxima and minima: x^* in V solves problem P if and only if $0 \in \partial f(x^*)$. When f is identically $-\infty$, there are no solutions which satisfy the constraints. Thus dom f is the set of *feasible solutions* to the primal problem P. Similarly, $p^* \in V^*$ solves the dual problem D if and only if $\partial g(p^*) = 0$, and here dom g is the set of *dual-feasible solutions*. Saddlepoints of the Lagrangean also have a subdifferential characterization. Adapting the obvious partial differential notion and notation, (x^*, p^*) is a saddle point for L if and only if $0 \in \partial_x L(x^*, p^*)$ and $0 \in \partial_p L(x^*, p^*)$ (these are different 0's since they live in different spaces), which we write $(0, 0) \in \partial L(x^*, p^*)$. This condition is often called the *Kuhn–Tucker* condition. The discussion so far can be summarized in the following theorem, which is less general than can be found in the sources:

Kuhn–Tucker theorem Suppose that $F(x, y)$ is concave and usc. Then the following are equivalent:

1. $\sup f = \inf g$,
2. φ is usc and concave,
3. the saddle value of the Lagrangean L exists,
4. γ is lsc and convex.

In addition, the following are equivalent:

5. x^* solves P, p^* solves D, and the saddle value of the Lagrangean exists.
6. (x^*, p^*) satisfy the Kuhn–Tucker condition.

For economists, the most interesting feature of the dual is that it often describes how the value of the primal problem will vary with parameters. This follows from properties of the subdifferential and the key relation between the primal value function and the dual objective function, $g = (-\varphi)^* : -\partial\varphi(0) = \partial(-\varphi)(0)$, and this equals the set $\{p : (-\varphi)^*(p) = p \cdot 0 - (-\varphi)(0)\}$, and this is precisely the set $\{p : g(p) = \sup_x f(x)\}$. In words, if p is a solution to the dual problem D, then $-p$ is in the subgradient of the primal value function. When $\partial\varphi(0)$ is a singleton, there is a unique solution to the dual, and it is the derivative of the value function with respect to the parameters. More generally, from the subdifferential of a convex function one can construct directional derivatives for particular changes in parameter values. Similarly, $-\partial\gamma(0) = \{x : f(x) = \inf_p g(p)\}$, with an identical inpt. In summary, add to the Kuhn–Tucker theorem the following equivalence:

7. $-p^* \in \partial\varphi(0)$ and $-x^* \in \partial\gamma(0)$

The remaining question is, when is any one of these conditions satisfied? A condition guaranteeing that the subdifferentials are non-empty is that $0 \in$ ri dom φ, since concave functions always have subdifferentials on the relative interior of their effective domain. In the constrained optimization problem whose Lagrangean is described in (1), an old condition guaranteeing the existence of saddlepoints is the *Slater condition*, that there is an $x \in$ ri C such that for all k, $g_k(x) > 0$. This condition implies that $0 \in$ ri dom φ, because there is an open neighbourhood around 0 such that for y in the neighbourhood and for all k, $g_k(x) > y_k$. Thus $\varphi(y) \geq F(x, y) > -\infty$ for all y in the neighbourhood. Conditions like this are called *constraint qualifications*. In the standard calculus approach to constrained optimization, they give conditions under which derivatives sufficiently characterize the constraint set for calculus approximations to work (see Arrow et al. 1961).

Finally, it is worth noting that infinite dimensional constrained optimization problems, such as those arising in dynamic economic models and the study of uncertainty, can be addressed with extensions of the methods discussed here. The main difficulty is that most infinite dimensional vector spaces are not like $\mathbf{R^n}$. There is no 'natural' vector space topology, and which topology one chooses has implications for demonstrating the existence of optima. The existence of separating hyperplanes is also a difficulty in infinite dimensional spaces. These and other problems are discussed in Mas-Colell and Zame (1991). Nonetheless, much of the preceding development does go through. See Rockafellar (1974).

Convexity is the modern expression of the classical law of diminishing returns, which was prominent in political economy from Malthus and Ricardo through the neoclassical revolution. Its importance today rests less on any utilitarian or behavioural psychological rationale or physical principle than on its utility as a tool of mathematical analysis. In general equilibrium and game theory, proofs of the existence of equilibrium, competitive and Nash, respectively, rely on the application of a fixed-point theorem to a set-valued, convex-valued map from a convex set to itself. Welfare economics provides another example: The second theorem of welfare economics, which asserts that optimal allocations can be supported by competitive prices, relies on an application of the supporting hyperplane theorem to an appropriate convex set.

Convexity is a property of real vector spaces, and its domain of application in economic analysis is not just Euclidean spaces but also the infinite dimensional vector spaces which arise in the study of uncertainty and dynamics, where infinite numbers of goods are required. Nonetheless, this brief exposition will be confined to Euclidean spaces.

Definitions

A set $C \subset \mathbf{R^n}$ is *convex* if the line segment connecting any two points in C lies wholly within C. Formally put, C is convex if and only if for all points x and y in C and all scalars t in the unit interval $[0, 1]$, the point $tx + (1 - t)y$ is also in C. A ball is convex; a boomerang is not. An extended real-valued function f defined on a convex set $C \subset \mathbf{R^n}$ is *convex* if its *epigraph* or *supergraph*, $\{(x, \mu) : x \in C, \mu \in \mathbf{R}, f(x) \leq \mu\}$ is convex. For real-valued functions, this is equivalent to the more familiar definition that for all x and y in C and $t \in [0, 1]$, $f(tx + (1 - t)y) \geq tf(x) + (1 - t)f(y)$. A function f is *concave* if $-f$ is convex.

Optimization

Students of economics first encounter convexity in the study of optimization. If $x^* \in \mathbf{R^n}$ is a critical point of a smooth function, and if x^* a local maximum, then the Hessian matrix at x^*, the matrix of second-order partial derivatives, must be negative semi-definite; that is, it is locally concave. Any critical point with a negative definite Hessian must be a local maximum. Negative definiteness of the Hessian implies but is not implied by strict (local) concavity. For Jevons, utility was additively separable, and so the principle of diminishing marginal utility itself was enough to derive concavity. Edgeworth, the first economist to consider non-separable utility functions, realized that diminishing marginal utility was not, in general, enough to guarantee convexity. His development of demand theory relied on a differential condition that can be shown to imply *quasi-concavity.* A real-valued function f with a convex domain C is *quasi-concave* if for each real number α, the set $\{x \in C : f(x) \geq \alpha\}$ is convex. To appreciate the difference between concavity and quasi-concavity, note that any strictly increasing function on the real line is quasi-concave. The differential description of convexity and its variants (quasi-convexity, pseudo-convexity) and the associated necessary and sufficient second-order conditions for constrained optimization problems has produced a volume of analysis, most of which is of second-order importance to contemporary economic theory. Exhaustive coverage can be found in Simon and Blume (1994).

Duality

The representation of consumers by expenditure functions and firms by profit functions is said to be 'dual' to the 'primal' representations by preferences and production sets, respectively. These representations rely on alternative ways of representing closed convex sets: The 'primal' description is a list of its elements, and the 'dual' description is the list of closed half-spaces containing it. The dual representation for closed convex sets is equivalent to the separating hyperplane theorem: If x in $\mathbf{R^n}$ is not in a closed convex set C, then there is a hyperplane $H \subset \mathbf{R^n}$ with x on one side and C on the other. That is, there is a $p \in \mathbf{R^n}$ and a number α such that $p \cdot x < \alpha$ and $p \cdot y > \alpha$ for all $y \in C$. (See ▶ Convex Programming and ▶ Duality.)

Large Numbers and Convexity

Convexity is sometimes an inappropriate assumption. Half a box of two left shoes and half a box of two right shoes is surely preferred to either box, but the 50:50 mixture of a good burgundy and a good stout is only a headache. Fortunately, the analysis of perfectly competitive markets rests not on the preferences of any individual consumer, but on the average behaviour of a large number of consumers. A central insight behind much research of the 1970s and 1980s (and which was anticipated by Edgeworth 1881, a century before) is that averaging is a convexifying operation. This is the content of the Shapley–Folkman theorem as applied to large finite economies, and Lyapunov's theorem in the analysis of economies with a continuum of agents. (See ▶ Cores, ▶ Large Economies and ▶ Perfect Competition.) For economies with large numbers of small consumers and small firms, the important analytical constructs are approximately convex. With respect to the existence of equilibrium and its welfare properties, large economies look like convex economies. Hildenbrand (1974) is an entry point to this important body of research.

Convict Labour

Some European countries banished convicts to labour in overseas colonies – sometimes using private markets to transport and employ this labour.

Punishing felons who did not warrant execution and were too poor to pay monetary fines posed a dilemma for early modern societies. The long-standing punishments of one-off physical chastisements, such as whippings, increasingly seemed too barbaric and returned malefactors to society too quickly. While long-term incarceration was more civilized and removed malefactors from society, penitentiaries were expensive to build and operate, and the criminal's labour was lost to society. Sentencing felons to labour in overseas colonies thus became an attractive solution.

Between 1854 and 1920 France sent between 20,000 and 30,000 convicts to French Guiana and New Caledonia. Spain sent convicts to North Africa, Cuba, and Puerto Rico. Britain, however, was the largest participant, sending 6000–10,000 convicts to its colonies between 1614 and 1718 and another 50,000 mostly to its American colonies Virginia and Maryland between 1718 and 1775 (Coldham 1992; Ekirch 1987). After the United States closed its shores to British convicts, convict transportation was shifted to Australia where approximately 160,000 were landed between 1787 and 1868 (Nicholas 1988). Another 18,000 were shipped to Bermuda and Gibraltar.

The Transportation Act of 1718 shifted the overseas banishment of British felons from a case-by-case petitioning of the Crown to a routine sentence imposed by courts. The sentences allowed were 7 years, 14 years, or a lifetime of banishment – 74%, 24% and 2%, respectively, of those transported – which became the length of the convict's overseas labour contract. Most transported convicts were guilty of property crimes and were Englishmen. Between 13 and 23% were Irish, and between 10 and 15% were female (Ekirch 1987). Sentences were not rigidly tied to crimes; for example, highway robbers received 7-year, 14-year, and lifetime sentences – 38%, 50%, and 12%, respectively (Grubb 2000). Not until convicts had completed their sentences could they return to Britain without facing being hanged if caught.

The privatization of overseas convict disposal reached its zenith after the Transportation Act. The government minimized its cost of overseas convict disposal by channelling convicts through the existing competitive markets for voluntary servant labour, where emigrants traded forward-labour contracts to shippers for passage to America. Shippers recouped their cost by selling these contracts (emigrants) to private employers in America. Potential shipping profits related to labour heterogeneity were arbitraged away by bargaining over contract length. The typical voluntary servant negotiated a four-year labour contract and sold in America for eight and half pounds sterling. By contrast, courts fixed the length of convict sentences (labour contracts) independently of labour heterogeneity. Convicts were then transferred to private shippers for transportation overseas. Shippers sold their convicts as servant labour to private employers in America to recoup their shipping expense. The average convict sold for 11 lb sterling (Grubb 2000).

By fixing contract lengths – the parameter used to arbitraged shipping profits in the voluntary servant market – the courts altered the convict auction price distribution and profit arbitrage process from that which existed in the voluntary servant market. The distribution of convict contract prices had a higher mean, higher standard deviation, and lower kurtosis than that of voluntary servant contract prices. Shippers did not earn excess profits on convicts. The higher sale price was matched by the higher cost of chaining convicts during shipment and paying variable fees charged by county jailers. Jailers played shippers off against each other for access to convict cargo. The government subsidized one shipper in the London market who earned, net of political bribes, excess profits (Grubb 2000).

Shippers carried both voluntary and convict servants concurrently. Potential employers were shown the conviction papers that stated each convict's sentence and crime. Post-auction convicts were largely indistinguishable from voluntary servants. Most were employed in agriculture and at iron forges alongside slaves and voluntary servants. They lived in their employer's house and ate at their employer's table. Criminal conviction, however, carried a stigma that led to price discounts. A year's worth of convict labour sold for a 21% discount on average over that of comparable voluntary servant labour. Convicts guilty of more serious and professional crimes, such as arsonists and receivers of stolen goods, sold for even greater discounts. Convicts also ran away more often than did voluntary servants: 16% versus 6%, respectively (Grubb 2001).

Per given crime, a 14-year versus a 7-year sentence signalled the courts' perception of the severity of harm inflicted by, and incorrigibility of, the convict. American employers responded to this information by demanding additional price discounts of 48% and 68% per year of labour for convicts sentenced to 14 years and to life, respectively, as opposed to seven years for the same crime. Employers also paid premiums and received discounts for certain convict attributes, other things equal. For example, taller convicts sold for a substantial premium, and female convicts with venereal disease sold for 19% less than females without the disease (Grubb 2001).

For underpopulated colonies lacking competitive labour markets, such as Australia, European governments typically had to transport convicts to the colonies themselves, directly employing them on government projects there (Nicholas 1988). During the nineteenth century, European governments also became increasingly reluctant to use existing competitive markets to auction convict labour for fear that it would look like government-sanctioned slavery. Instead, convicts were transferred via bureaucratic petition or assignment systems. Under these conditions, the system struggled to employ convict labour efficiently and to be a cost-effective punishment. Convict transportation waned as social reformers succeeded in replacing it with incarceration in newly built penitentiaries and as maturing colonies increasingly resisted being convict dumping-grounds.

Cooperation

Samuel Bowles and Herbert Gintis

Abstract

We review game-theoretic models of cooperation with self-regarding agents. We then study the folk theorem in large groups of self-regarding individuals with imperfect information. In contrast to the dyadic case with perfect information, the level of cooperation deteriorates with larger group size and higher error rates. Moreover, no plausible account exists of how the dynamic, out-of-equilibrium behaviour of these models would support cooperative outcomes. We then analyse cooperation with other-regarding preferences, finding that a high level of cooperation can be attained in large groups and with modest informational requirements, and that conditions allowing the evolution of such social preferences are plausible.

Cooperation is said to occur when two or more individuals engage in joint actions that result in mutual benefits. Examples include the mutually beneficial exchange of goods, the payment of taxes to finance public goods, team production, common pool resource management, collusion among firms, voting for income redistribution to others, participating in collective actions such as demonstrations, and adhering to socially beneficial norms.

A major goal of economic theory has been to explain how wide-scale cooperation among self-regarding individuals occurs in a decentralized setting. The first thrust of this endeavour involved Walras's general equilibrium model, culminating in the celebrated 'invisible hand' theorem of Arrow and Debreu (Arrow and Debreu 1954; Debreu 1959; Arrow and Hahn 1971). But, the assumption that contracts could completely specify all relevant aspects of all exchanges and could be enforced at zero cost to the exchanging parties is not applicable to many important forms of cooperation. Indeed, such economic institutions as firms, financial institutions, and state agencies depend on incentive mechanisms involving strategic interaction in addition to explicit contracts (Blau 1964; Gintis 1976; Stiglitz 1987; Tirole 1988; Laffont 2000).

The second major thrust in explaining cooperation eschewed complete contracting and developed sophisticated repeated game-theoretic models of strategic interaction. These models are based on the insights of Shubik (1959), Taylor (1976), Axelrod and Hamilton (1981) and others that repetition of social interactions plus retaliation against defectors by withdrawal of cooperation may enforce cooperation among self-regarding individuals. A statement of this line of thinking, applied towards understanding the broad historical and anthropological sweep of human experience is the work of Ken Binmore (1993, 1998, 2005). For Binmore, a society's moral rules are instructions for behaviour in conformity with one of the myriad of Nash equilibria of a repeated n-player social interaction. Because the interactions are repeated, and these rules form a Nash equilibrium, the self-regarding individuals who comprise the social order will conform to the moral rules.

We begin by reviewing models of repeated dyadic interaction in which cooperation may occur among players who initially cooperate and in the next round adopt the action of the other player in the previous round, called *tit for tat*. These models show that as long as the probability of game repetition is sufficiently great and

individuals are sufficiently patient, a cooperative equilibrium can be sustained once it is implemented. This reasoning applies to a wide range of similar strategies. We then analyse *reputation maintenance* models of dyadic interaction, which are relevant when individuals interact with many different individuals, and hence the number of periods before a repeat encounter with any given individual may be too great to support the tit-for-tat strategy.

We then turn to models of cooperation in larger groups, arguably the most relevant case, given the scale on which cooperation frequently takes place. The folk theorem (Fudenberg and Maskin 1986) shows that, in groups of any size, cooperation can be maintained on the assumption that the players are sufficiently future-oriented and termination of the interaction is sufficiently unlikely. We will see, however, that these models do not successfully extend the intuitions of the dyadic models to many-person interactions. The reason is that the level of cooperation that may be supported in this way deteriorates as group size increases and the probability of either behavioural or perceptual error rises, and because the theory lacks a plausible account of how individuals would discover and coordinate on the complicated strategies necessary for cooperation to be sustained in these models. This difficulty bids us investigate how other-regarding preferences, *strong reciprocity* in particular, may sustain a high level of cooperation, even with substantial errors and in large groups.

Repetition Allows Cooperation in Groups of Size Two

Consider a pair of individuals who play the following *stage game* repeatedly: each can *cooperate* (that is, help the other) at a cost $c > 0$ to himself, providing a benefit to the other of $b > c$. Alternatively, each player can *defect*, incurring no cost and providing no benefit. Clearly, both would gain by cooperating in the stage game, each receiving a net gain of $b - c > 0$. However, the structure of the game is that of a *Prisoner's Dilemma*, in which a self-regarding player earns higher payoff by defecting, no matter what his partner does.

The behaviour whereby each individual provides aid as long as this aid has been reciprocated by the other in the previous encounter, is called *tit for tat*. Although termed 'reciprocal altruism' by biologists, this behaviour is self-regarding, because each individual's decisions depend only on the expected net benefit the individual enjoys from the long-term relationship.

On the assumption that after each round of play the interaction will be continued with probability δ, and that players have discount factor d (so $d = 1/(1 + r)$, where r is the rate of time preference), then provided

$$\delta d b > c \tag{1}$$

each individual paired with a tit-for-tat player does better by cooperating (that is, playing tit for tat) rather than by defecting. Thus tit for tat is a best response to itself. To see this, let $\mathbf{v}$ be the present value of cooperating when paired with a tit-for-tat player. The

$$\mathbf{v} = b - c + \delta d \mathbf{v} \tag{2}$$

which gives

$$\mathbf{v} = \frac{b - c}{1 - \delta d} \tag{3}$$

The present value of defecting for ever on a tit-for-tat playing partner is b (the single period gain of b being followed by zero gains in every subsequent period as a result of the tit-for-tat player's defection), so playing tit-for-tat is a best response to itself if and only if $(b - c)(1 - \delta d) > b$, which reduces to (1). Under these conditions unconditional defect is also a best response to itself, so either cooperation or defection can be sustained.

But suppose that, instead of defection for ever, the alternative to tit for tat is for a player to defect for a certain number of rounds, before returning to cooperation on round $k > 0$. The payoff to this strategy against tit for tat is $b - (\delta d)^k c + (\delta d)^{k+1}\mathbf{v}$. This payoff must not be greater than $\mathbf{v}$ if tit for tat is to be a best response to itself. It is

an easy exercise in algebra to show that the inequality

$$\mathbf{v} \geq b - (\delta d)^k c + (\delta d)^{k+1}\mathbf{v}$$

simplifies to (1), no matter what the value of k. A similar argument shows that when (1) holds, defecting for ever (that is, $k = \infty$) does not have a higher payoff than cooperating.

Cooperation Through Reputation Maintenance

Tit for tat takes the form of frequent repetition of the Prisoner's Dilemma stage game inducing a pair of self-regarding individuals to cooperate. In a sizable group, an individual may interact frequently with a large number of partners but infrequently with any single one, say on the average of once every k periods. Players then discount future gains so that a payoff of $\mathbf{v}$ in k periods from now is worth $d^k\mathbf{v}$ now. Then, an argument parallel to that of the previous section shows that cooperating is a best response if and only if

$$\frac{b-c}{1-\delta d^k} > b$$

which reduces to

$$\delta d^k b > c \tag{4}$$

Note that this is the same equation as (1) except that the effective discount factor falls from d to d^k. For sufficiently large k, it will not pay to cooperate. Therefore, the conditions for tit-for-tat reciprocity will not obtain.

But cooperation may be sustained in this situation if each individual keeps a mental model of exactly which group members cooperated in the previous period and which did not. In this case, players may cooperate in order to cultivate a *reputation for cooperation*. When individuals tend to cooperate with others who have a reputation for cooperation, a process called *indirect reciprocity* can sustain cooperation. Let us say that an individual who cooperated in the previous period *in good standing*, and specify that the only way an individual can fall into *bad standing* is by defecting on a partner who is in good standing. Note that an individual can always defect when his partner is in bad standing without losing his good standing status. In this more general setting the tit-for-tat strategy is replaced by the following *standing strategy*: cooperate if and only if your current partner is in good standing, except that, if you accidentally defected the previous period, cooperate this period unconditionally, thereby restoring your status as a member in good standing. This *standing model* is due to Sugden (1986).

Panchanathan and Boyd (2004) have proposed an ingenious deployment of indirect reciprocity, assuming that there is an ongoing dyadic helping game in society based on the indirect reciprocity information and incentive structure, and there is also an n-player public goods game, played relatively infrequently by the same individuals. In the dyadic helping game, two individuals are paired and each member of the pair may confer a benefit b upon his partner at a cost c to himself, an individual remaining in good standing so long as he does not defect on a partner who is in good standing. This random pairing is repeated with probability δ and with discount factor d. In the public goods game, an individual produces a benefit b_g that is shared equally by all the other members, at a cost c_g to himself. The two games are linked by defectors in the public goods game being considered in bad standing at the start of the helping game that directly follows. Then, cooperation can be sustained in both the public goods game and in the dyadic helping game so long as

$$c_g \leq \frac{b(1-\mathcal{E}) - c}{1-\delta d} \tag{5}$$

where ε is the rate at which cooperators unintentionally fail to produce the benefit. Parameters favouring this solution are that the cost c_g of cooperating in the public goods game be low, the factor δd is close to unity, and the net benefit $b(1-\varepsilon) - c$ of cooperating in the reputation-building reciprocity game be large.

The major weakness of the standing model is its demanding informational requirements. Each

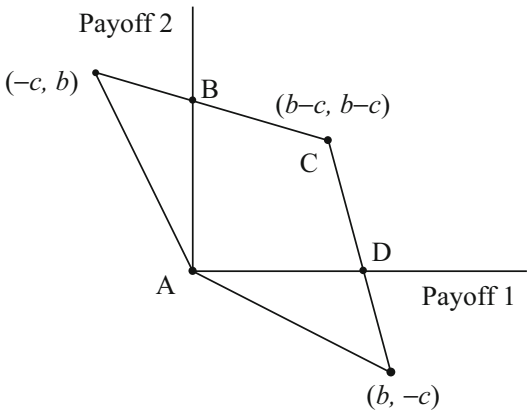
individual must know the current standing of each member of the group, the identity of each member's current partner, and whether each individual cooperated or defected against his current partner. Since dyadic interactions are generally private, and hence are unlikely to be observed by more than a small number of others, errors in determining the standing of individuals may be frequent. This contrasts sharply with the repeated game models of the previous section, which require only that an individual know how many of his current partners defected in the previous period. Especially serious is that warranted noncooperation (because in one's own mental accounting one's partner is in bad standing) may be perceived to be unwarranted defection by some third parties but not by others. This will occur with high frequency if information partially private rather than public (not everyone has the same information). It has been proposed that gossip and other forms of communication can transform private into public information, but how this might occur among self-regarding individuals has not been (and probably cannot be) shown, because in any practical setting individuals may benefit by reporting dishonestly on what they have observed, and self-regarding individuals do not care about the harm to others induced by false information. Under such conditions, disagreements among individuals about who ought to be punished can reach extremely high levels, with the unravelling of cooperation as a result.

In response to this weakness of the standing model, Nowak and Sigmund (1998) developed an indirect reciprocity model which they term *image scoring*. Players in the image scoring need not know the standing of recipients of aid, so the informational requirements of indirect reciprocity are considerably reduced. Nowak and Sigmund show that the strategy of cooperating with others who have cooperated in the past, *independent of the reputation of the cooperator's partner*, is stable against invasion by defectors, and weakly stable against invasion by unconditional cooperators once defectors are eliminated from the population. Leimar and Hammerstein (2001), Panchanathan and Boyd (2003), and Brandt and Sigmund (2004, 2005), explore the applicability of image scoring.

Cooperation in Large Groups of Self-Regarding Individuals

Repeated game theory has extended the above two-player results to a general *n*player stage game, the so-called *public goods game*. In this game each player cooperates at cost $c > 0$, contributing an amount $b > c$ that is shared equally among the other $n - 1$ players. We define the *feasible payoff set* as the set of possible payoffs to the various players, assuming each cooperates with a certain probability, and each player does at least as well as the payoffs obtaining under mutual defection. The set of feasible payoffs for a two-player public goods game is given in Fig. 1 by the four-sided figure ABCD. For the *n*-player game, the figure ABCD is replaced by a similar *n*-dimensional polytope.

Repeated game models have demonstrated the so-called folk theorem, which asserts that any distribution of payoffs to the n players that lies in the feasible payoff set can be supported by an equilibrium in the repeated public goods game, provided the discount factor times the probability of continuation, δd, is sufficiently close to unity. The equilibrium concept employed is a refinement of subgame perfect equilibrium. Significant contributions to this literature include Fudenberg and



Cooperation, Fig. 1 Two-player public goods game

Maskin (1986), assuming perfect information, Fudenberg et al. (1994), assuming imperfect information, so that cooperation is sometimes inaccurately reported as defection, and Sekiguchi (1997), Piccione (2002), Ely and Välimäki (2002), Bhaskar and Obara (2002) and Mailath and Morris (2006), who assume that different players receive different, possibly inaccurate, information concerning the behaviour of the other players.

The folk theorem is an *existence theorem* affirming that any outcome that is a Pareto improvement over universal defection may be supported by a Nash equilibrium, including point C (full cooperation) in the figure and outcomes barely superior to A (universal defection). The theorem is silent on which of this vast number of equilibria is more likely to be observed or how they might be attained. When these issues are addressed two problems are immediately apparent: first, equilibria in the public goods game supported in this manner exhibit very little cooperation if large numbers of individuals are involved or errors in execution and perception are large, and second, the equilibria are not robust because they require some mechanism allowing coordination on highly complex strategies. While such a mechanism could be provided by centralized authority, decentralized mechanisms, as we will see, are not sustainable in a plausible dynamic.

The Dynamics of Cooperation

The first difficulty, the inability to support high levels of cooperation in large groups or with significant behavioural or perceptual noise, stems from the fact that the only way players may punish defectors is *to withdraw their own cooperation*. In the twoperson case, defectors are thus targeted for punishment. But for large n, withdrawal of cooperation to punish a single defector punishes all group members equally, most of whom, in the neighbourhood of a cooperative equilibrium, will be cooperators. Moreover, in large groups, the rate at which erroneous signals are propagated will generally increase with group size, and the larger the group, the larger the fraction of time group members will spend punishing (miscreants and fellow cooperators alike). For instance, suppose the rate at which cooperators accidentally fail to produce b, and hence signal defection, is five per cent. Then, in a group of size two, a perceived defection will occur in about ten per cent of all periods, while in a group of size 20, at least one perceived defection will occur in about 64 per cent of all periods.

As a result of these difficulties, the folk theorem assertion that we can approximate the per-period expected payoff as close to the efficient level (point C in Fig. 1) as desired as long as the discount factor δ is sufficiently close to unity is of little practical relevance. The reason is that as $\delta \to 1$, the current payoff approximates zero, and the expected payoff is deferred to future periods at very little cost, since future returns are discounted at a very low rate. Indeed, with the discount factor δ held constant, the efficiency of cooperation in the Fudenberg, Levine and Maskin model declines at an exponential rate with increasing group size (Bowles and Gintis 2007, ch. 13). Moreover, in an agent-based simulation of the public goods with punishment model, on the assumption of a benefit/cost ratio of $b/c = 2$ (that is, contributing to the public good costs half of the benefit conferred on members of the group) and a discount factor times probability of repetition of $d\delta = 0.96$, even for an error rate as low as $\varepsilon = 0.04$, fewer than half of the members contribute to the public good in groups of size $n = 4$, and less that 20 per cent contribute in groups of size $n = 6$ (Bowles and Gintis 2007, ch. 5).

The second limitation of the folk theorem analysis is that it has not been shown (and probably cannot be shown) that the equilibria supporting cooperation are dynamically robust, that is, asymptotically stable with a large basin of attraction in the relevant dynamic. Equilibria for which this is not the case will seldom be observed because they are unlikely to be attained and if attained unlikely to persist for long.

The Nash equilibrium concept applies when each individual expects all others to play their parts in the equilibrium. But, when there are multiple equilibria, as in the case of the folk theorem,

where there are many possible patterns of response to given pattern of defection, each imposing distinct costs and requiring distinct, possibly stochastic, behaviours on the part of players, there is no single set of beliefs and expectations that group members can settle upon to coordinate their actions (Aumann and Brandenburger 1995).

While game theory does not provide an analysis of how beliefs and expectations are aligned in a manner allowing cooperation to occur, sociologists (Durkheim 1902; Parsons and Shils 1951) and anthropologists (Benedict 1934; Boyd and Richerson 1985; Brown 1991) have found that virtually every society has such processes, and that they are key to understanding strategic interaction. Borrowing a page from sociological theory, we posit that groups may have *focal rules* that are common knowledge among group members. Focal rules could suggest which of a countless number of strategies that could constitute a Nash equilibrium should all individuals adopt them, thereby providing the coordination necessary to support cooperation. These focal rules do not ensure equilibrium, because error, mutation, migration, and other dynamical forces ensure that on average not all individuals conform to the focal rules of the groups to which they belong. Moreover, a group's focal rules are themselves subject to dynamical forces, those producing better outcomes for their members displacing less effective focal rules.

In the case of the repeated public goods game, which is the appropriate model for many forms of large-scale cooperation, Gintis (2007) shows that focal rules capable of supporting the kinds of cooperative equilibria identified by the folk theorem are not evolutionarily stable, meaning that groups whose focal rules support highly cooperative equilibria do worse than groups with less stringent focal rules, and as a result the focal rules necessary for cooperation are eventually eliminated.

The mechanism behind this result can be easily explained. Suppose a large population consists of many smaller groups playing n-person public goods games, with considerable migration across groups, and with the focal rules of successful groups being copied by less successful groups. To maintain a high level of cooperation in a group, focal rules should foster punishing defectors by withdrawing cooperation. However, such punishment is both costly and provides an external benefit to other groups by reducing the frequency of defection-prone individuals who might migrate elsewhere. Hence, groups that 'free ride' by not punishing defectors harshly will support higher payoffs for its members than groups that punish assiduously. Such groups will then be copied by other groups, leading to a secular decline in the frequency of punishment suggested by focal rules in all groups. Thus, suppose that the groups in question were competitive firms whose profits depend on the degree of cooperation among firm members. If all adopted a zero-tolerance rule (all would defect if even a single defection was perceived), then a firm adopting a rule that tolerated a single defection would sustain higher profits and replace the zero-tolerance firms. But this firm would in turn be replaced by a firm adopting a rule that tolerates two defections.

These two problems – the inability to support efficient levels of cooperation in large groups with noisy information, and dynamic instability – have been shown for the case where information is public. Private information, in general the more relevant case, considerably exacerbates these problems.

Cooperation with Other-Regarding Individuals

The models reviewed thus far have assumed that individuals are entirely self-regarding. But cooperation in sizable groups is possible if there exist other-regarding individuals in the form of *strong reciprocators*, who cooperate with one another and punish defectors, even if they sustain net costs. Strong reciprocators are altruistic in the standard sense that they confer benefits on other members of their group (in this case, because their altruistic punishment of defectors sustains cooperation) but would increase their own payoffs by adopting self-regarding behaviours. A model with *social preferences* of this type can explain large-scale decentralized cooperation with noisy

information as long as the information structure is such that defectors expect a level of punishment greater than costs of cooperating.

Cooperation is not a puzzle if a sufficient number of individuals with social preferences are involved. The puzzle that arises is how such altruistic behaviour could have become common, given that bearing costs to support the benefits of others reduces payoffs, and both cultural and genetic updating of behaviours is likely to favour traits with higher payoffs. This evolutionary puzzle applies to strong reciprocity. Since punishment is costly to the individual, and an individual could escape punishment by cooperating, while avoiding the costs of punishment by not punishing, we are obliged to exhibit a mechanism whereby strong reciprocators could proliferate when rare and be sustained in equilibrium, despite their altruistic behaviour.

This is carried out in Sethi and Somanathan (2001), Gintis (2000), Boyd et al. (2003), Gintis (2003) and Bowles and Gintis (2004). The evolutionary viability of other types of altruistic cooperation is demonstrated in Bowles et al. (2003), Boyd et al. (2003), Bergstrom (1995) and Salomonsson and Weibull (2006). The critical condition allowing the evolution of strong reciprocity and other forms of altruistic social preferences is that individuals with social preferences are more likely than random to interact with others with social preferences. Positive assortment arises in these models due to deliberate exclusion of those who have defected in the past (by ostracism, for example), random differences in the composition of groups (due to small group size and limited between-group mobility), limited dispersion of close kin who share common genetic and cultural inheritance, and processes of social learning such as conformism or group level socialization contributing to homogeneity within groups. As in the repeated game models, smaller groups favour cooperation, but in this case for a different reason: positive assortment tends to decline with group size. But the group sizes that sustain the altruistic preferences that support cooperative outcomes in these models are at least an order of magnitude larger than those indicated for the repeated game models studied above.

In sum, we think that other-regarding preferences provide a compelling account of many forms of human cooperation that are not well explained by repeated game models with self-regarding preferences. Moreover, a number of studies have shown that strong reciprocity and other social preferences are a common human behaviour (Fehr and Gächter 2000; Henrich et al. 2005) and could have emerged and been sustained in a gene-culture co-evolutionary dynamic under conditions experienced by ancestral humans (Bowles 2006). The above models also show that strong reciprocity and other social preferences that support cooperation can evolve and persist even when there are many self-regarding players, where group sizes are substantial, and when behavioural or perception errors are significant.

Conclusion: Economics and the Missing Choreographer

The shortcomings of the economic theory of cooperation based on repeated games strikingly replicate those of economists' other main contribution to the study of decentralized cooperation, namely, general equilibrium theory. Both prove the existence of equilibria with socially desirable properties, while leaving the question of how such equilibria are achieved as an afterthought, thereby exhibiting a curious lack of attention to dynamics and out-of equilibrium behaviour. Both purport to model decentralized interactions but on close inspection require a level of coordination that is not explained, but rather posited as a *deus ex machina*. To ensure that only equilibrium trades are executed, general equilibrium theory resorts to a fictive 'auctioneer'. No counterpart to the auctioneer has been made explicit in the repeated-game approach to cooperation. Highly choreographed coordination on complex strategies capable of deterring defection are supposed to materialize quite without the need for a choreographer.

Humans are unique among living organisms in the degree and range of cooperation among large numbers of substantially unrelated individuals.

The global division of labour and exchange, the modern democratic welfare state, and contemporary warfare alike evidence our distinctiveness. These forms of cooperation emerged historically and are today sustained as a result of the interplay of self-regarding and social preferences operating under the influence of group-level institutions of governance and socialization that favour cooperators, in part by protecting them from exploitation by defectors.

The norms and institutions that have accomplished this evolved over millennia through trial and error. Consider how real-world institutions addressed two of the shoals on which the economic models foundered. First, the private nature of information, as we have seen, makes it virtually impossible to coordinate the targeted punishment of miscreants. Converting private information about transgressions into public information that can provide the basis of punishment often involves civil or criminal trials, elaborate processes that rely on commonly agreed upon rules of evidence and ethical norms of appropriate behaviour. Even these complex institutions frequently fail to transform the private protestations of innocence and guilt into common knowledge. Second, as in the standing models with private information, cooperation often unravels when the withdrawal of cooperation by the civic-minded intending to punish a defector is interpreted by others as a violation of a cooperative norm, inviting further defections. In all successful modern societies, this problem was eventually addressed by the creation of a corps of specialists entrusted with carrying out the more severe of society's punishments, whose uniforms conveyed the civic purpose of the punishments they meted out, and whose professional norms, it was hoped, would ensure that the power to punish was not used for personal gain.

Like court proceedings, this institution works imperfectly. It is hardly surprising then that economists have encountered difficulty in devising simple models of how large numbers of self-regarding individuals might sustain cooperation in a truly decentralized setting.

Modelling this complex process is a major challenge of contemporary science. Economic theory, favouring parsimony over realism, has instead sought to explain cooperation without reference to other-regarding preferences and with minimalist or fictive descriptions of social institutions.

Cooperative Equilibrium

A. Mas-Colell

Introduction

The term 'cooperative equilibria' has been imported into economics from game theory. It refers to the equilibria of economic situations modelled by means of cooperative games and solved by appealing to an appropriate cooperative solution concept. The influence is not entirely one way, however. Many game theoretic notions (e.g. Cournot–Nash equilibrium, the Core) are formalizations of pre-existing ideas in economics.

The distinguishing feature of the cooperative approach in game theory and economics is that it

does not attempt to model how a group of economic agents (say a buyer and a seller) may communicate among themselves. The typical starting point is the hypothesis that, in principle, any subgroup of economic agents (or perhaps some distinguished subgroups) has a clear picture of the possibilities of joint action and that its members can communicate freely before the formal play starts. Obviously, what is left out of cooperative theory is very substantial. The justification, or so one hopes, is that the drastic simplification brings to centre stage the implications of actual or potential coalition formation. In their classic book, von Neumann and Morgenstern (1944) already emphasized that the possibility of strategic coalition formation was the key aspect setting apart two from three or more players' games.

The previous remarks emphasize free preplay communication as the essential distinguishing characteristic of cooperative theory. There is a second feature common to most of the literature but which nonetheless may not be intrinsic to the theory (this the future will determine). We refer to the assumed extensive ability of coalitions' players to commit to a course of action once an agreement has been reached.

The remaining exposition is divided in three sections. Sections "The Dominance Approach" and "The Valuation Approach" discuss the two main approaches to cooperative theory (domination and valuation, respectively). Section "Consistency Qualifications" contains qualifications to the domination approach.

An excellent reference for the topic of this entry is Shubik (1983).

The Dominance Approach

Suppose we have N economic agents. Every agent has a strategy set S_i. Denote $S = S_1 \times \ldots \times S_N$ with generic element $S = (S_1, \ldots, \times S_N)$. Given s and a coalition $C \subset N$, the expression s_C denotes the strategies corresponding to members of C. Letting C' be complement of C, the expression $(s_C, s_{C'}$ defines s in the obvious way. For every i there is a utility function $u_i(s)$. If $u = (u_1, \ldots, u_N)$ is an N-list of utilities, expressions such as u_C or $(u_C, u_{C'})$ have the obvious meaning.

Example 1 (Exchange economies): There are N consumers and l desirable goods. Each consumer has a utility function $u_i(x_i)$ and initial endowments ω_i. A strategy of consumer i is an N non-negative vector $S = (S_{i1}, \ldots, \times S_{iN})$ such that $\sum_{j=1}^{N} s_{ij} \leqslant \omega_i$, i.e. s_i is an allocation of the initial endowments of i among the N consumers. Of course, $u_j(s) = u_j\left(\sum_i s_{ij}\right)$.

Example 2 (Public goods): Suppose that to the model of Example 1 we add a public good y with production function $y = F(v)$. Utility functions have the form $u_j(x_j,y)$. A strategy for i is now an $(N + 1)l$ vector $S_i = (S_{i1}, \ldots, S_{i,N+1})$ where $S_{i,N+1}$ is allocated as input to production. We have $u_j(s) = u_j\left[\sum_i s_{ij}\left(\sum_i s_{i,N+1}\right)\right]$.

Example 3 (Exchange with private bads): This is as the first example, except that there is no free disposal, i.e. $\sum_{j=1}^{N} s_{ij} = \omega_i$ for every i. Some of the goods may actually be bads. To be concrete, suppose that $l = 2$, one of the goods is a desirable numéraire and the other is garbage. All consumers are identical and each owns one unit of numéraire and one of garbage (see Shapley and Shubik 1969).

For a strategy profile s to be called a *cooperative equilibrium* we require that there is no coalition C that *dominates* the utility vector $u(S) = (u_1(s),\ldots,u_N(s))$ i.e. that can 'make effective' for its members utility levels $u_{i,\, i \in C}$, such that $u_i > u_i(s)$ for all $i \in C$ Denote by $V(C)$ the utility levels that C can 'make effective' for its members. The precise content of the equilibrium concept depends, of course, on the definition of $V(C)$. I proceed to discuss several possibilities (Aumann 1959, is a key reference for all this).

(A) In line with the idea of Cournot–Nash equilibrium, we could define $V_s(C) = \{u_C : u_C \leqslant u_C(s'_C, s_C)$ for some $S'_C \in S_C\}$, that is, the agents in C take the strategies of C' as fixed. They do not anticipate, so to speak, any retaliatory move. The cooperative solution concept that uses $V_s(C)$ is called *strong Cournot–Nash equilibrium*. It

is very strong indeed. So strong, that it rarely exists. Obviously, this limits the usefulness of the concept. It is immediately obvious that it does not exist for any of the three examples above.

Note that $V_s(C)$ depends on the reference point s. We now go to the other extreme and consider definitions where when a coalition contemplates deviating, it readies itself for a retaliatory behaviour on the part of the complementary coalition; that is, the deviation erases the initial position and is carried out if and only if better levels of utility can be reached, no matter what the agents outside the coalition do. On defining $V(C)$, however, there is an important subtlety. The set $V(C)$ can be defined as either what the members of C cannot be prevented from getting (i.e. the members of C move second) or, more strictly, as what the members of C can guarantee themselves (i.e. they move first). More precisely:

(B) For every C, define:

$$V_\beta(C) = [u_C\text{: for any } s_C \text{ there is an } s_C \text{ such that } u_C \leq u(s_C, s_{C'})].$$

This is what C cannot be prevented from getting. The set of corresponding cooperative equilibria is called the β-core of the game or economy. For any s we have $V_\beta(C) \subset V_s(C)$, and so there is more of a chance for a β-core equilibrium to exist than for a strong Cournot–Nash equilibrium. But there is no general existence theorem. As we shall see, the β-core is non-empty in examples 1 and 2. It is instructive to verify that it is empty in example 3. By symmetry, it is enough to check that the strategies where each agent consumes its own endowment is not an equilibrium. Take the coalition formed by two of the three (identical) agents. As a retaliatory move, the third agent would, at worst, be dumping its unit of garbage on one of the members of the coalition (or perhaps splitting it among them), but the coalition can still be better off than at the initial endowment point by dumping its two units on the third member *and* transferring some money from the nonreceptor to the receptor of outside garbage.

(C) For every C define:

$$V_\alpha(C) = [u_C : \text{ there is } s_C \text{ such that } u_C \leq u_C(s_C, s_{C'}) \text{ for any } s_{C'}].$$

This is what C can guarantee itself of getting. It represents the most pessimistic appraisal of the possibilities of C. The set of corresponding equilibria is called the α-core of the game or economy. For any s we have $V_\alpha(C) \subset V_\beta(C)$ and so there is more of a chance for an α-core equilibrium to exist than for a β-core equilibrium. For the α-core there is a general existence theorem:

Theorem (Scarf 1971): If S is convex, compact and every $u_i(s)$ is continuous and quasiconcave, then the α-core is non-empty.

The conditions of the above theorem are restrictive. Note that the quasiconcavity of u_i is required for the entire s and not only (as for Cournot–Nash equilibrium) for the vector s_i of own strategies. Nonetheless, it is a useful result. It tells us, for instance, that under the standard quasiconcavity hypothesis on utility functions, the α-core is non-empty in each of the three examples above. It will be instructive to verify why the initial endowment allocation is an equilibrium in example 3. In contrast to the β-core situation, a coalition of two members cannot now improve over the initial endowments because they have to move first and therefore cannot know who of the two will receive the outside member's garbage and will need, as a consequence, some extra amount of money.

If, as in examples 1 and 2, there are no bads, the distinction between V_α and V_β disappears. There is a unique way for the members of C' to hurt C, namely withholding its own resources. So in both the α and β senses the set $V(C)$ represents the utility combinations that can be attained by the members of C using only its own resources. This, incidentally, shows that the β-core is non-empty in examples 1 and 2 (since it is equal to the α-core!). There is another approach to existence in the no-bads case. Indeed, a Walrasian equilibrium (in the case of example 2 this takes the guise of a Lindahl equilibrium) is always in this core with no

need of α or β qualification. In the context of example 1, the Core was first defined and exploited by Edgeworth (1881) (*see* "▶ Cores").

Underlying both the α- and the β-core there is a quite pessimistic appraisal on what C' may do if C deviates. The next two remarks discuss, very informally, other, less extreme, possibilities.

(D) In the context of exchange economies (such as example 1) it seems sensible to suppose that a coalition of buyers and sellers in one market may neglect retaliation possibilities in unrelated markets. As it stands in subsections "The Bargaining Set" and "Coalition-Proof Cournot–Nash Equilibrium", it is very difficult for a group of traders to improve, since, so to speak, they have to set up a separate economy covering all markets. See Mas-Colell (1982) for further discussion of this point.

(E) For transferable utility situations (and for purposes more related to the valuation theory to be discussed in section "The Valuation Approach"), Harsanyi (1959), taking inspiration in Nash (1953), proposed that the total utility of the coalition C be defined as $\sum_{i \in C} u_i(\bar{s}_C, \bar{s}_C)$ where $(\bar{s}_C, \bar{s}_{C'})$ are the minimax strategies of the zero sum game between C and C' obtained by letting the payoff of C be $\sum_{i \in C} u_i(s_C, s_{C'}) - \sum_{i \in C'} u_i(s_C, s_{C'})$. Note: if the minimax strategies are not unique, a further qualification is required.

Consistency Qualifications

In this section, several solution concepts are reviewed. Loosely, their common theme is that coalitions look beyond the one-step deviation possibilities.

The Von Neumann–Morgenstern Stable Set Solutions

Suppose that the game is described to us by the sets $V(C)$ that the members of coalitions of C can make effective for themselves. These sets do not depend on any reference combination of strategies. They are constructed from the underlying situation in some of the ways described in section "The Dominance Approach". One says that the N-tuple of utilities $u \in V(N)$ dominates the N-tuple $v \in V(N)$ via coalition C, denoted $u \succ C^{\upsilon}$ if $u_c \in V$. We write $u \succ \upsilon$ if $\bar{u}$ dominates $\bar{v}$ via some coalition. A *core utility computation* is then any maximal element of $\succ$, i.e. any $u \in V(N)$ which is not dominated by any other imputation.

The following paradoxical situation may easily arise. An imputation u is not in the core. Nonetheless, all the members of any coalition that dominates u are treated, at any core imputation, worse than at u (consider for example, the predicament of a Bertrand duopolist at the joint monopoly outcome). If $\succ$ was transitive, then this could not happen, since (continuity complications aside) for any u there would be a core imputation directly dominating u. But $\succ$ is very far from transitive. The approach of von Neumann and Morgenstern consists in focusing on *sets* of imputations K, called *stable sets*, having the properties: (i) if $\upsilon \in K$ then there is no $\upsilon \in K$ that dominates u (internal stability) and (ii) if $u \in K$ then $\upsilon \succ u$ for some $\upsilon \in u$ (external stability). Note that these are the properties that the set of maximal elements of $\succ$ would have if $\succ$ was transitive. The interpretation of K is as a standard of behaviour. If for any reason the imputations of K are regarded as acceptable, then there is an inner consistency to this: drop all the imputations dominated by an acceptable imputation and what you have left is precisely the set of acceptable imputations.

Important as the von Neumann–Morgenstern solution is, its impact in economics has been limited. There is an existence problem, but the main difficulty is that the sets are very hard to analyse.

The Bargaining Set

This solution was proposed by Aumann and Maschler (1964) and is available in several versions. Describing one of them will give the flavour of what is involved. For an imputation u to be disqualified, it will be necessary, but not sufficient, that it be dominated (in the terminology of bargaining set theory: objected to) via some coalition C*. The objection will not 'stick', i.e. throw u out of the negotiation table as a tentative equilibrium, unless it is found justified. The

justifiability criterion is the following: there is no other coalition C^* having a $v_c^* \in K(C^*)$ with the property that $v_i \geqslant u_i$ for every i and which gives to every common member of C and C^* at least as much as they get at the objection. In other words, an objection can be countered if one of the members left out of the objecting coalition can protect themselves in a credible manner (credible in the sense that they can give to any member of C they need, as much as C gives them).

The bargaining set contains the core and, while it is conceptually quite different from a von Neumann–Morgenstern stable set solution, it still does avoid the most myopic features of the core. It is also much easier to analyse than the stable sets, although it is by no means a straightforward tool. But, again, its impact in economics has so far been limited.

A common aspect of stable set and bargaining set theory is that, implicitly or explicitly, a deviating coalition takes into consideration a subsequent, induced move by other coalitions. This is still true for the next two concepts, with one crucial qualification: a deviating coalition only takes into account subsequent moves of its own subcoalitions.

Coalition-Proof Cournot–Nash Equilibrium

This solution concept has been proposed recently by Bernheim et al. (1987). It can be viewed as a self-consistent enlargement of the set of strong Cournot–Nash equilibria. Consider the simplest case, a three-player game. Given a strategy profile $\bar{s}$, which deviations are possible for two players coalitions? If anything, then we are led to strong Cournot–Nash equilibria. But, there is something inconsistent about this. If the strategy profile $\bar{s}$ is not immune to deviations (i.e. there is no commitment at $\bar{s}$), why should the deviation be so? That is, why should it be possible to commit to a deviation? This suggests that the deviation should be required to be immune to further deviations, that is, they should be Cournot–Nash equilibria of the induced two person game (the third player remains put at $\bar{s}$). Obviously, deviating becomes more difficult and the equilibrium set has more of a chance of being non-empty. Unfortunately, there is no general existence theorem. For three-person games, this is precisely the Coalition-Proof Cournot–Nash equilibrium. By recursion, one obtains a definition for any number of players.

The Core

It may be surprising to list the core in a section on concepts that attempts to be less myopic than the core. But, in fact, the core as a set can be made consistent against further deviations by *subcoalitions* of the deviating coalition. Simply make sure always to deviate via coalitions of smallest possible cardinality.

The Valuation Approach

The aim of the valuation approach to games and conflict situations (of which the Shapley value is the central concept) is to associate to every game a reasonable outcome taking into account and compromising among all the conflicting claims. In games, those are expressed by sets $V(C)$ of utility vectors for which C is effective. The criteria of reasonableness are expressed axiomatically. Thus the valuation approach has to be thought of more as input for an arbitrator than as a descriptive theory of equilibrium. Except perhaps for the bargaining set, this point of view is strikingly different to anything discussed so far.

Sometimes the term ‘fair’ is used in connection with the valuation approach. There are at least two reasons to avoid this usage. The first is that the initial position [embodied in the sets $V(C)$] is taken as given. The second is that the fairness of a solution to a game can hardly be judged in isolation, i.e. independently of the position of the players in the overall socioeconomic game.

The valuation of a game will depend on the claims, i.e. on how the sets $V(C)$ are constructed. We saw in section “The Dominance Approach” that there was nothing straightforward about this. We will not repeat it here. It may be worthwhile to observe informally, however, that the valuation approach is altogether less strategic than the dominance one and that a useful way to think of $V(C)$ is as the utility levels the members of C could get if the members of C' did not exist, rather than as what the members of C could get if they go it

alone [in defining $V(C)$ this point of view can make a difference].

Consider first games with transferable utilities (N,υ) where N is a set of players and $\upsilon:2^N \to R$ is a real valued function satisfying $\upsilon(\varphi) = 0$. The restriction of υ to a $C \in N$ is denoted (C, υ). The *Shapley value* is a certain rule that associates to every game (N,v) an imputation $Sh(N,v)$, i.e. $\sum_{i \in N} Sh^i(N,\upsilon) = \upsilon(N)$.

The *Shapley value* was characterized by Shapley (1953) by four axioms that can be informally described as: (i) efficiency, i.e. $Sh(N,v)$ is an imputation, (ii) symmetry, i.e. the particular names of the players do not matter, (iii) linearity over games and (iv) dummy, i.e. a player that contributes nothing to any coalition receives nothing.

There is a simply way to compute the Shapley value. Put $P(\varphi,v) = 0$ and, recursively, associate to every game (N,v) a number $P(N,v)$ such that

$$\sum_{i \in N} [P(N,\upsilon) - P(N/(i),\upsilon)] = \upsilon(N) \qquad (1)$$

That is, the sum of marginal increments of P equals $\upsilon(N)$. This function is called the *potential* and it turns out that the marginal increments of P constitute precisely the Shapley valuations, i.e. $Sh^i(N, \upsilon) - P[N/(i), \upsilon]$ for all (N, υ) and $i \in N$. This is discussed in Hart and Mas-Colell (1985).

The Shapley value for transferable utility games admits several generalizations to the non-transferable utility case [with convex sets $V(C)$]. See Harsanyi (1959), Shapley (1969), and Aumann (1985). Perhaps the most natural, although not necessarily the simpler to work with, was proposed by Harsanyi (1959) and has recently been axiomatized by Hart (1985). For a given game, an Harsanyi value imputation is obtained by rescaling individual utilities so as to guarantee the existence of an N-tuple $u \in V(N)$ satisfying, simultaneously, (i) the convex set $V(N)$ is supported at u by a hyperplane with normal $q = (1,\ldots,1)$, (ii) if a potential P on the set of all games is defined by formula (1) (but replacing '$=v(N)$' by '$\in$ *Bdry.* $V(N)$') then, as before, $u_i = P(N/(i), V)$ for all $i \in N$.

One of the most striking features of the applications of Shapley value theory to economics is that, in economies with many traders, it has turned out to be intimately related to the notion of Walrasian equilibrium. Interestingly, this is in common with the dominance approach. Aumann (1975) is a representative paper of the very extensive literature on the topic.

Cooperative Games

Martin Shubik

The title 'cooperative games' would be better termed games in coalitional form. The theory of games originally developed different conceptual forms, together with their associated solution concepts, namely, games in extensive form, in strategic form, and in coalitional form (von Neumann and Morgenstern 1944). The game in strategic form is sometimes referred to as the game in normal form, while that in coalitional form is also referred to as the game in characteristic form.

The game in extensive form provides a process account of the detail of individual moves and information structure; the tree structure often employed in its description enables the researcher to keep track of the full history of any play of the game. This is useful for the analysis of reasonably well-structured formal process models where the beginning, end and sequencing of moves is well-defined, but is generally not so useful to describe complex, loosely structured social interaction.

A simple example shows the connections among the three representations of a game.

Consider a game with two players where the rules prescribe that Player A moves first. He must decide between two moves. After he has selected a move, Player B is informed and in turn selects between two moves. After B has selected a move the game ends and depending upon the history of the game each player obtains a payoff. Figure 1a shows this game in extensive form. The vertex labelled 0 indicates the starting point of the game. It is also circled to indicate the information structure. Figure 2a shows a game whose only difference from the game in Fig. 1a is that in the latter Player B when called upon to select a move does not know to which of the choice points in his information set the game has progressed. In the game in Fig. 1a, when Player B makes his choice he knows precisely if Player A has selected move 1 or 2. Each vertex of the game is a choice point except the terminal vertices. Several vertices may be enclosed in the same information set. The player who 'owns' a particular information set is unable to distinguish among the choice points in a set. An arc (or branch of a tree) connecting a choice point with another choice point or a terminal point is a move. The moves emanating from any choice point are indexed so that they can be identified.

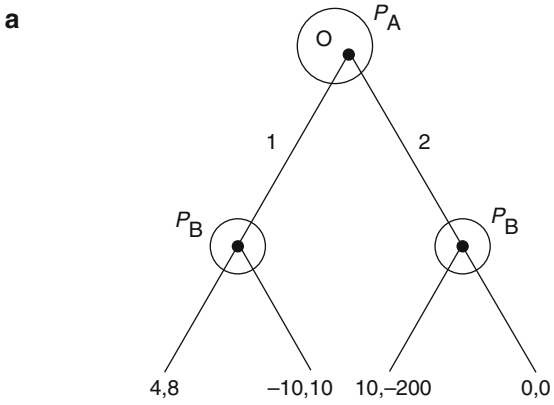
The final nodes at the bottom of the tree are not choice points but points of termination of the game and the numbers displayed indicate the value of the outcome to each player. The first number is the payoff to Player A and the second to Player B.

The extensive form may be reduced to the strategic form by means of strategies. A strategy is a plan covering all contingencies. Figure 1b shows that the moves and strategies for P_A are the same, choose 1 or 2. But P_B has four strategies as he can plan for the contingency that P_B selects 1 or 2. A sample strategy 1, 1; 2, 1 may be read as: 'If P_A selects 1, select 1; if P_A selects 2, select 1'.

The progression from extensive form to strategic form entails loss of fine structure. Details of information are no longer available. There are many extensive forms other than Fig. 1a which are consistent with Fig. 1b.

A further compression of the game representation beyond the strategic form may be called for. At the level of bargaining or diplomacy details of strategy may be of little importance. Instead emphasis is laid upon the value of cooperation. The cooperative or coalitional form represents the game in terms of the jointly optimal outcomes obtainable by every set of players. If payoffs are comparable and side-payments are

Cooperative Games, Fig. 1



b

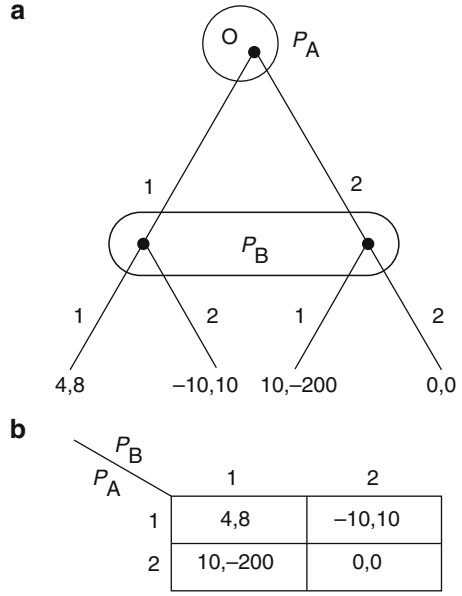
P_A / P_B	1,1;2,1	1,1;2,2	1,2;2,1	1,2;2,2
1	4,8	4,8	–10,10	–10,10
2	10,–200	0,0	10,–200	0,0

possible the gain from cooperation can be represented by a single number. If not then the optimal outcomes attainable by a set S of players will be a Pareto optimal surface in $s = |S|$ dimensions (where $|S|$ is the number of elements in S).

A game in cooperative form with side-payments can be represented by a characteristic function which is a superadditive set function. We use the symbol $\mathbf{\Gamma}(N, \upsilon)$ to stand for a game in coalitional form with a set N of players and a characteristic function v defined on all of the 2^n subsets of N (where $n = |N|$). The condition of superadditivity is a reasonable economic assumption in a transactions cost-free world. $\upsilon(S) + \upsilon(T) \leq \upsilon(S \cup T)$ where $S \cap T = \theta$ states that the amounts obtained by two independent coalitions S and T will be less than or at most equal to the amount that they could obtain by cooperating and acting together.

Returning to Figs. 1b and 2b we can reduce them to coalitional form by specifying how to calculate $\upsilon(\theta), \upsilon(\overline{1}), \upsilon(\overline{2})$ and $\upsilon(\overline{1,2})$. The notation '$\overline{1,2}$' reads as the set consisting of the players whose names are 1 and 2.

Let $\overline{S} = N - S$ be the complement to S. The worst that could happen to S is that $\overline{S}$ acts as a unit



b

2	10,–200	0,0

Cooperative Games, Fig. 2

to minimize the joint payoff to S. Applying this highly pessimistic view to the games in Figs. 1b and 2b letting $P_A = 1$ and $P_B = 2$ we obtain the following:

$\upsilon(\theta) = 0$, the coalition of no one obtains nothing, by convention.
$\upsilon(\overline{1}) = 0, \upsilon(\overline{2}) = 0$
$\upsilon(\overline{1,2}) = 12$

Although the extensive and strategic forms of these games differ, they coincide in this coalitional form. More detail has been lost. The coalitional form is symmetric but the underlying games do not appear to be symmetric. The pessimistic way of calculating $\upsilon(S)$ may easily overlook the possibility that it is highly costly for $\overline{S}$ to minimize the payoff to S. Thus it is possible that $\upsilon(S)$ does not reflect the threat structure in the underlying game. Prior to carrying out further game theoretic analysis on a game in characteristic function form the modeller must decide if the characteristic function is an adequate representation of the game. Harsanyi and Selten have suggested a way to evaluate threats (see Shubik 1982).

Applications

Depending upon the application, the extensive, strategic or coalitional forms may be the starting point for analysis. Thus in economic applications involving oligopoly theory one might go from economic data to the strategic form in order to study Cournot-type duopoly. Yet to study the relationship of the Edgeworth contract curve to the price system one can model the coalitional form directly from the economic data without being able even to describe an extensive or strategic form.

In any application, the description of the game in coalitional form is a major step in the specification of the problem. After the coalitional form has been specified a solution is applied to it. There are many solution concepts which have been suggested for games in coalitional form. Among the better known are the core, the value, the nucleolus, the kernel, the bargaining set and the stable set solutions. Only the core and value are noted here (for an exposition of the other see Shubik 1982).

The core of an n-person game in characteristic function form was originally investigated by Gillies and adopted by Shapley as a solution. The value was developed by Shapley (1951) and has been considered in several modifications to account for the presence or absence of threats and sidepayments.

We define $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_n)$ where $\alpha_i \geq 0$ for all $i \in N$ and $\Sigma_{i \in N} \alpha_i = \upsilon(N)$ to be an imputation for the game $\Gamma(N, \upsilon)$ It is an individually rational division of the proceeds from total cooperation. The core is the set of imputations such that $\Sigma_{i \in S} \alpha_i \geq \upsilon(S)$ for all $S \subset N$. It is, in some sense, the set of imputations impervious to countervailing power. No subset of players can effectively claim that they could obtain more by acting by themselves. The core may be empty. An exchange economy with the usual Arrow–Debreu assumptions modelled as a game in coalitional form always has a core, and the imputation (or imputations) selected by the competitive equilibria of an exchange economy are always in the core of the associated market game.

The Shapley value is intuitively the average of all marginal contributions that an individual i can make to all coalitions. He developed the explicit formula to calculate the value imputation for any game in coalitional form with sidepayments. It is

$$\phi_i = \sum_{i \in S} \sum_{S \subset N} \frac{(n-s)!(s-l)!}{n!} [\upsilon(S) - \upsilon(S/i)]$$

The term $\upsilon(S) - \upsilon(S/i)$ measures the marginal contribution of i to the coalition S. The remaining terms provide the count of all of the ways the various coalitions involving i can be built up. For exchange economies with many traders a relationship between the competitive equilibria and the value can be established (for further discussion, see Shubik 1984).

Many situations involving voting can be modelled as a game in coalitional form where the characteristic function takes only two values, 0 and 1. Such games are called simple games (Shapley 1962). Shapley and Shubik (1954) suggested the use of the value to provide a power index for committee voting. The basic observation is that the power of a player increases in a nonlinear manner as the number of votes he controls increases. The value applied to a simple game provides an index of this power.

Cooperative games provide a way to carry out an analysis of many problems of interest to the

social sciences without concern for the detail of the structure of process. Von Neumann and Morgenstern aptly noted that the difficulties to be encountered in the development of theories of dynamics in the social sciences were so large that the development of a primarily static theory of games in cooperative form was called for as a first step, bearing in mind that the eventual form of a theory of dynamics might have little resemblance to the statics. Some forty years after their seminal work much still remains to be done in the development of games in coalitional form.

Cooperatives

Ken Coates

It is a very good question to ask why the factory system substituted capitalist for workers' control over the production process. As Andrew Ure remarked,

> To devise and administer a successful code of factory discipline, suited to the necessities of factory diligence, was the Herculean enterprise, the notable achievement of Arkwright . . . it required, in fact, a man of a Napoleon nerve and ambition to subdue the refractory tempers of work-people, accustomed to irregular paroxisms of diligence . . . such was Arkwright (*The Philosophy of Manufactures*, 1835).

Obviously factory discipline was learned reluctantly, and with understandable resentment. Co-operative association did not emerge as a coherent alternative, however, until Robert Owen and his school began to advocate them in the 1820s. Before that date, some friendly societies experimented with cooperative forms of distribution, by bulk purchases of grain and other necessities. Otherwise, those disaffected by the rise of industrial production were more prone, at the beginning, to look to the ownership of land as the basis for communistic experiments. True, there was the pioneering work of the Quaker John Bellers, who proposed a 'college of industry' as early as 1695. But producer co-operatives did not begin to flourish until the 1830s, and even then they had a high failure rate. Industrial disputes, notably the Derby turnouts of 1834, were associated with an insurrectionary idea of co-operation: the Derby workers appealed for help from surrounding towns, not simply to feed those locked out for supporting the Owenite trade union, but also to purchase machinery, so that they could enter into production on their own accord, and begin to construct the co-operative commonwealth.

The defeat of Owenism led to a more gradualist concept of co-operation, although the birth in 1844 of the consumer co-operative movement was far from a devaluation of older communistic ideas. Opening their shop in Toad Lane, the 'Rochdale pioneers' reaffirmed their intentions of raising money in order to embark upon co-operative production. As their initiative spread, it became possible to create a wholesale department servicing several societies, and to open a cornmill and a tobacco factory. Consumer co-operation established the principle of democratic control by its membership, with every member having only one vote, irrespective of the size

of his or her capital investment. Profits were distributed in a dividend on purchases, after collective charges and interest payments had been met.

Because each co-operator votes only once, co-operation establishes a completely different principle of economic administration from that involved in the limited liability company. Retail co-operative societies in Britain frequently grew from the scale at which they could administer one local store to extended chains of shops covering an entire region. Each retail society would be governed by a management committee regularly elected by the membership. Consumer co-operation grew steadily, involving a million people by 1891, five million by 1926, and ten million by 1948. By the 1960s, consumer co-operatives reached a membership of over thirteen million.

With growth, however, there arose problems of involvement. In the original small ventures, all members would be directly involved not only in decision making but in a host of voluntary practical activities. As the movement grew, and recruited professional staff, so its internal democracy became greatly more attenuated. Rates of participation in management meetings declined, reaching very low levels by the middle of the 20th century. A commission under the chairmanship of Hugh Gaitskell and the secretaryship of Anthony Crosland, investigated the decline in co-operative membership involvement. They reported that 'only the few will ever wish to devote their evenings to voluntary public work. In the early days of the co-operative movement, when its total membership was numbered in thousands, almost the entire membership was drawn from among these few . . .. Today, when the movement, has twelve million members, the few have become a small minority . . . the figures of participation have fallen correspondingly.' The assumption of a fixed quota of activists only makes sense, however, on the basis of an assumption of fixed activities in which they might engage. Early co-operation involved a division of tasks among all members, and necessarily engendered high participation ratios. It was professionalization, not simply increase of scale, which changed this situation. As early as 1851, the Rochdale Society had resolved that 'No paid officer be a member of the Board, or a member of the Board a paid servant'. In other words, consumer co-operation in Britain had then established a professional civil service, which was constitutionally excluded from policy control, but increasingly expected to undertake executive management. This is an unreal separation of functions which inevitably eroded the effective powers of individual members. Indeed, when decline set in, apathy, if anything, increased. By 1984 members of co-operatives had declined to 8.5 million, but the 'fixed quota' of activists weighed, if anything, less than before, not more.

Things were quite different in the area of producer co-operation. This grew in labourintensive industries, after the middle of the 19th century, following a successful lobby by Christian Socialists for legislation which could enable them to function. Between 1862 and 1880, 163 producer associations were registered under the Industrial and Provident Societies Acts, of 1852 and subsequently, which had been brought in as a result of careful lobbying by Ludlow, Neale and others. The First International welcomed these new co-operatives, saying of the movement that 'Its great merit is to practically show that . . . the despotic system of the subordination of labour to capital can be superseded by the republican and benificient system of the association of free and equal producers.' A new upsurge in experiments in co-operative workshops followed later, with the labour unrest out of which grew the 'New Unionism' and the 1889 dock strike.

By 1890 Beatrice Webb (Potter) distinguished four classes of producer co-operatives: those modelled on Christian Socialist doctrine, which elected their management committees, and only employed full members; those consisting only of full members who had accepted management by a person (or group) that was (or were) irremovable; those self-governing co-ops which employed outside labour; and those in which outside shareholders supplied most of the capital, but in which workers were encouraged or obliged to take shares, even though they were excluded from the management committee.

While Beatrice Webb documented some exploitative practices in the last three of these

categories, she also pronounced strong judgement on those co-operatives which administered themselves according to strict principles. These, she thought, had a high failure rate, due to their propensity to eat their seed corn and thus fail to make adequate provision for investment. The Webbs' assumption became part of the conventional wisdom about workers' producer co-operatives until the 1970s, when Derek Jones undertook a careful study of the failure rate of producer co-operatives from 1875 onwards and showed that it was not greater than that of small businesses in general. By 1900 there were more than 100 producer co-operatives in Britain, the majority of which had joined forces in a body known as the Co-operative Productive Federation. This organization underwent slow decline, until it listed only 23 societies in the late 1960s. The largest of these, the Leicester Equity Boot and Shoe Manufacturers, employed 1600 people at its peak. Most societies were very much smaller, employing a few dozen.

Producer co-operation underwent a serious revival in the 1970s. Various organizations came into being to argue the case for industrial democracy. A growing discussion on workers' control resulted in the formation of the Institute for Workers' Control (IWC) in 1968, and the extension of debate throughout the organizations of the Labour movement. A specialist body, the Industrial Common Ownership Movement (ICOM) began to organize new co-operatives outside the framework of the Co-operative Productive Federation. This was originally based on initiatives by the Scott Bader Commonwealth, a self-managed chemical company. The industrial policy of the 1974 Labour Government was influenced by the arguments of these new pressure groups, and producer co-operation received major publicity when attempts were made to rescue three failed enterprises from closure by converting them to co-operative management with funding from the Department of Trade and Industry, of which the Secretary of State was then Tony Benn. The 'Benn' co-operatives, as these became known, at Kirkby Manufacturing and Engineering near Liverpool, Triumph–Meriden and the Scottish Daily News, stimulated widespread debate and attracted a number of would-be imitators. A series of 'work ins' and sit-ins, beginning with that at the Upper Clyde shipyards in 1971 had encouraged workers not to accept plant closure when their employers' businesses failed, and some experiments in co-operative production resulted from these struggles. A women's co-operative manufacturing leather goods arose at Fakenham after a factory occupation, and Leadgate Engineering, in the North, followed the same pattern. By 1975, when Imperial typewriters closed their two factories in Hull and Leicester, it had become 'normal' to accept factory occupations as a reflex response to such decisions. The workers in Hull sat in, emblazoning a banner outside the factory, announcing 'We stay in till Benn says when'. But before the typewriter co-operative could be established, Mr Benn was relegated from the Department of Industry to that of Energy, and under his successor no more co-operatives of this kind were to be formed. Soon afterwards, KME and the Scottish Daily News failed for lack of adequate capital. The KME project had been particularly difficult, because it inherited a bizarre product mix, which had itself contributed to the collapse of the original enterprise. The Scottish Daily News came to an end after a series of agreements and disagreements with Robert Maxwell, the publishing entrepreneur, who had been brought in by the workers to assist in the rescue.

But as a result of such colourful events and the persistent lobbying of the industrial democrats, the Labour Party had committed itself to support new co-operatives, and a Co-operative Development agency was established in 1978, with limited funds to promote new organizations. The new agency was not without some opponents in the established co-operative movement, but it was soon to receive a remarkable fillip from the work of Local Government Enterprise Boards, which were established with the onset of slump in the late 1970s in an effort to create employment in local communities. The result was a rapid and spectacular increase in the number of producer organizations. By 1985 there were 750 organizations with an average turnover of £199,000. New co-operatives were being formed all the time, so

that the number of new firms was growing at a rate of 20% per annum.

The recovery of impetus by industrial co-operation already raises important questions for the consumer co-operative movement, and could generate pressures for its reform. It also begins to make possible closer involvement with producer co-operatives in Europe, where they have maintained, in many countries, a consistent strength and vitality. There can be little doubt that, if the upsurge of new co-operative continues, this will bring about-important changes in the political field, as the Labour Movement digests their implications.

Coordination Problems and Communication

Jack Ochs

Abstract

Coordination problems arise when a game has multiple Nash equilibria and all players have a common interest in avoiding a non-equilibrium state. To achieve an equilibrium state, agents must come to understand one another's intentions. Communication can facilitate this understanding under some, but not all, circumstances. In the absence of communication among agents, coordination may also sometimes be achieved with the aid of extrinsic signals that have come to be associated with the actions of others. In some settings, past actions themselves serve as precedents, without the benefit of any communication.

Lewis (1969) defined a *coordination equilibrium* as a Nash equilibrium in which no agent would be better off if any other agent had chosen a different action. When there are multiple coordination equilibria, agents face an obvious coordination problem. The resolution of coordination problems

rests upon individuals coming to understand the intentions of one another. The most explicit way of developing this understanding is for the individuals to communicate with one another. Common knowledge of a language must precede communication. Even with common knowledge of a language, individuals may not be bound to do what they say they will do. In such circumstances, talk is 'cheap'.

When will the receiver, having received a message from a sender, behave differently from how the receiver would have behaved if no message had been sent? According to Farrell and Rabin (1996) *highly credible* messages will not be ignored. A message that signals an intention to take action X is highly credible if it satisfies two conditions: it is (*a*) *self-signalling* and (*b*) *self-committing*. A message that the sender is taking action X is self-signalling if, and only if, it is both true and it is in the sender's interest to have it believed to be true. A message is self-committing if a belief by the receiver that the message is true creates an incentive for the sender to do what the sender said he or she would do. A message that is self-committing, if believed, will lead to an outcome that is a Nash equilibrium. A message can be self-committing without being self-signalling. For example, in the classic game of Chicken, if one player announces that he will be Passive, that message is self-committing since, if it is believed by the receiver then the receiver's best response is to be Aggressive, and the best response of the sender to the receiver's aggression is to be Passive. However, the sender would prefer to have the receiver believe that the sender will play Aggression. So the message, 'I intend to play Passive', is not selfsignalling because it is not in the interest of the sender to have the receiver believe it is true.

A message is *cheap talk* if the sender is not bound to do what the message says. Crawford (1998) provides a survey of a number of cheap talk experiments. In experiments with structured communication, either only one player may send a message (one-sided communication) or more than one player can send a message. When the payoff functions of the players are symmetrical, one-sided communication breaks the symmetry of the game without communication. This is sufficient to allow a very high level of coordination. Indeed, in such games one-sided communication is much more effective in promoting coordination that is simultaneous, two-sided communication. This suggests that, when payoff functions are symmetric but players have different preference orderings over equilibria, as in the Battle of the Sexes, the principal impact of one-sided communication is to create an extensive form game in which the symmetry is broken by designating one player as the first mover. In games with Pareto-ordered equilibria communication is not needed to break symmetry, but may be effective in reducing uncertainty about the intentions or, in Crawford's terms, to give 'reassurance'. Empirically this 'reassurance' appears to be most effective in achieving coordination on the Pareto-dominant equilibrium when communication is two-sided, but even one-sided communication has a positive effect on the likelihood of achieving the Pareto-optimal outcome. Furthermore, this effect has been found to be greater when a message was self-signalling than when such a message was only self-committing.

When there are multiple players each player must be interested in, and possibly condition his actions on, the entire message profile. Therefore, the concepts of selfsignalling and self-committing messages may not have much meaning in this context. Nevertheless, there is some evidence that costless pre-play communication can help groups whose members repeatedly interact to achieve more efficient outcomes than is attainable without such communication (Blume and Ortmann 2007).

A signal that is commonly observed may be used to coordinate actions even if the signal does not emanate from any of the players. Traffic signals play this role. We do as these signals say we should do because we believe that others will also do what the signals say they should do. This belief is reinforced by experience, so doing as the signals suggest has simply become a convention that is adopted by drivers. While this convention is backed by law, there is good reason to believe that it is so ingrained in people's expectations that they would continue to act as the signals

suggest even in the absence of any law. Can signals be effective in coordinating actions when the signals are not sent by any of the players and do not themselves have any payoff consequences? Van Huyck et al. (1992) found that, when a game has multiple coordination equilibria, all of which yield the same payoff, a signal from an outside 'moderator' that specifically says 'play a particular equilibrium' produces a very high degree of coordination on the suggested equilibrium, even though absent any signal there is a high frequency of coordination failure. However, in games where the equilibria are Pareto ordered the introduction of a recommendation to play any equilibrium other than the payoff-dominant equilibrium significantly reduces the degree of coordination that is achieved. The authors also found that when there was an equilibrium that provided equal payoff a recommendation to play an equilibrium with unequal payoffs had little influence on how the game was played. Evidently some features, such as symmetry, may be sufficiently strong focal points that the introduction of extrinsic signals may have little influence. Similarly, some features of a game may make some coordination equilibria, once achieved by repeated interaction, exceedingly difficult to displace through the introduction of communication, even if everyone would gain by moving to another coordination equilibrium (Cooper 2006).

A 'sunspot' is a commonly observable event that may have been correlated in the past with different outcomes. For example, published forecasts may have this property. When agents coordinate their actions on a 'sunspot' the resulting equilibrium is called a 'sunspot equilibrium'. Marimon et al. (1993) devised an experiment to see whether they could generate a sunspot equilibrium where prices fluctuate with an extrinsic signal even though the fundamental parameter values remained fixed. During a 'training interval', the colour of a blinking light on a screen was perfectly correlated with a change in a parameter that induced changes in equilibrium prices. After this 'training period' the parameter value was fixed, but the signal continued to vary according to the same process. Prices continued to be volatile but there was little evidence that the variation in the sunspot variable had any effect on the observed price volatility. Duffy and Fisher (2005), using a quite different design, were able to induce sunspot equilibria under restricted conditions. They found that the semantics of the sunspot variable mattered. There were two fundamental equilibria in their design. One equilibrium had a high price, the other a low price. When the sunspot message was either 'high' or 'low' the outcomes of the actions were sometimes correlated with the message. But when the message was either 'sunshine' or 'rain' this correlation was never observed. Evidently, correlation of expectations with the signal depends upon how confident people are that everyone is interpreting the signal in the same way. They also found that information that is generated by observable actions subsequent to the observation of the signal itself tends to diminish the focal power of the signal.

Sometimes actions might 'speak' louder than words. In a Prisoners' Dilemma game the cooperative outcome is not a Nash equilibrium, but it does Pareto-dominate the Nash equilibrium. Since non-cooperation is a dominant strategy a message that one intends to play 'Cooperate' is neither self-committing nor self-signalling. Nevertheless, Duffy and Feltovich (2002) found that when this message was sent it tended to be truthful and also tended to induce a cooperative response. Similarly, when their past actions with other players were observable, subjects were more likely to cooperate than if neither communication nor observability was possible. Furthermore, observation increased the frequency of cooperative choices by more than cheap talk. This suggests that observability of past actions may sometimes be more effective than mere words in helping people achieve a good outcome.

Copland, Douglas Berry (1894–1971)

M. Harper

Copland was born at St Andrews, New Zealand, in 1894 and died at Kilmore, Australia, in 1971. Australia's most public applied economist from the 1920s to 1960, he pioneered opportunities for professional economists. He was the first occupant of positions such as Professor of Economics at the University of Tasmania (1920–24), Professor of Commerce at the University of Melbourne (1924–44), President of the Economic Society of Australia and New Zealand (1925), chief editor of the *Economic Record* (1924–45), Australian/New Zealand representative for the Social Sciences Division of the Rockefeller Foundation (1925–54), Vice-Chancellor of the Australian National University (1948–53), Principal, Australian Administrative Staff College (1956–60), and Chairman, Committee for the Economic Development of Australia (1960–66).

Copland was particularly interested in monetary and capital flows and their relation to prices, business cycles and economic development. Stressing Australia's world position as a small, dependent, primary-producing country, his policy advice was often controversial. In 1929 he contributed to the Australian case for tariff protection. During the 1930s depression, he advocated the 'middle way' towards recovery – a policy-mix of deflationary cost, wage and fiscal measures, with reflationary exchange depreciation, expansionary monetary policy and tariff protection. In the 1950s he recommended that Australia avoid restrictions of the sterling area by pursuing a policy of rapid development based on dollar borrowings.

Copland's experiences as economic adviser to governments, Commonwealth Prices Commissioner (1939–45), Australian Minister to China (1946–8) and President of the Economic and Social Council of the United Nations (1955) while High Commissioner to Canada, led to publications on the parameters and mechanisms of economic control, especially within group frameworks – the Australian Commonwealth, the British Commonwealth and international organizations.

Copulas

Pravin K. Trivedi

Abstract

Copulas are functional forms that parameterize the joint distribution of random variables based on their stated marginal distributions and a dependence parameter. The approach is based on Sklar's theorem. Copulas provide a general method for modelling dependence between random variables that may exhibit asymmetric dependence, which is often inadequately captured by measures of linear dependence. Copulas are often generated by using mixtures and convex sums. Although a bivariate distribution is the most commonly encountered specification, higher dimensional joint distributions can also be generated.

Clayton copula; Copulas; Cumulative distribution functions; GARCH effects; Gaussian copula; Gumbel copula; Marginal distributions; Selection models; Sklar, A.; Sklar's theorem; Tail dependence

JEL Classifications

C1; C51

Sklar introduced copulas in 1959 (Sklar 1973, 1996). Concisely stated, copulas are functions that connect multivariate distributions to their one-dimensional margins. If F is an m-dimensional continuous cumulative distribution function (CDF) with one-dimensional margins $F_1, \ldots, F_m$, then there exists an m-dimensional unique copula C such that $F(x_1, \ldots, x_m) = C(F_1(x_1), \ldots, F_m(x_m))$. In general, marginal distributions alone cannot determine the joint distributions.

Copulas are useful because, first, they represent a method for deriving joint distributions given the fixed marginals, even when marginals belong to different parametric families of distributions; second, in a bivariate context copulas can be used to define nonparametric measures of dependence for pairs of random variables that can capture asymmetric (tail) dependence as well as correlation or linear association.

Copulas and Dependence

We begin with Sklar's theorem. An m-copula is an m-dimensional CDF whose support is contained in $[0,1]^m$ and whose one-dimensional margins are uniform on [0,1]. In other words, an m-copula is an m-dimensional distribution function with all m univariate margins being $U(0,1)$. To see the relationship between distribution functions and copulas, consider a continuous m-variate distribution function $F(y_1, \ldots y_m)$ with univariate marginal distributions $F_1(y_1), \ldots, F_m(y_m)$ and inverse probability transforms (quantile functions) $F_1^{-1}, \ldots, F_m^{-1}$. Then $y_1 = F_1^{-1}(u_1) \sim F_1, \ldots, y_m = F_m^{-1}(u_m) \sim F_m$ where $u_1, \ldots, u_m$ are uniformly distributed variates. Copulas are expressed in terms of marginal CDFs. The transforms of uniform variates are distributed as $F_i (i = 1, \ldots, m)$. Hence

$$F(y_1, \ldots, y_m) = F\left(F_1^{-1}(u_1), \ldots, F_m^{-1}(u_m)\right) = C(u_1, \ldots, u_m), \quad (1)$$

is the unique copula associated with the distribution function. The copula parameterizes a multivariate distribution in terms of its marginals. For an m-variate distribution F, the copula satisfies

$$F(y_1,\ldots,y_m) = C(F_1(y_1),\ldots,F_m(y_m);\theta), \quad (2)$$

where θ is usually a scalar-valued dependence parameter. For many empirical applications, the dependence parameter is the main focus of estimation. Because the marginal distributions may come from different families, copulas are a 'recipe' for generating joint distributions by combining given marginal distributions using a known copula. This construction allows researchers to consider marginal distributions and dependence as two separate, but related, issues.

The functional form of a copula places restrictions on the dependence structure; for example, it may support only positive dependence. Therefore, a pivotal modelling problem is to choose a copula that adequately captures dependence structures of the data without sacrificing attractive properties of the marginals. Copulas are multivariate distribution functions, hence Fre: chet bounds apply. A copula may impose restrictions such that the full coverage between the bounds is not attained.

An important advantage of copulas is that they generate more general measures of dependence than the correlation coefficient. Correlation is a symmetric measure of linear dependence, bounded between + 1 and −1 and invariant with respect to only linear transformations of the variables. By contrast, copulas have an attractive invariance property: the dependence captured by a copula is invariant with respect to increasing and continuous transformations of the marginal distributions. The same copula may be used for, say, the joint distribution of (Y_1, Y_2) as ($ln\ Y_1$,$ln\ Y_2$).

Measures of dependence based on concordance, such as Spearmans's rank correlation (ρ) and Kendall's τ, overcome limitations of the correlation coefficient. In some cases the concordance between extreme (tail) values of random variables is of interest. For example, one may be interested in the probability of the event that stock indexes in two countries exceed (or fall below) given levels. This requires a dependence measure for upper and lower tails of the distribution, rather than a linear correlation measure. Measures of lower and upper tail dependence can be readily derived for a stated copula. The copula dependence parameter θ can be converted to measures of concordance such as Spearman's ρ and Kendall's τ (Nelsen 1999).

C

Examples

Nelsen (1999) and Joe (1997) catalogue many functional forms for copulas. Particularly important is the Archimedean class. Bivariate Archimedean copulas take the general symmetric form

$$C(u_1,u_2;\theta) = \phi^{-1}(\phi(u_1)+\phi(u_2)), \quad (3)$$

where the generator function $\phi(\cdot)$ is a convex decreasing function; for example, $\phi(t) = -\ln(t)$. The dependence parameter θ in imbedded in the functional form of the generator.

The *Clayton copula*, a member of the Archimedean class, takes the form

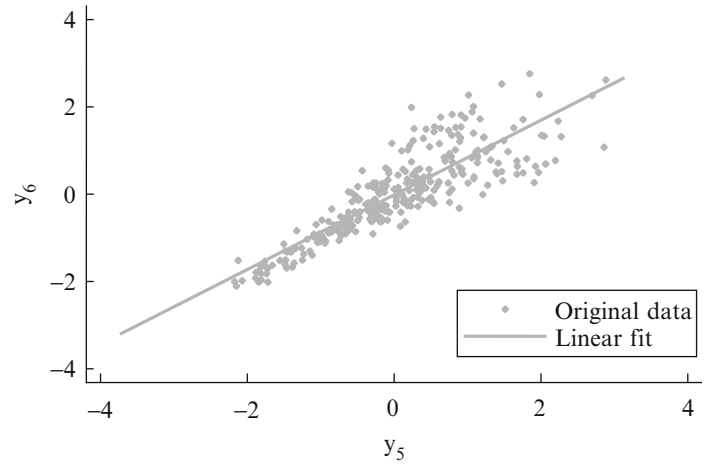
$$C(u_1,u_2;\theta) = \left(u_1^{-\theta}+u_2^{-\theta}-1\right)^{-1/\theta} \quad (4)$$

with the dependence parameter θ restricted on the region $(0,\infty)$. As θ approaches zero, the marginals become independent. The Clayton copula cannot account for negative dependence. It has been used to study correlated risks because it exhibits strong left tail dependence and relatively weak right tail dependence.

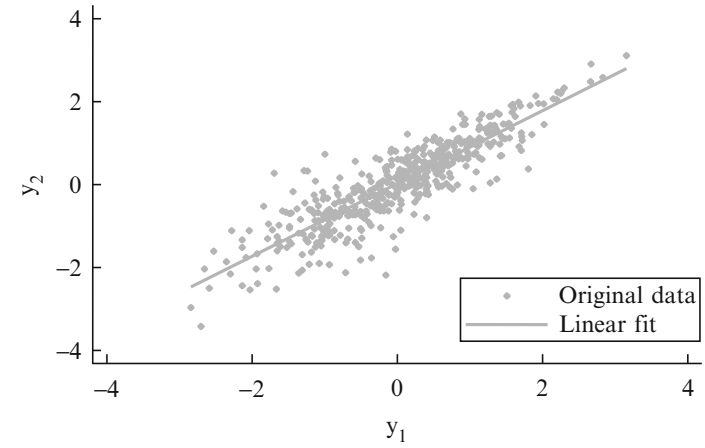
The *Gumbel copula* is another member of the Archimedean class and takes the form

$$C(u_1,u_2;\theta) = \exp\left(-\left(\tilde{u}_1^{\theta}+\tilde{u}_2^{\theta}\right)^{1/\theta}\right) \quad (5)$$

where $\tilde{u}_j = -\log u_j$. The dependence parameter is restricted to the interval $[1,\infty)$. Like the Clayton copula, Gumbel does not allow negative dependence, but in contrast it exhibits strong right tail dependence and relatively weak left tail dependence. If outcomes are strongly correlated at high values but less correlated at low values, then the Gumbel copula is an appropriate choice.



Copulas, Fig. 1 Sample from Clayton copula, theta = 4.67



Copulas, Fig. 2 Sample from Gumbel copula, theta = 3.3

The (non-Archimedean) *Gaussian copula* takes the form

$$C(u_1, u_2; \theta) = \Phi_G\left(\Phi^{-1}(u_1), \Phi^{-1}(u_2); \theta\right), \quad (6)$$

where Φ is the CDF of the standard normal distribution, and $\Phi_G(u_1, u_2)$ is the standard bivariate normal distribution with correlation parameter θ restricted to the interval $(-1, 1)$. This copula allows equal degrees of positive and negative dependence.

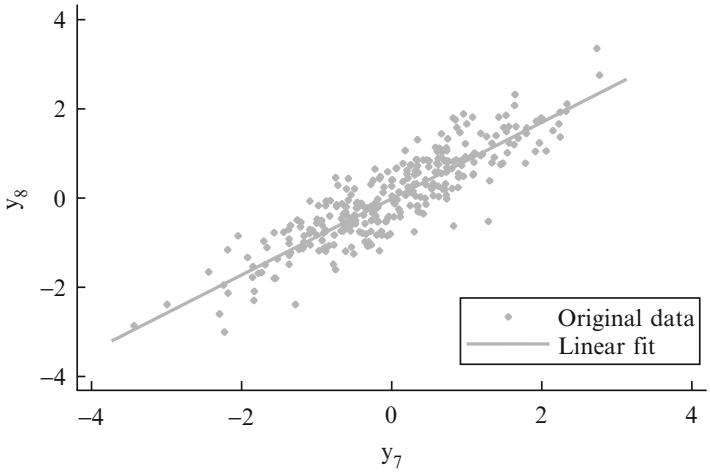
Figures 1, 2, and 3 illustrate lower and upper tail dependence using three samples generated using Monte Carlo draws from the above three copulas. The samples have comparable degrees of linear dependence but different tail dependence properties.

Estimation and Applications

In some applications it would natural to parameterize the marginals in terms of a regression function with covariates z, that is, $u_j = F(y_j|z_j; \beta_j)$, where z_j is a vector of covariates. Then the bivariate copula takes the form $C(y_1, y_2|\, z_1, z_2, \beta_1, \beta_2, \theta) = C(F(y_1|\, z_1, \beta_1), F(y_2|\, z_2, \beta_2), \theta)$. The copula density, defined as

$$\frac{d}{dy_2 dy_1} C(F_1(\cdot), F_2(\cdot); \theta) = C_{12}(F_1(\cdot), F_2(\cdot), f_1(\cdot) f_2(\cdot), \quad (7)$$

$f_j(\cdot) = \partial F_j(\cdot)/\partial y_j$, can be used to build the likelihood, which can be maximized simultaneously



Copulas, Fig. 3 Sample from Gaussian copula, theta = .89

with respect to all unknown parameters. Alternatively, the marginal densities can be estimated first, either parametrically or nonparametrically, and then the likelihood can be maximized with respect to θ only at the second stage.

Multivariate models of survival data pioneered the application of copulas. Econometric applications are more recent, but growing rapidly. There are numerous time series and financial market applications of copulas (Cherubini et al. 2004). Few models in this literature include regressors. Other areas of applications include volatility and exchange rate modelling where GARCH effects and tail dependence are expected (Patton 2006). Selection models provide leading examples of microeconometric applications of copulas (Smith 2003; Zimmer and Trivedi 2006).

Core Convergence

Robert M. Anderson

Abstract

The core of an economy is the set of all economic outcomes that cannot be 'blocked' by any group of individuals; it is an institution-free concept. A Walrasian equilibrium is an economic outcome based on the institution of market-clearing via prices: each individual consumes his or her demand, taking prices as given, and the demand for each good equals the

supply of that good. Core convergence asserts that, for sufficiently large economies, every core allocation approximately satisfies the definition of Walrasian equilibrium; it is an important test of the price-taking assumption inherent in the definition of Walrasian equilibrium.

JEL Classification

C7; D5

The core of an economy, first defined by Edgeworth (1881), is the set of all economic outcomes such that no group of individuals ('coalition') can make each of its members better off ('improve on' or 'block' the outcome), using only the resources available to the group. (A common mistake is to ask, in reference to a particular core allocation, 'what coalition(s) have formed?' An allocation is in the core precisely when no coalition can improve on it, and a core allocation does not identify an associated coalition or coalitions. It is when an allocation is *not* in the core that one can identify one or more coalitions that are associated with it, because they can improve on it and thus demonstrate that the coalition is not in the core.)

The most important reason for studying the core is the light it sheds on Walrasian equilibrium, introduced by Walras (1874). While the notion of Walrasian equilibrium is based entirely on the institution of trading via prices, and assumes that individuals take prices as given, the definition of the core is completely institution-free; this is one of its major virtues.

The core has both normative and positive significance apart from its relationship to Walrasian equilibrium. Normatively, if one accepts the distribution of the economy's initial resources as equitable, then any allocation outside the core is unfair to at least one coalition. Regardless of whether the distribution of initial resources is equitable, it would be surprising to find the economy settling on an allocation outside the core, since that would indicate there is a coalition which *could* have made each of its members better off, using only its own resources, but for some reason has failed to coalesce and do so; this is the positive significance.

While there has been much work on the cores of production economies, the bulk of the work on the core has been carried out in exchange economies, in which trading and consuming are the only economic activities. In part, this is because there are a number of competing definitions of the core in production economies, based on how the ownership of the production technology is assigned to individuals and groups. For simplicity, we shall focus our attention on exchange economies.

Walrasian equilibrium is an economic equilibrium notion based on market clearing, mediated by prices. Consumers choose the consumption vector which maximizes utility over their budget sets; firms choose production plans which maximize profit. Critically, it is assumed that individuals and firms take prices as given, without taking into account any ability they may have to influence those prices through their actions. A price vector is a Walrasian equilibrium price if the choices made by individuals and firms, taking prices as given, are consistent in the sense that market supply equals market demand. A Walrasian allocation is the vector of individual consumptions and firm productions generated by a Walrasian equilibrium price. A Walrasian equilibrium is a pair consisting of a Walrasian equilibrium price and its associated Walrasian allocation.

An income transfer is a vector which assigns to each agent a real number, and which satisfies budget balance: the sum of the numbers is zero. An allocation is a Walrasian equilibrium with transfers if there is an income transfer and a price vector such that the demand of each agent, given the prices and the budget of the agent, taking into account the agent's endowment of goods and income transfers, just equals the individual's consumption at the allocation.

The First and Second Welfare Theorems are two of the most important results concerning Walrasian

equilibrium. Recall that, in an exchange economy, an allocation is Pareto optimal if there is no reallocation of consumption which makes every agent better off. In other words, the coalition consisting of all agents (coalition of the whole) cannot improve upon the allocation. Thus, it is clear that every core allocation is Pareto optimal.

The First Welfare Theorem asserts that every Walrasian allocation with transfers is Pareto optimal. A slight modification of the proof suffices to show that every Walrasian allocation lies in the core. (Note that it is *not* true that every Walrasian allocation with transfers lies in the core. The income transfers allow us to move consumption among agents. For example, consider the allocation which gives the entire social consumption to a single agent. If we choose a price vector which supports that agent's preference at the social consumption, then there is an income transfer that makes this allocation a Walrasian allocation with transfers. But this allocation will rarely lie in the core, since the coalition consisting of all the other agents will generally be able to improve on it.) This is an important strengthening of the First Welfare Theorem, which has both positive and normative significance. On the positive side, it is a strong stability property of Walrasian equilibrium, since it asserts that no group of individuals would choose to upset the equilibrium by recontracting among themselves, making it more plausible that we will see Walrasian equilibrium arise in real economies. On the normative side, if we accept the distribution of initial endowments as equitable, it tells us that Walrasian allocations are fair to all groups in the economy.

The Second Welfare Theorem asserts that, in an exchange economy with standard assumptions on preferences (convexity is the crucial assumption), every Pareto optimal allocation is a Walrasian equilibrium with transfers. Note that while the definition of Pareto optimality makes no mention of prices, the Second Welfare Theorem asserts that every Pareto optimal allocation is closely associated to a price vector. The price vector appears magically; mathematically, this is a consequence of the separating hyperplane theorem, for which convexity is a critical assumption. As noted above, the most important use of the core is as a test of the price-taking assumption inherent in the definition of Walrasian equilibrium; a number of other tests have been proposed, but *core convergence* is the most commonly used. Core convergence is closely analogous to the conclusion of the Second Welfare Theorem. The definition of the core makes no mention of prices. However, if an exchange economy is sufficiently large, it is a remarkable fact that every core allocation is closely associated with a price vector that 'approximately decentralizes' it; in other words, every core allocation approximately satisfies the definition of Walrasian equilibrium, *without transfers*. This is an important strengthening of the Second Welfare Theorem. The notion of approximate decentralization depends to a considerable extent on the assumptions one is willing to make on the preferences and endowments of the individuals in the economy. (One version states that core allocations can be realized as *exact* Walrasian equilibrium with *small* income transfers.)

Core convergence has a number of implications, both normative and positive. The extent to which each of these implications is justified in a particular setting depends a great deal on the form of convergence, and thus on the assumptions one is willing to make on the economy. For an extensive survey focusing on the relationship between assumptions and the form of convergence, see Anderson (1992).

On the normative side, core convergence is a strong 'unbiasedness' property of Walrasian equilibrium, since it asserts that restricting attention to Walrasian allocations does not narrow the set of outcomes much beyond the narrowing that occurs in the core. Thus, Walrasian equilibrium has no hidden implications for the welfare of different groups, beyond whatever equity concerns one might have over the initial endowments. If one accepts the distribution of initial endowments as equitable, then any allocation that is far from Walrasian will not be in the core, and hence will treat some group of agents unfairly. On the positive side, if one accepts the core as a positive description of the allocations one is likely to see in practice in any economy, then core convergence tells us that the allocations we see will be nearly Walrasian.

However, the greatest significance of core convergence is as a test of the reasonableness of the price-taking assumption that is hidden in plain sight in the definition of Walrasian equilibrium. In real markets, we see prices used to equate supply and demand, but this does not guarantee Walrasian outcomes. Agents possessing market power may choose to demand quantities different from their price-taking demands at the prevailing price, thereby altering that price and leading to a non-Walrasian outcome. If the outcome is not at least approximately Walrasian, then the welfare theorems and the results on existence and generic determinacy of Walrasian allocations would have limited implications for real economies.

Core convergence and non-convergence allows us to identify situations in which price-taking is more or less reasonable. Core convergence implies that all trade takes place at almost a single price. An agent who tries to bargain cannot influence the prices much, so there is little incentive to be anything other than a price-taker. On the other hand, core non-convergence makes price-taking an implausible assumption.

Edgeworth (1881) doubted the positive significance of Walrasian equilibrium, and argued that the core, not the set of Walrasian equilibria, was the best positive description of the outcomes of a market mechanism. Moreover, while Edgeworth's name is closely associated with core convergence, and he did prove a core convergence theorem, he argued that in real economies, the presence of firms and syndicates which possess market power ensures that the core does *not* converge.

Edgeworth's argument about the effects of market power applies most strongly to the production side of the economy, where we do in fact see large firms, syndicates and labour unions. However, on the consumption side, the wealthiest individual in the world consumes a small part of the world's annual consumption. In exchange economies in which each consumer is small, core convergence holds. So core convergence provides a justification for the price-taking assumption on the consumption side, provided one views the world as an exchange economy in which the production decisions have been previously made by some exogenous process, outside the scope of the model, endowments include the income obtained by selling one's labour in the exogenous production process, and the only economic activity is trade and consumption of what has been produced.

The proof of the most basic core convergence theorem, which assumes very little about preferences and endowments, and establishes approximate decentralization in a relatively weak sense, is closely analogous to the proof of the Second Welfare Theorem. The approximately decentralizing price vector appears magically, as a consequence of the separating hyperplane theorem and the Shapley–Folkman theorem, which asserts that the sum of a large number of sets is approximately convex. Convexity of preferences plays no role. Indeed, the definition of the core, because it allows for individuals to be included or excluded from potential coalitions, introduces a non-convexity which is not present in the Second Welfare Theorem, and the Shapley–Folkman theorem controls that non-convexity, whether or not preferences themselves are convex.

The definitions and results just described verbally are presented more formally below.

Many people have made important contributions to the study of core convergence. A survey of these contributions is given in Anderson (1992), and a list of some of the more important contributions is included in the bibliography.

Now, We Turn to a More Formal Presentation

Definition 1 In an exchange economy with agents $i = 1, \ldots, I$ having strict preferences $\succ i$ and endowments $\omega_i \in \mathbf{R}^L_+$, a *coalition* is a set $S \subseteq \{1, \ldots, I\}$. An *exact allocation* is $x \in \left(\mathbf{R}^L_+\right)^I$ such that $\sum_{i=1}^I x_i = \sum_{i=1}^I \omega_i$. An exact allocation is *weakly Pareto optimal* if there is no other exact allocation x' satisfying $x'_i \succ {}_i x_i (i = 1, \ldots, I)$. A coalition S *blocks* or *improves on* an exact allocation x by x' if $\sum_{i \in S} x'_i = \sum_{i \in S} \omega_i$ and $\forall_{i \in S}\ x'_i \succ {}_i x_i$. The *core* is the set of all exact allocations which cannot be improved

on by any nonempty coalition. The *price simplex* is $\Delta = \left\{p \in \mathbf{R}_+^k : \sum_{\ell=1}^{L} p_\ell = 1\right\}$.

Theorem 2 *In an exchange economy, every core allocation is weakly Pareto optimal.*

Proof If x is not weakly Pareto optimal, then there exists x' such that $\sum_{i=1}^{I} x_i' = \sum_{i=1}^{I} x_i$, $x_i' \succ_i x_i$. Then $S = \{1, \ldots, I\}$ improves on x by x', so x is not in the core.

Theorem 3 (Strong First Welfare Theorem) *In an exchange economy, every Walrasian Equilibrium lies in the core.*

Proof Suppose (p^*, x^*) is a Walrasian Equilibrium. If x^* is not in the core, there exists $S \subseteq I$, $S \neq \varnothing$ and $x_i'(i \in S)$ such that $\sum_{i \in S} x_i' = \sum_{i \in S} \omega_i$ and $x_i' \succ_i x_i^*$ for each $i \in S$. Since x_i^* lies in i's demand set at the price p^*, $p^* \cdot x_i > p^* \omega_i$, so $p^* \cdot \sum_{i \in S} x_i' = \sum_{i \in S} p^* \cdot x_i > \sum_{i \in S} p^* \cdot \omega_i = p^* \cdot \sum_{i \in S} \omega_i$ but $\sum_{i \in S} \omega_i$, a contradiction. Therefore, x^* is in the core.♦

Theorem 4 (Core convergence, E. Dierker 1975, and Anderson 1978) Suppose we are given an exchange economy with L commodities, I agents and preferences $\succ_1, \ldots, \succ_I$ satisfying weak monotonicity (if $x \gg y$, then $x \succ_i y$) and the following free disposal condition: $x \gg y, y \succ_i z \Rightarrow x \succ_i z$. If x is in the core, then there exists $p \in \Delta$ such that

$$\frac{1}{I}\sum_{i=1}^{I} |p \cdot (x_i - \omega_i)| \leq \frac{2L}{I} \max\{||\omega_1||_\infty, \ldots ||\omega_I||_\infty\} \tag{1}$$

$$\frac{1}{I}\sum_{i=1}^{I} \left|\inf\{p \cdot (y - x_i) : y \succ_i x_i\right| \leq \frac{4L}{I} \max\{||\omega_1||_\infty, \ldots ||\omega_I||_\infty\} \tag{2}$$

where $||x||_\infty = \max\{|x_1|, \ldots, |x_L|\}$.

If there are many more agents than goods, and the endowments are not too large, the bounds on the right-hand sides of Eqs. (1) and (2) will be small. In that case, Eq. (1) says that trade occurs almost at the price p, and that each x_i is almost in the budget set, while Eq. (2) says that the price p almost supports $\succ_i$ at x_i, in the sense that everything preferred to x_i costs almost as much as x_i. Taken together, Eqs. (1) and (2) say that the pair (p, x) satisfies a slightly perturbed version of the *def* of Walrasian equilibrium. Indeed, if we knew the left sides of Eqs. (1) and (2) were *zero*, then $p \cdot (x_i - w_i) = 0$, so x_i lies in i's budget set, and $y \succ_i x_i \Rightarrow p \cdot y \geq p \cdot \omega_i$, so x would be a Walrasian quasi-equilibrium! (A pair (p^*, x^*) is said to be a Walrasian quasi-equilibrium if it satisfies the definition of a Walrasian equilibrium except that instead of requiring that x_i^* lie in i's demand set, we only require that x_i^* lie in i's quasi-demand set, that is $p^* \cdot x_i^* \leq p^* \cdot \omega_i$ and every $y \succ_i x_i^*$ satisfies $p^* \cdot y \leq p^* \cdot \omega_i$.)

Outline of Proof Follow the proof of the Second Welfare Theorem.

- Suppose x is in the core. Define $B_i = \{y - \omega_i : y \succ_i x_i\} \cup \{0\} = (\{y : y \succ_i x_i\} \cup \{\omega_i\}) - \omega_i$ and $B = \sum_{i=1}^{I} B_i$. The first term in the definition of B_i corresponds to members of a potential improving coalition; for accounting purposes, we assign members outside the coalition their endowments. Note that B_i is *not* convex, even if $\succ_i$ is a convex preference.

Claim If x is in the core, then $B \cap \boldsymbol{R}_{--}^L = \varnothing$. Suppose $z \in B \cap \boldsymbol{R}_{--}^L$. Then there exists $z_i = B_i$ such that $z = \sum_{i=1}^{I} z_i$. Let $S = \{i : z_i \neq 0\}$; since $z \ll 0$, $S \neq \varnothing$. For $i \in S$, let $x_i' = \omega_i + z_i - \frac{z}{|S|}$. Then $x_i' \gg \omega_i + z_i \succ_i x_i$ by the definition of B_i, $x_i' \succ_i x_i$ by free disposal, and $\sum_{i \in S} x_i' = \sum_{i \in S} \omega_i$, so S can improve on x by x', so x is not in the core.

- Let $v = -L(\max_{i=1,\&,I}||\omega_i||_\infty, \ldots, \max_{i=1,\&,I} ||\omega_i||_\infty$.

Claim $(\text{con } B) \cap \left(v + \boldsymbol{R}_{--}^L\right) = \varnothing$. If $z \in \text{con} B$, by the Shapley–Folkman theorem, and relabelling the agents, we may write

$$z = \sum_{i=1}^{I} z_i, \quad z_i \in \text{con} \quad B_i (i = 1, \ldots, I),$$
$$z_i \in B_i \quad (i \neq \{1, \ldots, L\})$$

Choose

$$\widehat{z_i} = \begin{cases} 0 & \text{if} \quad i = 1, \ldots, L \\ z_i & \text{if} \quad i = L+1, \ldots, I \end{cases}$$

Then $\sum_{i=1}^{I} \widehat{z_i} \in B$ so $\sum_{i=1}^{I} \widehat{z_i} \not\leq / < 0$. If $z \ll v$, then, $\sum_{i=1}^{I} \widehat{z_i} = \sum_{i=1}^{L} 0 + \sum_{i=L+1}^{I} z_i \leq \sum_{i=1}^{L} (\omega_i + z_i) + \sum_{i=L+1}^{I} z_i = \sum_{i=1}^{L} \omega_i \, \text{c} + \sum_{i=1}^{I} z_i = \sum_{i=1}^{L} \omega_i + z \ll \sum_{i=1}^{L} \omega_i + v \leq 0$, so $B \cap \mathbf{R}^L_{--} \neq \varnothing$ a contradiction which proves the claim.

- By the separating hyperplane theorem, there exists $p \neq 0$ such that $\sup p \cdot \left(v + \mathbf{R}^L_{--}\right) \leq \inf p \cdot (\text{con}\, B)$. If $p_\ell < 0$ for some ℓ, then $\sup p \cdot \left(v + \mathbf{R}^L_{--}\right) = +\infty$, while $\inf p \cdot (\text{con}\ B) \leq 0$, a contradiction, so $\text{p} = 0$ and we can normalize $p \in \Delta$. Then $\inf p \cdot B \geq \inf p \cdot (\text{con}\ B) \geq p \cdot v = -L \max \left\{ \|\omega_1\|_{\infty, \ldots,} \|\omega_I\|_{\infty} \right\}$.
- Adapt the remainder of the proof of the Second Welfare Theorem; this requires a few tricks.

The *core* of an economy consists of those states of the economy which no group of agents can 'improve upon'. A group of agents can improve upon a state of the economy if, by using the means available to that group, each member can be made better off. Nothing is said in this definition of how a state in the core actually is reached. The actual process of economic transactions is not considered explicitly.

To keep the presentation as simple as possible, we shall consider only the core for exchange economies with an arbitrary number l of commodities, even though the core concept applies to more general situations.

Consider a finite set A of economic agents; each agent a in A is described by his *preference relation* $\precsim_a$ (defined on the positive orthant R^l_+) and his *initial endowments* $e_{a.}$ (a vector in R^l_+). The outcome of any exchange, that is to say, a state (x_a) of the exchange economy $\mathscr{E} = \{\precsim_a, e_a\}_{a \in A}$, is a *redistribution* of the total endowments, i.e.

$$\sum_{a \in A} x_a = \sum_{a \in A} e_a.$$

A *coalition* of agents, say $S \subset A$, can *improve upon* a redistribution (x_a), if that coalition S, by using the endowments available to it, can make each member of that coalition better off, that is to say, there is a redistribution, say $(y_a)_{a \in S}$, such that

$$y_a \succ_a x_a \text{ for every } a \in S \text{ and } \sum_{a \in S} y_a = \sum_{a \in S} e_a.$$

The set of redistributions for the exchange economy $\mathscr{E}$ that no coalition can improve upon is called the core of the economy $\mathscr{E}$, and is denoted by $C(\mathscr{E})$.

The core is a rather theoretical, however, fundamental equilibrium concept. Indeed, the core provides a theoretical foundation of a more operational equilibrium concept, the *competitive equilibrium* which, in fact, is a very different notion of equilibrium. The allocation process is organized through markets; there is a price for every commodity. All economic agents take the price system as given and make their decisions independently of each other. The equilibrium price system coordinates these independent decisions in such a way that all markets are simultaneously balanced.

More formally, an allocation $\left(x^*_a\right)$ for the exchange economy $\mathscr{E} = \{\precsim_a, e_a\}_{a \in A}$ is a *competitive equilibrium* (or a *Walras allocation)* if there exists a price vector $p^* \in R^l_+$ such that for every $a \in A, x^*_a \in \varphi_a(p^*)$ and

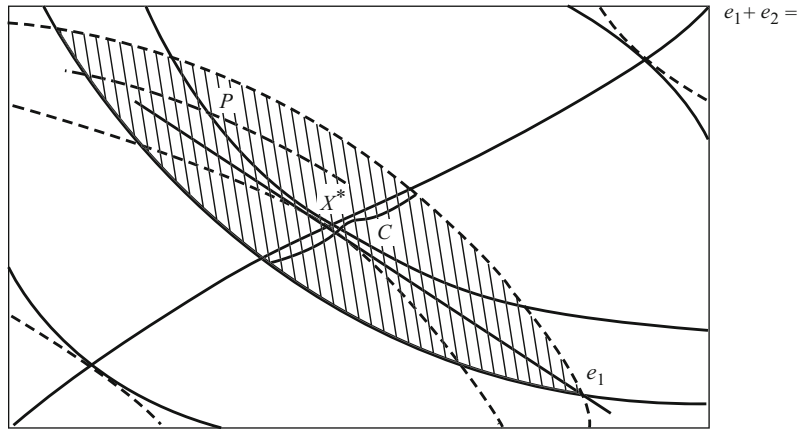
$$\sum_{a \in A} x^*_a = \sum_{a \in A} e_a.$$

Here $\varphi_a(p^*)$ or more explicitly, $\varphi(p^*, e_a, \precsim_a)$ denotes the demand of agent a with preferences $\precsim_a$ and endowment e_a, i.e. the set of most desired commodity vectors (with respect to $\precsim_a$) in the budget-set $\left\{x \in R^l_+ \mid p^* \cdot x \leq p^* \cdot e_a\right\}$.

The set of all competitive equilibria for the economy $\mathscr{E}$ is denoted by $W(\mathscr{E})$.

The core and the set of competitive equilibria for an economy with two agents and two commodities can be represented geometrically by the well-known Edgeworth–Box (see Fig. 1). The size of the box is determined by the total endowments $e_1 + e_2$. Every point P in the box represents

Cores, Fig. 1



a redistribution; the first agent receives $x_1 = P$ and the second receives $x_2 = (e_1 + e_2) - P$.

It is easy to show that for every exchange economy $\mathscr{E}$ a competitive equilibrium belongs to the core,

$$W(\mathscr{E}) \subset C(\mathscr{E}).$$

Thus, a state of the economy $\mathscr{E}$ which is decentralized by a price system cannot be improved upon by cooperation. This proposition strengthens a well-known result of Welfare Economics – every competitive equilibrium is Pareto-efficient.

The inclusion $W(\mathscr{E}) \subset C(\mathscr{E})$ is typically strict. Indeed, if the initial allocation of endowments is not Pareto-efficient, which is the typical case, then, if there are any allocations in the core at all, there are core-allocations which are not competitive equilibria.

This leads us to the *basic problem* in the theory of the core:

> For which kind of economies is the 'difference' between the core and the set of competitive equilibria small? Or in other words, under which circumstances do cooperative barter and competition through decentralized markets lead essentially to the same result?

Naturally, the answer depends on the way one measures the 'difference' between the two equilibrium concepts. However this is done one expects that the economy must have a large number of participants.

In answering the basic questions we try to be comprehensible (for example by avoiding the use of measure-theoretic concepts) but not comprehensive. Therefore, if we refer in the remainder of this entry to an economy $\mathscr{E} = \{\precsim_a, e_a\}_{a \in A}$ we shall always assume that preference relations are continuous, complete, transitive, monotone and strictly convex. The total endowments $\Sigma_{a \in A} e_a$ of an economy are always assumed to be strictly positive. We shall not repeat these assumptions. Furthermore, if we call an economy smooth, then we assume in addition that preferences are smooth (hence representable by sufficiently differentiable utility functions) and individual endowments are strictly positive.

These assumptions simplify the presentation tremendously. For generalizations we refer to the extensive literature.

We remark that under the above assumptions there always exists a competitive equilibrium, and hence, the core is not empty.

Large Economies

The simplest and most stringent measure of difference between the two equilibrium sets, $C(\mathscr{E})$, and $W(\mathscr{E})$, which we shall denote by $\delta(\mathscr{E})$, can be defined as follows.

Let $\delta(\mathscr{E})$ be the smallest number δ with the property: for every allocation $(x_a) \in C(\mathscr{E})$ there exists an allocation $\left(x_a^*\right) \in W(\mathscr{E})$ such that

$$|x_a - x_a^*| \leq \delta$$

for every agent a in the economy $\mathscr{E}$.

Thus, if $\delta(\mathscr{E})$ is small, then from every agent's view a core allocation is like a competitive equilibrium.

Unfortunately for this measure of difference, it is not true that $\delta(\mathscr{E})$ can be made arbitrarily small provided the number of agents in the economy $\mathscr{E}$ is sufficiently large (even if one restricts the agents' characteristics $(\precsim_a, e_a)$ to an a priori given finite set).

Consequently one considers also weaker measures for the 'difference' between the two equilibrium concepts $C(\mathscr{E})$ and $W(\mathscr{E})$ For example, define $\delta_1(\mathscr{E})$ and $\delta_2(\mathscr{E})$, respectively, as the smallest number δ with the property: for every $(x_a) \in C(\mathscr{E})$ there exists a price vector $p \in R^l_+$ such that

$$(\delta_1)|x_a - \varphi_a(p)| \leq \delta \text{ for every agent } a \text{ in } \mathscr{E}$$

or

$$(\delta_2)\frac{1}{\#A}\sum_{a \in A}|x_a - \varphi_a(p)| \leq \delta.$$

Clearly, the measures δ_1 and δ_2 are weaker than δ since the price vector p is not required to be an equilibrium price vector for the economy $\mathscr{E}$. The number $\delta_1(\mathscr{E})$ (and, *a fortiori*, $\delta_2(\mathscr{E})$) does not measure the distance between the sets $C(\mathscr{E})$ and $W(\mathscr{E})$. But the degree by which an allocation in the core can be decentralized via a price system. Obviously one has $\delta_2(\mathscr{E}) \leq \delta_1(\mathscr{E}) \leq \delta(\mathscr{E})$.

One can show that $\delta_2(\mathscr{E})$ becomes arbitrarily small for sufficiently large economies. More precisely,

Theorem 1 Let T be a finite set of agents' characteristics $(\precsim, e)$ and let b be a strictly positive vector in R^l. Then for every $\varepsilon > 0$ there exists an integer N such that for every economy $\mathscr{E} = \{\precsim_a, e_a\}_{a \in A}$ with $\#A \geq N$,

$$\frac{1}{\#A}\sum_{a \in A} e_a \geq b$$

and $(\succsim_a, e_a) \in T$ one has.

$$\delta_2(\mathscr{E}) \leq \varepsilon.$$

(The finite set T in Theorem 1 can be replaced by a compact set with respect to a suitably chosen topology: see Hildenbrand 1974.) We emphasize that this result does not imply that in large economies core-allocations are near to competitive equilibria. In fact, Theorem 1 does not hold if δ_2 is replaced by the measure of difference δ or even δ_1. Theorem 1 does imply, however, that for sufficiently large economies one can associate to every core-allocation a price vector which 'approximately decentralizes' the core-allocation. Some readers might consider this conclusion as a perfectly satisfactory answer to our basic problem. If one holds this view, then the rest of the paper is a superfluous intellectual pastime. We would like to emphasize, however, that the meaning of 'approximate decentralization' is not very strong. First, the demand $\varphi_a(p)$ is not necessarily near to x_a for every agent a in the economy; only the mean deviation

$$\frac{1}{\#A}\sum_{a \in A}|x_a - \varphi_a(p)|$$

becomes small. Second, total demand is not equal to total supply; only the mean excess demand

$$\frac{1}{\#A}\sum_{a \in A}[\varphi_a(p) - e_a]$$

becomes small.

There are alternative proofs in the literature, e.g. Bewley (1973), Hildenbrand (1974), Anderson (1981) or Hildenbrand (1982). These proofs are based either on a result by Vind (1965) or Anderson (1978).

Sharper conclusions than the one in Theorem 1 will be stated in the following sections. There we consider a sequence $(\mathscr{E}_n)_{n=1,\ldots}$ of economies and then study the asymptotic behaviour of $\delta(\mathscr{E}_n)$.

Before we present these limit theorems we should mention another approach of analysing the inclusion $W(\mathscr{E}) \subset C(\mathscr{E})$. Instead of analysing the asymptotic behaviour of the difference $\delta(\mathscr{E}_n)$ for a sequence of finite economies one can define a large economy where every agent has strictly no

C

influence on collective actions. This leads to a *measure space without atoms* of economic agents (also called a *continuum of agents).* For such economies the two equilibrium concepts coincide. See Aumann (1964).

Replica Economies

Let $\mathscr{E}; = \{\precsim_i, e_i\}$ be an exchange economy with m agents. For every integer n we define the n-fold *replica economy* $\mathscr{E}_n$ of $\mathscr{E}$ as an economy with $n{\cdot}m$ agents; there are exactly n agents with characteristics $(\precsim_i, e_i)$ for every $i = 1,\ldots, m$.

More formally,

$$\mathscr{E}_n = \left\{\precsim_{(i,j)}, e_{(i,j)}\right\} \begin{matrix} 1 \le i \le m \\ 1 \le i \le n \end{matrix}$$

where $\precsim_{(i,j)} = \precsim_i$ and $e_{(i,j)} = e_i$, $1 \le i \le m$ and $1 \le j \le n$. Thus, an agent a in the economy $\mathscr{E}_n$ is denoted by a double index $a = (i,j)$. We shall refer to agent (i,j) sometimes as the jth agent of type i.

Replica economies were first analysed by F. Edgeworth (1881) who proved a limit theorem for such sequences in the case of two commodities and two types of agents. A precise formulation of Edgeworth's analysis and the generalization to an arbitrary finit/e number of commodities and types of agents is due to Debreu and Scarf (1963).

Here is the basic result for replica economies.

Theorem 2 For every sequence $(\mathscr{E}_n)$ of replica economies the difference between the core and the set of competitive equilibria tends to zero, i.e.,

$$\lim_{n\to\infty} \delta(\mathscr{E}_n) = 0.$$

Furthermore, if $\mathscr{E}$ is a smooth and regular economy then $\delta(\mathscr{E}_n)$ converges to zero at least as fast as the inverse of the number of participants, i.e., there is a constant K such that

$$\delta(\mathscr{E}_n) \le \frac{K}{n}.$$

The proof of this rmkably neat result is based on the fact that a core–allocation (x_{ij}) assigns to every agent of the same type the same commodity bundle, i.e., $x_{ij} = x_{ik}\,\mathscr{E}$, This 'equal treatment' property simplifies the analysis of $\delta(\mathscr{E}_n)$ tremendously. Indeed, an allocation (x_{ij}) in $C(\mathscr{E}_n)$, which can be considered as a vector in $R^{l\cdot m\cdot n}$, is completely described by the commodity bundle of one agent in each type, thus by a vector $(x_{11}, x_{21},\ldots, x_{m1})$ in $R^{l\cdot m}$, a space whose dimension is independent of n.

Thus, let

$$C_n = \left\{(x_{11}, x_{21}, \ldots, x_{m1}) \in R^{l\cdot m} \middle| \left(x_{ij}\right) \in C(\mathscr{E}_n)\right\}.$$

One easily shows that $C_{n+1} \subset C_n$. It is not hard to see that Theorem 1 follows if

$$\cap_{n=1}^{\infty} C_n = W(\mathscr{E}_1).$$

But this is the well-known theorem of Debreu and Scarf (1963). The essential arguments in the proof go as follows. Let $(x_1, \ldots, x_m) \in \cap_{n=1}^{\infty} C_n$. One has to show that there is a price vector p^* such that $x \succ_i x_i$ implies $p^* \cdot x > p^* \cdot e_i$ For this it suffices to show that there is a p^* such that

$$p^* \cdot z \ge 0 \text{ for every } z \in \cup_{i=1}^{m} \left(\left\{x \in R^l_+ \mid x \succ_i x_i\right\}\right) - e_i) = Z,$$

i.e., there is a hyperplane (whose normal is p^*) which supports the set z. One shows that the assumption $(x_1, \ldots, x_m) \in \cap_{n=1}^{\infty} C_n$ implies that 0 does not belong to the convex hull of z. Minkowski's Separation Theorem for convex sets then implies the existence of the desired vector p^*.

The second part of the conclusion of Theorem 2 is due to Debreu (1975).

Type Economies

The limit theorem on the core for replica economies is not fully satisfactory since replication is a very rigid way of enlarging an economy. The conclusion '$\delta(\mathscr{E}_n) \to 0$' in Theorem 2, to be of general relevance, should be robust to small deviations from the strict replication procedure.

Consider a sequence $(\mathscr{E}_n)$ of economies where the characteristics of every agent belong to a given finite set of types $T = \{(\precsim_1, e_1), \ldots, (\precsim_m, e_m)\}$. We do not consider this as a restrictive assumption (considered as an approximation, one can always group agents' characteristics into a finite set of types). Let the economy $\mathscr{E}_n$ have N_n agents; $N_n(1)$-agents of the first type, $N_n(i)$ agents of type i. Of course the idea is that N_n tends to ∞ with increasing n. Consider the fraction $\nu_n(i)$ of agents in the economy $\mathscr{E}_n$ which are of type i, i.e.,

$$\nu_n(i) = \frac{N_n(i)}{N_n}.$$

The sequence $(\mathscr{E}_n)$ is a replica sequence of an economy $\mathscr{E}$ (not necessarily of $\mathscr{E}_1$) if and only if the fractions $\nu_n(i)$ are all independent of n. It is this rigidity which we want to weaken now.

A sequence $(\mathscr{E}_n)$ of economies with characteristics in a finite set T is called a *sequence of type economies* (over T) if

(i) the number N_n of agents in $(\mathscr{E}_n)$ tends to infinity and

(ii) $\nu_n(i) = \frac{N_n(i)}{N_n} \underset{(n\to\infty)}{\to} \nu(i) > 0.$

EX (random sampling of agents' characteristics):

Let π be a probability distribution over the finite set T. Define the economy $\mathscr{E}_n$ as a random sample of size n from this distribution $\pi(\cdot)$. The law of large numbers them implies property (ii): $\nu_n(i) \to \pi(i)$.

The step from replica economies to type economies – as small as it might appear to the reader – is conceptually very important. Yet with this 'small' generalization the analysis of the limit behaviour of $\delta(\mathscr{E}_n)$ or $\delta_1(\mathscr{E}_n)$ is made more difficult. Even worse, it is no longer true that for *every* sequence $(\mathscr{E}_n)$ of type economies one obtains $\delta(\mathscr{E}_n) \to 0$ – even if the preferences of all types are assumed to be very nice, say smooth. There are some 'exceptional cases' where the conclusion $\delta(\mathscr{E}_n) \to 0$ does not hold. But these are 'exceptional' cases and the whole difficulty in the remainder of this section is to explain in which precise sense these cases are 'exceptional' and can therefore be ignored. We shall first exhibit the 'cases' where the conclusion fails to hold. Then we shall show that these cases are exceptional.

We denote by $\Pi(\mathscr{E})$ the set of normalized *equilibrium price vectors* for the economy $\mathscr{E} = \{\precsim_a, e_a\}_{a\in A}$ Thus, for $p^* \in \Pi(\mathscr{E})$ the excess demand is zero, i.e.,

$$\sum_{a\in A}[\varphi_a(p^*) - e_a] = 0.$$

To every sequence $(\mathscr{E}_n)$ of type economies we associate a '*limit economy*' $\mathscr{E}_\infty$. This economy has an 'indefinitely large' number of agents of every type; the fraction of agents of type i is given by $\nu(i)$. The mean (per capita) excess demand of that limit economy $\mathscr{E}_\infty$ is defined by

$$z_\nu(p) = \sum_{i=1}^{m} \nu(i)[\varphi(p, e_i, \precsim_i) - e_i].$$

An equilibrium price vector p^* of the limit economy $\mathscr{E}_\infty$ is defined by $z_\nu(p^*) = 0$. Let $\Pi(\nu)$ denote the set of normalized equilibrium price vectors for $\mathscr{E}_\infty$. Obviously for a replica sequence $(\mathscr{E}_n)$ we have $\Pi(\mathscr{E}_n) = \Pi(\nu)$ for all n. However, for a sequence of type economies the set $\Pi(\mathscr{E}_n)$ of equilibrium prices of the economy $\mathscr{E}_n$ depends on n, and it might happen that the set $\Pi(\nu)$ is not similar to $\Pi(\mathscr{E}_n)$ even for arbitrarily large n. To fix ideas, it might happen that $\Pi(\mathscr{E}_n) = \{p_n\}$ and $\Pi(\nu)$ contains not only $p = \lim p_n$ but also another equilibrium price vector. Such a situation has to be excluded.

We call a sequence of type economies *sleek* if $\Pi(\mathscr{E}_n)$ converges (in the Hausdorff-distance) to $\Pi(\nu)$.

It is known (Hildenbrand 1974) that the sequence $(\Pi(\mathscr{E}_n))$ converges to $\Pi(\nu)$ if $\Pi(\nu)$ is a singleton (i.e., the limit economy has a unique equilibrium) or, in general, if (and only if) for every open set O in R^ℓ with $O \cap \Pi(\nu) \neq \emptyset$ it follows that $O \cap \mathscr{E}\,\Pi(\mathscr{E}_n) \neq \emptyset$ for all n sufficiently large.

We now have exhibited the cases where a limit theorem on the core holds true.

Theorem 3 For every sleek sequence $(\mathscr{E}_n)$ of type economies

$$\lim_{n\to\infty} \delta(\mathscr{E}_n) = 0$$

Unfortunately there seems to be no short and easy proof. The main difficulty arises from the fact that for allocations in the core of a type economy the 'equal treatment' property, which made the replica case so manageable is no longer true. For a proof see Hildenbrand and Kirman (1976) or Hildenbrand (1982) and the references given there. The main step in the proof is based on a result of Bewley (1973).

It remains to show that non-sleek sequences of type economies are 'exceptional cases'.

The strongest form of 'exceptional' is, of course, 'never'. We mentioned already that a sequence $(\mathscr{E}_n)$ is sleek if its limit economy has a unique equilibrium. Unfortunately, however, only under very restrictive assumptions on the set T of agents' characteristics does uniqueness prevail; for example,

(1) if every preference relation leads to a demand function which satisfies gross-substitution (Cobb–Douglas utility functions are typical exs),
(2) if every preference relation is homothetic and the endowment vectors $e_i (i = 1,\ldots, m)$ are collinear.

Since there is no reasonable justification for restricting the set T to such special types of agents we have to formulate a model in which we allow non-sleek sequences to occur provided, of course, this can be shown to be 'exceptional cases'. Let S^{m-1} denote the open simplex in R^m, i.e.

$$S^{m-1} = \left\{ x \in R^m \mid x_i > 0, \sum_{i=1}^{m} x_i = 1 \right\}.$$

The limit distribution $\nu(i)$ of a sequence of type economies with m types is a point in S^{m-1}.

A closed subset C in S^{m-1} which has (m – 1 dimensional Lebesgue) measure zero is called *negligible*. Thus, if a distribution ν is not in C then a sufficiently small change will not lead to C. Furthermore, given any arbitrary small positive number $\mathscr{E}$ one can find a countable collection of balls in S^{m-1} such that their union covers C, and that the sum of the diameters of these balls is smaller than $\mathscr{E}$. Thus, in particular, if $\nu \in C$ then one can approximate ν by points which do not belong to C. Clearly, a negligible set is a small set in S^{m-1}.

Theorem 4 Given a finite set T of m smooth types of agents, there exists a negligible subset C in S^{m-1} and a constant K such that for every sequence $(\mathscr{E}_n)$ of type economies over T whose limit distribution ν does not belong to C one has $\delta(\mathscr{E}_n) \leq K/\#A_n$, thus in particular, $\lim_{n\to\infty} \delta(\mathscr{E}_n) = 0$.

The convergence of $\delta(\mathscr{E}_n)$ follows from Theorem 3 and Theorems 5.4.3 and 5.8.15 in Mas–Colell (1985). For the rate of convergence see Grodal (1975).

Corn Laws

B. Hilton

The British Corn Laws were parliamentary statutes which attempted to regulate the trade in corn (mainly wheat, barley, rye, and oats) for the benefit of producers during periods of plenty and low prices. Legislation to prohibit or discourage importation can be traced back to the 15th century, though it only became effective with an Act of 1663, while bounties to encourage export date from the 14th century and became more systematic after an Act of 1689. However, no economic tracts or pamphlets seem to have been devoted exclusively to this subject before 1750 (Barnes 1930, p. 16) and it was only in the 19th century that such legislation became controversial, mainly because the growth of population and especially of towns fuelled the concern about food supply that had been provoked by the scarcity of 1795 and by Malthus's *Essay* of 1798. In particular the 1815 Corn Law, which aimed to encourage domestic production by prohibiting importation until home prices had reached a certain level (80 shillings per quarter in the case of wheat), was the object of violent abuse both from radicals representing the interests of the consumer and also from middle-class manufacturers and exporters. In practice the 1815 Law satisfied no one. The sudden switch from total prohibition to total freedom of import at a particular price was destabilizing and failed to safeguard supply, since by the time (usually October or November) that prices reached the specified level, signalling a scarcity, the Baltic Sea was likely to have frozen over making cheap foreign imports unavailable for the remainder of the season. To meet these problems a sliding scale of duties was introduced in 1828, modified downwards in 1842, and finally abandoned seven years later after a major political crisis in 1846 had brought down Sir Robert Peel's second government and fundamentally divided the Conservative Party. The repeal of the Corn Laws was considered to mark the final triumph of free trade theories in Britain and quickly acquired symbolic importance, though with the drying up of European wheat supplies from the mid-1830s the Corn Laws had ceased to make very much practical difference to the trade in grain (Fairlie 1965). Repeal did not (as was widely expected) lead to reductions in the price of wheat, though it did reduce fluctuations in the amounts annually imported.

An assessment of the place of the Corn Laws in political economy must depend on what is understood by 'political economy'. In the first half of the 19th century the term was often used in a vulgar sense, and often abusively, to denote the prescriptions of those members of the middle classes who were leading the attack on 'old corruption', as the monopoly of power and privilege by the landed elite was commonly termed. At this level the assault on protection generally, and on agricultural protection in particular, was the sharpest weapon in the political economist's armoury, and for many the work of the Anti-Corn Law League under Cobden and Bright, and the promptings of the *Economist* newspaper, marked 'the high tide of *laissez-faire*'. If, on the other hand, political economy is taken to denote a body of formal economic thought, the Corn Laws must be accorded considerably less significance. Smith had exempted food supply and defence from the areas of public life to which the maxim of free trade should be made to apply, and most of his 19th-century successors were similarly well disposed to the Laws. Malthus consistently defended them while protesting that in all other matters he was a friend to free trade; Senior, who of all economists was the one most engaged in

advising on public policy, and whose political views inclined him against the agricultural lobby, in fact had little to say on the subject. Even J.S. Mill, while welcoming Corn Law repeal, consistently played down the beneficial effects which were likely to flow from it (Blaug 1968, pp. 192, 215). Probably only Ricardo placed hostility to the Corn Laws at the centre of his system. His corn model postulated that without access to cheap supplies of foreign grain, population pressure would either force domestic farmers onto more marginal land or else would compel them to cultivate the old land more intensively. In either case prices would rise, money wages would rise, profits would decline, and the economy would move towards a stationary state. Similar arguments were made by Torrens in his early work, though later he significantly qualified his opposition to the Corn Laws, and also by McCulloch, though he was always more concerned that the Laws caused excessive price fluctuations, and he eventually came to reject most aspects of the Ricardian corn model (O'Brien 1970, pp. 378–95). Indeed it has been argued that even for Ricardo the corn model was essentially an abstraction, and that his real animus against the Laws was based on their contribution to price instability and the shelter which they afforded to inefficient producers (Hollander 1979, pp. 605, 629–37, 647).

Moreover, the reduction and then finally the repeal of the Corn Laws seems to have owed little to economic doctrine. As early as 1821 Lord Liverpool's government envisaged the gradual dismantling of a system which it had always regarded as designed largely to ease the transition from a prolonged state of warfare and de facto protection (1793–1815) to a state of peace. Its main concern was with the supply situation, especially the unreliability of Ireland as a granary and increasing dependence on farmers in northern Europe in lean seasons. A subsidiary but significant factor was the return to the gold standard in 1821. It was now thought desirable to render the corn trade as regular (i.e. as little weather-related) as possible, in order to minimize fluctuations in bullion outflows (Hilton 1977, pp. 98–126). Both these factors operated on Peel in the prelude to repeal in 1846. The Irish Famine of 1845–9 emphasized the precariousness of the situation with regard to domestic supply (though it served to confirm and excuse the policy of repeal rather than initiating it), while the Bank Charter Act of 1844 rendered the money supply more than ever sensitive to movements of bullion. Political factors also obtruded in the decision to repeal: especially, the Anti-Corn Law League's activities threatened a whig victory in the next general election unless something was done to undermine its existence (Prest 1977, pp. 72–102). Undoubtedly there was also a mythical element in the campaign, the Corn Laws having become a symbol rather than a real guarantee of landed monopoly (Kemp 1961–2). There was, however, one theoretical argument which may have counted in the decision. This was the adoption of a market theory of wages in preference to the subsistence theory derived from Ricardo and the labour theory of value. The market theory was hardly novel in the 1840s, having been espoused by Malthus, but it was not given public prominence until Cobden bruited it emphatically in his campaign for repeal. Thus Peel ascribed his change of heart on agricultural protection in part at least to a discovery that 'the wages of labour do not vary with the price of grain'. He seems also to have been moved by Cobden's claims that in free trade conditions agriculturists would find it easier to capitalize and to engage in the 'high farming' that would be their competitive salvation. Such confidence seemed to be justified by the 'Golden Age of English Farming' which succeeded repeal, the real challenge to agriculture not occurring until the appearance of imports from the New World in the last quarter of the 19th century. By then, however, the Corn Laws had taken their place with king Richard III and the Inquisition among the 'bad things' of history, so much so that the cry of 'cheap loaf' was to prove politically irresistible, and to impair all early 20th-century attempts at tariff reform and imperial preference.

Corn Laws, Free Trade and Protectionism

John Nye

Abstract

In the 1840s, Britain repealed the export restrictions and import duties on wheat known as the Corn Laws. But the traditional story of British free trade was complicated by an unwillingness to eliminate the most binding tariffs on wine and other consumables. In contrast, Britain's avowedly protectionist rival France had a more liberal trade policy than did Britain for most of the 19th century. Only with the 1860 Anglo–French Treaty of Commerce did Britain and France both move to uniformly low tariffs on goods and services, ushering in a period of genuinely free trade throughout Europe.

The Corn Laws were the parliamentary statutes that regulated the import and export of grain for the benefit of British producers in the early 19th century. Though these laws derived from legislation in the period 1804–15, they were but the extension or modification of a system that had been introduced in 1773 to prohibit exports of wheat when prices rose above a given level and that limited imports through a variety of duties based on a sliding scale. The goal of these laws was ostensibly the desire to stabilize the price of grain, which had been a regular goal of parliament since the late 17th century.

The debates about the abolition of the Corn Laws in the early to mid-1800s hold a special place in the economic history of Great Britain on account of their central role in shifting commercial policy to nearly free trade. Because of Britain's dominance of industrial trade in the 19th century and the leadership she exerted in international commerce, the struggles over the Corn Laws have been seen as emblematic of all debates about the advisability of free trade or protectionism. Despite the symbolic importance of these events, it is easy to overlook the facts that Britain after the repeal of the Corn Laws did not immediately move to perfectly free trade and that the political struggle over their abolition had at

least as much to do with domestic concerns over the importance of agriculture in a modern economy as with ideological questions about the advisability of free trade.

Mercantilism and the Rise of British Liberalism

The regulation or promotion of international trade has been perhaps the oldest policy issue in the political economy of international relations.

It is a common belief that trade is a primary source of a nation's wealth. But this has often been misunderstood to mean that exports enhance wealth while imports detract from it. This view, a central component of what is called mercantilism, stems from the mistaken belief that the benefits of trade flow only one way. One view was that a nation's wealth derived from the quantity of specie or gold and silver coin in the country. Therefore, exports contributed to this while imports detracted from it.

Some of this reasoning was theoretical, but more commonly mercantile theory was simply the evolution of a set of policies deriving from the fiscal needs of the newly emerging nation-states. Unsurprisingly, many states viewed the success of the state as synonymous with the success of the nation itself. Revenue was essential to the maintenance of the large armies that were a prerequisite for the nation-state. So trade was viewed as an essentially zero-sum game with both losers and winners. Moreover, this concern about revenue often translated into a concern for specie. Whereas modern economics treats specie as virtually irrelevant to the supply of money, contemporaries viewed coin itself as a necessary prerequisite of sound financial policy. Hence trade surpluses were preferred because they brought more precious metals in than they took out of the kingdom.

One of the earliest theoretical discussions of this view comes from Thomas Mun, who wrote 'The ordinary means therefore to increase our wealth and treasure is by foreign trade, wherein we must ever observe this rule; to sell more to strangers yearly than we consume of theirs in value' (1664, p. 11).

Adam Smith, the founder of modern economics, was the most prominent critic of this view. Starting from the observation that voluntary trade was mutually beneficial, and noting that the wealth of a nation's inhabitants, not its quantity of coin, made for true wealth, Smith argued in the *Wealth of Nations* against what he labelled the 'mercantile system'. He articulated the virtues of free and open trade, both in international and in home commerce. Indeed, the term 'free trade' was employed throughout the 18th and 19th centuries to refer to unregulated domestic trade as least as often as it referred to the free flow of goods from abroad.

These ideas were later modelled more systematically by the English economist David Ricardo, who formalized the analysis and showed that nations could maximize their welfare by specializing in the production of goods with the lowest opportunity cost and trading with other nations. This is the central idea behind the law of comparative advantage, usually attributed to David Ricardo, and developed more thoroughly by Paul Samuelson and others in the 20th century. Most important for this claim was the idea that a nation did not even have to be the 'best' producer of any product for there to be gains from trade. A nation that was more productive that another in all industries would still do better by specializing in some areas and trading for the other goods with another country. Thus, any claim that a nation could not benefit if it had no comparative advantage would be false. Every nation has a comparative advantage in producing some product, even if it has an absolute advantage in none.

Smith's ideas and those of his successors provided the philosophical basis for the classical liberal movements of the late 18th and early 19th centuries. By the early 1800s, the idea of a limited state that minimized regulation and promoted welfare through the encouragement of open trade at home and abroad had emerged as an important ideological view, promoted by prominent intellectuals and supported by an influential subset of the British political class. Nonetheless, the strong interest in the liberal ideas derived from the Scottish Enlightenment persuaded states not to fully adopt a policy of free trade. This was often not so

much the result of any ideological predisposition as a response to the state's desire for greater revenue. Taxing trade – both at home and from abroad – was one of the most common means of generating the income that supported the expanding bureaucracy of the modern state. Furthermore, special interests often worked to distort policy to favour of specific producers or economic sectors.

Since the late 17th century, Britain had been especially dependent on customs and excise taxes of various sorts. The rise of British liberalism had come in the same century (the 18th) that had seen the British state grow to an unprecedented size. Growth of government revenue had vastly outstripped the rate of overall economic growth and served to fund a professional bureaucracy at home and an expanding imperialist policy abroad. This enabled the British to either defeat or stalemate their traditional rival, France, in a series of military struggles that extended from the late 1600s to the era of Napoleon a century later. Moreover, this expansion of the central government came with little change in the revenues from land, the traditional source of income. Most of the gains came from steep increases in revenue from trade; and rising excises were some of the abuses cited by the American colonists as the basis for the independence movement.

However, changes in the landscape of the British economy – most notably the urban and industrial expansion that began in the late 1700s and is known as the Industrial Revolution – made Britain the premier industrial producer of the early 19th century and put pressure on the government to transform legislation that had kept agricultural prices high and had limited imports for the benefit of the farmers who were an increasingly small share of the economy.

The 19th-Century Corn Law Repeal: Free Trade Rhetoric vs. Protectionist Reality

The interests of industrial producers who felt that workers would be better served by cheap bread and the ideas of liberal elites saw concrete expression in the creation of the Anti-Corn Law League beginning in the 1830s. Statesmen such as Richard Cobden explicitly saw the movement as the first step in an attempt to push the British government to adopt a general policy of free trade.

However, it is not clear that theoretical ideas played a large role in the actual dismantling of the Corn Laws. Furthermore, Smith had always held up the staple industries and national defence as areas that might be exceptions to the doctrine of pure laissez-faire. However, the end of the Napoleonic Wars in 1815 removed the basis for wartime support of the Corn Laws and pushed the government to consider modifying or abolishing the restrictions in a transition to a peacetime economy.

As early as 1821 the government of Lord Liverpool had begun to consider reforming a system that it regarded as temporary and motivated by a desire to secure stable prices during wartime with a mix of regulation and protection. The Corn Laws did not seem to be fulfilling that function and, in the absence of war, their maintenance seemed unnecessary for the public good. Of course, the farm interests that gained from these rules would have fought for the continuation of these protections. Nonetheless, the increased voting power of urban workers empowered by the 1832 Reform Act reinforced Prime Minister Peel's conviction that support for industry was vital to the future development of Britain and led him to push for the abolition of all Corn Laws in the 1840s. The onset of the Irish potato famine in 1845 gave a special impetus to the desire to promote lower prices for basic staples and allowed Peel to push for the full abolition of the Corn Laws in 1846.

This legislation repealing the Corn Laws is often cited as the pivotal moment in the rise of free trade in Britain and in Europe because it was followed over the next decade with the reduction or removal of duties on hundreds of imports in Britain – hence the claim that henceforth Britain moved swiftly to full free trade. However, this accomplishment has been somewhat exaggerated in conventional history. Partly because of the need for continued revenue and partly because of pressure from special interests, a few large and important tariffs on coffee, tea, wine, spirits, sugar and

tobacco continued up to the 1860s, tariffs which had a disproportionate impact on the trade of Britain.

The 1860 Anglo-French Trade Treaty and the True Coming of Free Trade

The wine and spirit tariffs were especially important and had been mentioned prominently in Smith's criticism of the mercantile system in the *Wealth of Nations*. These tariffs had arisen from Britain's desire to punish her rival France and had developed as a means of protecting domestic beverage interests such as beer and gin at home, and colonial imports such as rum. Lacking an equivalent slogan to that of the cry for 'cheap bread', there was no great movement to reform these substantial duties.

Consequently, despite the British reputation as the leading free trader in the 19th century, Britain in fact had higher average tariffs than the more openly interventionist nation of France for the first three quarters of that century. The burden on the working classes from the combination of high tariffs on imported wine and liquor and the regulation and taxation of domestic production meant that consumption of alcohol was repressed throughout the 18th and early 19th centuries, despite all the income gains during the Industrial Revolution. Where basic alcoholic beverages had been seen as a necessary staple in the 17th century, they were more likely to be treated as luxuries in the 19th.

Full reform had to wait until 1860, when Britain and France concluded the Anglo–French Treaty of Commerce. This landmark treaty can be said to have truly ushered in the age of free trade in Europe. Brokered by Cobden in Britain and Michel Chevalier in France, the treaty had come after many years of negotiation. Early overtures to the French to sign such a treaty had been rebuffed in the 1840s because Britain had been unwilling to compromise their duties on wine – which had been the category of greatest concern to the French. However, changes in British fiscal structure arising from the imposition of an income tax in the 1850s made it easier for the British government to contemplate tariff cuts that might have compromised the budget in the short run. (British Liberals believed that given enough time, lower rates on imported wine would be offset by increased trade, a belief that proved accurate.) Moreover, the political considerations that led to wine duties being designed from the early 1700s to favour the products of friendly nations such as Portugal and Spain over that of France grew less important in the decades of peace following the defeat of Napoleon Bonaparte in 1815.

Thus, it became possible to conclude a treaty in 1860 in which Britain lowered and modified all its wine and spirit tariffs to remove any anti-French bias and caused France to lower tariffs and remove all prohibitions on goods – primarily textiles – imported from Britain. The 1860 Treaty was also significant for being a Most Favoured Nation agreement in which any subsequent treaties with third countries negotiated by either party would cause concessions to be applied equally to the original signatories. Concern by other Western nations that they would be left out of a trading arrangement between the two leading European powers led to almost the whole of Europe concluding equivalent treaties with either Britain or France over the next decade. By the 1870s virtually the whole of Europe was an extremely open trading area with free movement of goods, capital, and labour that in some ways has never been matched even by today's European Union. And by the end of the 19th century Britain could be said to have genuinely become a free trader with few or modest tariffs on most items, and possibly the lowest average tariffs in all Europe.

It is also interesting to note that Britain provides something of a counterexample to the tendency of modern-day protectionists to fret about the trade balance. Britain was the undoubted leader in world trade throughout the 19th century yet she also ran a merchandise trade deficit for virtually the whole of that period up to the First World War.

The one major counter-example to the tendency in the West to move towards freer international commerce had been the United States. Whereas Europe was busy lowering or abolishing tariffs and trade restrictions after 1860, the USA raised tariffs substantially from the 1860s

onwards. Tariffs were the major source of revenue for the federal government before the constitutional amendment that permitted an income tax. Furthermore, the civil war gave control of the government to the Republicans under Lincoln, who had made protection an important plank in the party's platform. To some extent the United States was fortunate in that many of the negative potential effects of the tariffs were somewhat offset by the free movement of capital, the large size of the internal US market, and the benefits of an extremely open immigration policy. Thus, while goods trade was restricted, capital and labour remained mostly mobile.

By the end of the 19th century, however, the free trade regime brought on by the 1860 Anglo-French Treaty began to unravel. As early as 1878 Germany began to modify her agricultural tariffs in response to pressure from farmers due to increased competition from Russia and the United States. French textile manufacturers pushed the government to abandon the treaty in 1882 and a new set of tariffs were put into place at the beginning of 1892. However, it is worth noting that in both cases the resulting tariff regimes were still relatively moderate and not comparable to the high protection of early Britain or mid-19th-century USA, and Europe still enjoyed vigorous exchange up to 1914, when the European system of open trade was effectively destroyed, first by the war and then by the high tariff walls that nations began to enact during the Great Depression.

The 19th-century trade debates have remained an important touchstone for both scholars and political elites. The same general issues persist to this day. How vigorously should a nation pursue free trade? Is it best to liberalize unilaterally or bilaterally with treaties or collectively through groups like the World Trade Organization? Today we continue to hear concerns about the importance of the trade deficit in hampering or restraining economic growth. Large and small nations often invoke the need to protect infant industries as a justification for tariffs, although it is interesting that in most cases throughout the world it is ageing and decaying industries that are likely to receive protection rather than the newer, more innovative sectors of the economy. And, as with Great Britain in the 19th century, the USA today is seen as the leader in world trade, with some of the same questions being asked about the extent to which trade is manipulated to improve world welfare or merely to enhance the narrow interests of the leading nations. And with the rise of treaties such as the North American Free Trade Agreement and the Central American Free Trade Agreement, as well as the Eurozone, there remain questions as to the virtues of piecemeal reform or the extent to which these agreements are merely mechanisms for obstructing trade by parcelling out the world into separate trading blocs.

Corn Model

G. de Vivo

This expression is commonly used to denote Sraffa's interpretation of the theory of profits formulated by Ricardo in his 1815 *Essay on Profits*.

The characteristic feature of this theory is that in the production of corn there is a physical homogeneity between capital and product, because capital (which Ricardo tends to identify with the wages paid in the year) is conceived as entirely consisting of corn. Consequently the rate of profits in agriculture (production of corn) only depends upon the conditions of production of corn, and the amount of corn constituting the wage rate, and is determined independently of prices. The rate of profits of the other sectors will have to adjust to that of agriculture, by means of variations of the price of their product relative to corn. If r is the rate of profits established in agriculture, w the (corn) rate of wages, and L_i the number of workers employed in the production of commodity i, the price of i in terms of corn will be:

$$p_i = \mathrm{WL}_i(1 + r)$$

where p_i is the only unknown.

In this conception, the production of corn plays virtually the same role as the Standard system in Sraffa's *Production of Commodities* (as Sraffa himself remarks: 1960, p. 93): corn, being the only basic commodity in the system, is also the Standard commodity (only, it is not a *composite* commodity).

The expression 'corn model' is slightly misleading, in that it may easily suggest that in Ricardo's *Essay* we have a one-sector model, whereas there are in it as many sectors as in his *Principles*. (The expression might perhaps more appropriately be employed for those stylized formulations of Ricardo's theory which, though assuming the existence of another sector beside agriculture, have much in common with one-sector models: e.g. Kaldor 1955–6, pp. 211–15; Pasinetti 1960, pp. 6–10). A more appropriate expression would be that employed by Sraffa: 'corn-ratio theory' of profits (Sraffa 1951–73, I, p. xxxiii).

As Sraffa has written, the argument of the physical homogeneity of capital and product in agriculture 'is never stated by Ricardo in any of his extant letters and papers' (ibid., p. xxxi). Sraffa's reconstruction of Ricardo's argument has been questioned, in particular by S. Hollander, in his attempt to revive Marshall's interpretation of Ricardo's theory as an 'incomplete' version of marginalist theory (see Hollander 1973; 1979). It should be said, however, that Hollander does not deny the existence in Ricardo of a 'corn model'; he only denies its relevance in Ricardo's theoretical construction (Hollander 1979, p. 146; for a discussion of Hollander's arguments, see Eatwell 1975; Garegnani 1982).

A 'corn-ratio' theory of profits can be found in quite a few of Ricardo's comtemporaries (Hollander himself notices its existence in Malthus's *Measure of Value*: Hollander 1979, p. 722). The most interesting case is that of Torrens, in whose 1820 *External Corn Trade* a 'cornratio' theory is formulated much more clearly than in Ricardo. The fact that Torrens explicitly avows the Ricardian parentage of this conception, appears as a strong confirmation of Sraffa's reconstruction of Ricardo's argument (see Langer 1982; de Vivo 1985).

Corporate Economy

R. L. Marris

'The Corporate Economy' is a term of art used loosely to refer to the way the economic system of rich industrialized societies evolved after 1900: a system in which a major part of the production side of the economy is organized by large limited-liability corporations whose shares are traded on organized stock markets. The phrase itself was first used openly in this sense in the title of a book edited by R. Marris and A. Wood published in 1971 (Marris and Wood 1971). Associated with it are other terms such as 'The Organizational Revolution' (Boulding 1953), 'The Managerial Revolution' (James Burnham 1941) and more recently 'The Managerial Paradigm'. The last expression is intended to convey a body of ideas amounting to a picture of the world that is both internally consistent and an agenda of questions and answers. As such, the 'managerial' paradigm is clearly distinguished both from the neo-classical paradigm and from a more loosely conceived 'neo' Marxian paradigm. It particularly depends on the proposition that in the large corporation, owing to inherent difficulties for shareholders in monitoring the performance of managers, there is considerable separation between the vicarious role of stockholders, on the one hand, and the control, operating and policy-making roles of management, on the other. This state of affairs was first identified in a classic work published in 1932 by A.A. Berle and Gardner Means (1932).

In reality, the entities involved are diverse in character, and by no means confined to 'independent' or 'private' corporations or companies. They include nationalized industries producing for the market (such representing major elements, for example, in the second half of the twentieth century in the mixed economies of Western Europe), regulated public utilities (e.g. gas or electricity supply) or even, as in Yugoslavia, fairly large 'labour-managed' entities.

Although limited-liability laws were widely promulgated in most of the countries which we now called 'western' from around 1840, by 1910 the largest hundred industrial corporations typically controlled no more than 15% of total industrial value-added (see Prais 1976). Fifty years later, the figure had trebled. In 1890, Alfred Marshall had written 'there are few exceptions to the rule that large firms . . . are, in proportion to their size, inferior to businesses of moderate size, in energy, resources . . . and inventive power' (Marshall 1980). Marshall automatically assumed that all business was family business, ignoring the potentiality of continuing organization. (See e.g. the famous passage comparing firms to 'trees of the forest' in his *Principles*, 1st edition.) Nevertheless, Marshall's characterization of industrial organization remained at the heart of neoclassical economics for the next hundred years. It assumes, almost axiomatically, that the basic economic agents on the production side of the economy, namely firms, must have decreasing returns to scale. By contrast, modern corporations attain gigantic scales with little evidence of increasing internal inefficiency. If returns to scale should be typically *increasing* or even merely constant, however, competitive equilibrium does not exist.

Institutionalist writers such as Thorsten Veblen or John Kenneth Galbraith have ascribed this internal contradiction of the neoclassical system to conspiracy, to defects of the method of economic science or to both. There is some force in either accusation.

It is not the case, however, that the problem has been studied by heterodox economists only.

Since the late 1950s, an increasing number of mainstream writers have addressed the problem. The works of Masahiko Aoki, Robin Marris, Dennis Mueller, Hiroyuki Odagiri, Edith Penrose, Herbert Simon, Hirofumi Uzawa, Oliver Williamson and George Yarrow (alphabetical, not historical, order) may all be cited. Starting from the seminal book of Edith Penrose published in 1959, continuing through the later work of Williamson, Marris and Aoki, a sub-group of these writers have emphasized the significance of *organization* in the emergence of the corporate economy.

In the economic progress of the twentieth century, in contrast to that of the nineteenth century, organization, and especially large-scale organization, has played a major role. The key factor has been the human race's ability to devise means to restrain administrative inefficiency. The proposition that provided it is properly led and organized, a large army will usually beat a smaller army, is as true in the economic as in the military sphere. The typical solution – the organizational hierarchy – is also similar in both spheres. Oliver Williamson (1970) was the first economist to emphasize the significance of the bureaucratic hierarchy in business organization, but the seed of the idea is found in an earlier contribution of Williamson's teacher, Herbert Simon (1957). (The classic conceptualizations of bureaucracy and hierarchy in modern society are, of course, due to the sociologist Max Weber.) More generally, Williamson, in a massive life-work culminating in the publication, in 1985, of his *Economic Institutions of Capitalism*, has contributed to a reconstruction of the theory of the firm to accommodate modern realities. His approach is based on transactions-analysis: the business organization, large or small, is conceived as a hidden structure of implicit contracts, existing on account of the impracticality of competitive economic organization based mainly on explicit contracts. In Williamson's conception the problem of separation of ownership from control is thus an aspect of the general 'agency problem' (control of delegatee by delegator) which then inevitably arises.

Implications of the Paradigm

From the nature of the case, the full implications of a paradigm cannot easily be summarized; if they are not diverse or unanticipated, the paradigm is not a paradigm. Questions especially addressed by the managerial paradigm are the theory of the growth of the firm; the cooperative-game theory of the firm; role of producer organizations in the stimulation of innovation and technical progress; mergers and business concentration; the micro foundations of macro economics; the theory of economic growth.

The Theory of the Growth of the Firm

In the competitive paradigm, firms are neurons of the 'invisible hand'. Like actual neurons, they are not supposed to grow, nor indeed to have any motivation of their own. But in the corporate economy, if producer organizations can and do grow indefinitely, why has not the most successful among them swallowed the whole economy? More generally, *why* and *how* do firms grow? What forces stimulate, or, alternatively, constrain, the process? Is it possible that the standard model of neoclassical micro-theory, where the absolute sizes of firms are endogenous elements in the general solution for prices and quantities in industries and in the economy, can be replaced by a theory in which a similar role is played by the rate of change of size, i.e. by the firm's rate of growth?

Penrose postulated that both stimuli and constraints for growth arose out of the firm's inherent character as an administrative organization. Marris and Uzawa postulated closed models in which the stimuli arose from the internal motives of management, the constraints from external markets for goods, money and shares. The firm could grow faster by devoting more cash-flow to growth-creating activities – such as research and development – but in so doing reduced cash-flow available for dividends. If, thus created, growth was excessive, actual or potential owners of the shares would tend to become sellers, rather than buyers, tend to depress the market price of the

stock, these results tending in turn to invite unwelcome attentions from take-over raiders. This type of model can be, and (especially in the hands of Odagiri 1981) has been, developed to determine all other variables in the theory of the firm: product prices, production technology, research effort, diversification rate and profits.

From Marris onwards, all contributors have awarded the threat of merger a major role, as indicated, in *constraining* management. Mueller (1969), however, suggested that the other side of this coin could be equally significant. Who were the typical raiders? Mueller's answer was that they would be other managerially motivated corporations seeking mergers as a means to satisfy their own ambitions. Mueller (1972) also convincingly demonstrated a 'life-cycle' version of the managerial theory, in which the greatest potentiality for divergence of interest between management and stockholders came at a late stage of the life cycle, when special opportunities were exhausted and stockholders would do better with their money released to invest elsewhere.

Cooperative Theory of the Firm

The 'managerialist' theories, such as those of Marris, Uzawa, Yarrow and Odagiri (historical order), assume that management-controlled firms are governed by managers for the benefit of managers, subject only to *constraints* from shareholders, workers or society. In sharp contrast, Aoki (1984) conceives of high management as arbitrator between the interests of existing employees and existing shareholders. This means that the high management will aim for a solution, which Aoki calls 'organizational equilibrium', that is equivalent to the solution that would be obtained if both sides were perfectly represented by agents who would behave according to the axioms of rational bargaining in game theory (see literature cited by Aoki 1984, pp. 69 et seq.). In general such processes mostly conclude by equalizing each side's proportionate utility gain as compared with the respective expected outcomes if negotiation broke down. The result represents a distribution of *organizational rent*, the latter being the surplus derived by the organization, from society, through possessing specific synergistic human resources. The employees will usually have sufficient bargaining strength to obtain some share in this rent: so the wage will exceed the 'competitive' wage. Thus in the corporate economy, as conceived by Aoki, every business organization is engaged in a general game of monopolistic competition with every other, and each will divide the resulting proceeds in some way between rewarding existing workers, rewarding existing stockholders, and growth. At the micro level, the theory, like Odagiri's, can therefore uniquely determine price, output, wages, dividends, and growth.

Formal 'New' Theories of the Firm

In the managerialist models, the firm is assumed to earn profit in a traditional way from existing activities, but to devote a part of the result to various activities intended to expand its own environment and permit long-term growth without falling profitability. The faster a firm attempts thus to grow, however, the more it is liable to become subject to what has become known as the 'Penrose effect', that is, increased costs and inefficiency caused by internal organizational problems associated with the speed of expansion. The latter costs, together with other developmental costs, are now called generically 'the costs of growth'. Normalized by reference to the size of the firm, they can be represented as an increasing function of the growth rate itself (see Eq. 1 below). For simplicity the resulting models were then formulated as steady-state growth models.

Unlike tangible investment expenditure, in business statistics costs of growth are usually treated as current expenses, deducted from cash flow before reporting profits. Reported profits are therefore operating profits less costs of growth; dividends are reported profits less cash retained for tangible investment in plant and inventory also associated with expansion. Assuming for simplicity that expansion is 100% internally financed

(it can be shown that the assumption is not important), the result (Eq. 2) is a unique relationship between the level of the dividend and the growth rate. However, in steady state, with no new external finance, if the costs of growth are satisfied, growth occurs at a constant operating profit rate, hence, with a constant number of shareholders, the growth rates of assets and of dividends per share are equal. Thus the model generates a relationship, susceptible to *managerial* choice, between level of dividends and growth of dividends. It is then assumed that current dividends and expected growth of dividends (the latter being the equivalent of anticipated capital gains), together determine stock market valuation: Eq. 3 is the standard formula for the present value of a stream of dividends growing to infinity at the rate g, discounted at the rate i, subject to the restriction $g < i$. Hence the end result is a managerial choice between growth rate and stock market value (Eq. 4), now generally known as 'the v-g frontier'.

Management is then envisaged as possessing a utility function (Eq. 5) whose arguments are, in fact, the dimensions of the frontier, the one (growth rate) representing the aspirations for future salary and psychic satisfaction, the other (valuation ratio) the aversion to risk of take-over. If management was motivated to maximize the interests of the stockholders only, caring nothing for growth per se, they would simply use Eq. 4 to maximize valuation; the resulting growth rate would be smaller but not necessarily zero.

The algebra is as follows:

$$p = a - p(g) \tag{1}$$

$$d = \{1 - r\}p = p - g \tag{2}$$

$$\upsilon = d/\{i - g\} - \{p - g\}/\{i - g\} \tag{3}$$

$$\upsilon = \{a - p(g) - g\}/\{i - g\} \tag{4}$$

$$U = U(g, v) \tag{5}$$

where p = profits per unit of assets; g = steady-state proportional growth rate of assets = proxy for growth rate of organization; a = 'operating profit rate' (p under zero growth); $p(g)$ = costs of growth ($p' > 0$); d = dividend per unit of assets; r = profit retention ratio (model assumes 100% internal financing hence $r = g/p$); υ = stock market value of equity shares, per unit of assets ('valuation ratio'); i = rate at which stock market discounts expected future earnings; U = managerial utility (g', $\upsilon' \geq 0$).

The above model was tested, with somewhat negative results, by Cubbin (1986). It has also been criticized on two major theoretical grounds, namely firstly (see Solow 1971) that it can only determine the rate of change, and not the absolute level, of the size of the organization, a weakness which is most marked in applications of micro-economic general equilibrium; secondly that the utility function, and the v-g frontier are not independent (Williamson 1966; Yarrow 1976; Odagiri 1981). The first weakness is self-evident from the equations. The second arises from the fact that the strength of the fear of take-over (which must affect the 'shape' of the managerial U-function) partly depends on the attractiveness of the firm to outsiders, and the latter in turn depends on the maximum value that could be extracted under valuation-maximizing policies – i.e. on the location of the peak of the v-g frontier. In their different contexts, both flaws are serious.

Odagiri (1981) escapes both weaknesses first by marrying the model to a conventional static theory of the firm, with fully specified conventional elements (production function, factor prices etc.) and then by reconstructing the managerial utility-maximizing procedure. For the second stage, he assumes that (a) there is an exogenous 'cost of take over', i.e. premium over current market share price which, owing to capital-market imperfection, must be paid by any raider and (b) that management maximizes discounted expected future salary subject to the hazard of being taken over, i.e. subject to the hazard of employment and salary terminating entirely. As described below, Odagiri's further, major, achievement consisted of aggregating from the micro level, thus modified, to a macro-growth theory.

Similar algebra can also be used to illustrate Aoki's theory. In reviewing Aoki (1984) in a Japanese journal in 1986/1987, Marris suggested

that the real wage in the Aoki theory would become,

$$w = 1/z + s(z - 1) \tag{6}$$

where $z = 1–1/e$, and $e =$ monopolistic competition elasticity of demand. From which it follows (assuming constant returns and no non-labour non-capital inputs) that the operating profit rate is given by (7),

$$a = \{k - w\}/c \tag{7}$$

where $k =$ output per worker and $c =$ capital output ratio. Hence

$$a = f(k, c, z, s). \tag{8}$$

If (8) is substituted into (4) and U re-maximized subject to the reconstituted constraint it seems intuitively likely that the optimum growth rate, and the workers' bargaining share (s) will be negatively related. Aoki confirms rigorously that this is so (1984, pp. 78 et seq). Thus intuitive 'marriage' of Odagiri (see below) and Aoki suggests that other things being equal a corporate economy will grow faster (i) the less the workers' bargaining power; (ii) the less the shareholders' bargaining power (as reflected in take-over conditions); (iii) and the less the competitiveness of the economy as reflected in elasticity of demand! These are classic examples of conclusions from the managerial paradigm that cannot be obtained from the neoclassical paradigm.

General Micro-economics

At the end of the day, the concept of the 'industry' becomes blurred, and the production side of the economic stage becomes inhabited by agile dinosaurs, 'competing' for growth and profits but not necessarily engaging in strong price competition in individual markets. If the domestic economy becomes too small for them, they become multinational. Following a scheme suggested by Marris (1971), we may see an individual economy in this universe as a two-way table in which rows represent named organizations, columns, products or 'markets'. (In the Marshallian terminology, the rows would be 'firms', the columns 'industries'.) Elements in this matrix represent the contribution of a given organization to a given market. In the neoclassical paradigm, there is only one entry in each row (one firm, one industry) and many entries per column (perfect competition). In the corporate economy, there may be a number of entries in a row (any organization may be diversified); but, on account of economies of scale and the instability of competitive equilibrium, there will usually be only a moderate number of entries in columns, i.e. the typical situation is oligopoly.

It follows that the micro-economics of the corporate economy are essentially based on theories of imperfect competition and oligopoly; on this analysis the competitive economy is impossible.

But the matrix is not static. A major part of managerial effort is devoted to efforts to changing it. As a result of R&D, the list of columns (products) changes. As a result of mergers, the list of rows (organizations) changes. The general process needs analyzing by the micro theory of the growth of the firm, and, in turn, contributes to the micro foundations of macro growth economics.

Economic Concentration

In industrial economics it is usual to assess the potential competitiveness of a market by two factors, the proportion of sales controlled by the largest n firms (where n is a number like 4 or 5), and other elements in barriers to entry. In our matrix, 'industrial concentration' is therefore a characteristic of the columns. Entry occurs in the rows; its most likely cause is a previously zero element becoming positive; an existing organization enters a new field. Since existing organizations may well be large, the corporate economy does not reduce, and may increase, this type of competition. Nor does this system necessarily imply any long term tendency for increased average 'column-wise' (i.e. 'within-industry') concentration.

But another form of economic concentration occurs in the *row-totals*. Sometimes known as

'business concentration' or 'macro concentration', this type can be measured by the proportion of industrial output controlled by the *m* largest organizations, where *m* is a number like 100 or 200. That statistic increased sharply in all countries between 1910 and 1960, and is still apparently increasing in Europe. In the US, in the past 20 years, it has apparently been stabilized by new entry into the total organizational population (see Spillberg 1985).

Macro concentration will be the product of two forces: (i) the internal growth of firms (organizations); (ii) mergers. Building on the earlier work of Gibrat (1931) and Prais (1976) developed an elegant application of the theory of Markov chains to show how stochastic disturbance of internal growth rates could produce an automatic tendency towards concentration without invoking any other systematic forces. Marris (1979) married this theory with the theory of the growth of the firm, and also with a managerialist/stochastic model of the merger process, to produce a general theory of concentration. If there are constant returns to scale, in the absence of macro new entry, business concentration will increase at a constant rate through time. With increasing returns, the process is exploding. With decreasing returns, concentration increases at a diminishing rate converging to an asymptote. (Although decreasing returns in respect of absolute size is supposedly ruled out in the managerial paradigm, the same results are also obtained if there are corresponding associations between absolute size and rate of change of size.)

Micro Foundations of Macro Growth Economics

One of the weaknesses of macro-economic growth theory, as it emerged in the aftermath of the Keynesian revolution, lay in depending on a general rate of technological progress which was not only exogenous but unexplained. An advantage of corporate-economy theory lies in being able to explain the growth rate, at least in part, from *within the model*. The proposition was hinted at in the last chapter of Marris (1964) but was not further developed before the appearance of an extremely comprehensive theory published by H. Odagiri in 1981. After refining and synthesizing the micro theory of the growth of the firm, Odagiri elegantly succeeds in aggregating to the economy-wide level, producing a model in which a number of interpretable behavioural or technical variables, together with government-policy variables, such as monetary and fiscal variables, actually determine the growth rate of the economy. The crucial factor is that, in striving for growth of *itself*, an organization *creates* (via induced technical progress) growth for the economy. Two micro factors are keys to Odagiri's macro growth rate; the strength of management's risk aversion when trading fear of take-over with desire for growth-led salary increase; and the institutional ease or difficulty of take-overs. In the second half of the twentieth century, in Japan, on the one hand, under the system of 'life time employment' (informal security of tenure) managers, effectively locked into their firms, were in consequence likely to have comparatively strong growth preference, while on the other hand the organization of the Japanese capital market was not conducive to ease of take-overs. From such facts the managerial theory would predict fast growth of firms and the economy. The neoclassical theory, by contrast, would either have nothing to say, or give the opposite predictions. The actual result was that during this period, the growth rate of Japanese economy was by any standard exceptional; the 'Japanese miracle' may thus be seen as an outstanding achievement of the Corporate Economy.

Corporate Governance

Luigi Zingales

Abstract

Introduced in the mid-1980s, the term 'corporate governance' can be defined as the set of conditions that shapes the *ex post* bargaining over the quasi-rents generated by a firm. The incomplete contracts approach has been very successful in explaining the corporate governance of entrepreneurial firms and also some important features of large corporations, such as allocation of ownership to the providers of capital who are dispersed, and the importance of internal organization. Aspects that remain to be investigated include the role of the board of directors, interaction between different mechanisms of corporate governance, and the normative implications of the approach.

While some of the questions have been around since Berle and Means (1932), the term 'corporate governance' did not exist in the English language until the mid-1980s. Since then, however, corporate governance issues have become important not only in the academic literature but also in public polity debates. During this period, corporate governance has been identified with takeovers, financial restructuring and institutional investors' activism. But what exactly is corporate governance? Why is there a corporate governance 'problem'? Why does Adam Smith's invisible hand not automatically provide a solution? What role do takeovers, financial restructuring and institutional investors play in a corporate governance system?

In this article I will try to provide a systematic answer to these questions, making explicit the essential link between corporate governance and the theory of the firm. My goal is to provide a common framework that helps to analyse the results obtained in these two fields and identify the questions left unanswered. This is not a survey, so I make no attempt to be comprehensive. For an excellent survey on the topic the reader is referred to Shleifer and Vishny (1997).

When Do We Need a Governance System?

The word 'governance' is synonymous with the exercise of authority, direction, and control. These words, however, seem strange when used in the context of a free- market economy. Why do we need any form of authority? Isn't the market responsible for allocating all resources efficiently without the intervention of authority? The basic (neoclassical) undergraduate microeconomics courses rarely mention the words 'authority' and 'control'.

In fact, neoclassical microeconomics describes well only one set of transactions, which Williamson (1985) calls 'standardized'. Consider, for instance, the purchase of a commodity, like wheat. There are many producers of the same quality of wheat and many potential customers. In this context, Adam Smith's invisible hand ensures that the good is provided efficiently without the need of any form of authority.

Many daily transactions, however, do not fit this simple example. Consider, for instance, the purchase of a customized machine. The buyer must contact a manufacturer and agree upon the specifications and the final price. Unlike the case of wheat, the signing of the agreement does not represent the end of the relationship between the buyer and the seller. Producing the machine requires some time. During this time many events can occur, which alter the cost of producing the machine as well as the buyer's willingness to pay for it. More importantly, before the agreement was signed, the market for manufacturers was competitive. Once production has begun, though, the buyer and the seller are trapped in a situation of bilateral monopoly. The customized machine probably has a higher value to the buyer than to the market. On the other hand, the contracted manufacturer has probably the lowest cost, to finish the machine. The difference between what the two parties generate together and what they can obtain in the marketplace represents a quasi-rent, which needs to be divided *ex post.* In dividing this surplus Adam Smith's invisible hand is of no help, while authority does play a role.

In the spirit of Williamson (1985), I define a *governance system* as the complex set of constraints that shape the *ex post* bargaining over the quasi-rents generated in the course of a relationship. A main role in this system is certainly played by the initial contract. But the contract, most likely, will be incomplete, in the sense that it will not fully specify the division of surplus in every possible contingency (this might be too costly to do or outright impossible because the

contingency was unanticipated). This creates an interesting distinction between decisions made *ex ante* (when the two parties entered a relationship and irreversible investments were sunk) and *ex post* (when the quasi-rents are divided). This contract incompleteness also creates room for bargaining.

The outcome of the bargaining will be affected by several factors besides the initial contract. First, which party has ownership of the machine while it is being produced. Second, the availability of alternatives: how costly is it for the buyer to delay receiving the new machine; how costly is it for the manufacturer to delay the receipt of the final payment; how much more costly is it to have the job finished by another manufacturer, and so on. Finally, a major role in shaping the bargaining outcome is played by the institutional environment. For example: how effective and rapid is law enforcement; what are the professional norms; how quickly and reliably does information about the manufacturer's performance travel across potential clients, and so on. All these conditions constitute a governance system.

As illustrated by the machine example, there are two necessary conditions for a governance system to be needed. First, the relationship must generate some quasi-rents. In the absence of quasi-rents, the competitive nature of the market will eliminate any scope for bargaining. Second, the quasi-rents are not perfectly allocated *ex ante.* If they were, then there would be no scope for bargaining either.

Corporate Governance

The above definition of governance is quite general. One can talk about the governance of a transaction, of a club, and, in general, of any economic organization. In a narrow sense, corporate governance is simply the governance of a particular organizational form – a corporation.

Yet the bargaining over the *ex post* rents, which I defined as the essence of governance, is influenced, but not uniquely affected, by the legal structure used. A corporation, in principle, is just an empty legal shell. What makes a corporation valuable is the claims the legal shell has on an underlying economic entity, which I shall refer to as the firm. While often the legal and the economic entity coincide, this is not always the case. For this reason, I define *corporate governance* as the complex set of constraints that shape the *ex post* bargaining over the quasi-rents generated by a firm.

To be sure, many problems that fall within the realm of corporate governance can be (and have been) profitably analysed without necessarily appealing to such a broad definition. Nevertheless, all the governance mechanisms discussed in the literature can be reinterpreted in light of this definition. Allocation of ownership, capital structure, managerial incentive schemes, takeovers, boards of directors, pressure from institutional investors, product market competition, labour market competition, organizational structure, and so on can all be thought of as institutions that affect the process through which quasi-rents are distributed. The contribution of this definition in simply to highlight the link between the way quasi-rents are distributed and the way they are generated. Only by focusing on this link can one answer fundamental questions such as who should control the firm.

Of course, this definition of corporate governance raises the age-old question of what a firm is. But this question should be central to corporate governance. Before we can discuss how a firm should be governed, we need to define the firm. This question is also important because it helps us identify to what extent, if any, corporate governance is different from the governance of a simple contractual relationship (such as in the machine example).

There are two main definitions of the firm available in the literature. The first, introduced by Alchian and Demsetz (1972), is that the firm is a nexus of contracts. According to this definition, there is nothing unique in corporate governance, which is simply a more complex version of standard contractual governance.

The second definition, due to Grossman and Hart (1986) and Hart and Moore (1990) (henceforth GMH), is that the firm is a collection of physical assets that are jointly owned. Ownership matters because it confers the right to make

decisions in all the contingencies unspecified by the initial contract. On the one hand, this definition has the merit of differentiating between a simple contractual relationship and a firm. Since the firm is defined by the non-contractual element (that is, the allocation of ownership), corporate governance (as opposed to contractual governance) is defined by the effect of this non-contractual element. Not surprisingly, the focus of the corporate governance literature since the mid-1990s has been the allocation of ownership (hence this literature is called the property rights view of the firm). On the other hand, this definition has the drawback of excluding any stakeholder other than the owner of physical assets from being important to our understanding of the firm.

More recently, Rajan and Zingales (2001, 1998) have proposed a broader definition. They define the firm as a nexus of specific investments: a combination of mutually specialized assets and people. Unlike the nexus of contracts approach, this definition explicity recognizes that a firm is a complex structure that cannot be instantaneously replicated. Unlike the property rights view, this definition recognizes that all the parties who are mutually specialized belong to the firm, be they workers, suppliers or customers. While this definition does not necessarily coincide with the legal definition, it does coincide with the economic essence of a firm: a network of specific investments that cannot be replicated by the market.

Incomplete Contracts and Governance

In an Arrow–Debreu economy it is assumed that agents can costlessly write all state- contingent contracts. As a result, all decisions are made *ex ante* and all quasi-rents are allocated *ex ante*. Thus, there is no room for governance. More surprisingly, even if we relax the assumption that every state-contingent contract can be written and admit that certain future contingencies are not observable (and thus not contractible), we still find no room for governance as long as one can costlessly write contracts on all future observable variables.

Recall the example of the customized machine, and assume that the manufacturer's effort is unobservable to others and is, therefore, not contractible. The neoclassical approach to this problem is to design a mechanism (hence the term 'mechanism design'), contingent on all publicly observable variables, which provides the manufacturer with the best possible incentives to exert effort. Myerson (1979) shows that all optimal mechanisms are equivalent to a revelation (direct) mechanism in which the agent (manufacturer) publicly announces his information and receives compensation contingent on his announcement. An important consequence of this result is that, in the mechanism design approach, delegation (giving an agent discretion over certain decisions) is always weakly dominated by a fully centralized mechanism, where all decisions are made *ex ante* by the designer. The mechanism design approach reproduces several distinguishing features of an Arrow–Debreu economy: all decisions are made *ex ante* and executed only *ex post*; as a result, all conflicts are resolved and all rents are allocated *ex ante.* This leaves no room for *ex post* bargaining. All these features are incompatible not only with my definition of governance, but also with any meaningful (that is, related to the sense in which this term has been used) definition of governance. This is best illustrated with two examples.

One of the crucial questions in corporate governance concerns the party in whose interest corporate directors should act. In the mechanism design approach this question cannot even be raised. All possible future conflicts are resolved *ex ante* and the initial contract specifics how directors will behave in any observable state of the world. However, since this question is raised all the time, it must be that all possible conflicts are not resolved *ex ante.*

Second, the mechanism design approach avoids renegotiation: the initial contract is so designed that the agents do not want to renegotiate. As a result, the designer wants to make renegotiation as inefficient as possible: this reduces the costs of providing incentives to the agents with no efficiency costs, since renegotiation never occurs in equilibrium (Aghion et al. 1997).

If this result were to be taken seriously, the optimal public policy approach would be to preserve any inefficiency in the system in order to avoid destroying its beneficial incentives *ex ante.* In reality, though, the jurisprudential approach is completely different. For example, courts do not support punitive damages that are considered excessive with respect to the issue at stake.

Only in a world where some contracts contingent on future observable variables are costly (or impossible) to write *ex ante* is there room for governance *ex post.* Only in such a world are there quasi-rents that must be divided *ex post* and real decisions that must be made. Finally, only in a world of incomplete contracts can we define what a firm is and discuss corporate governance as being different from contractual governance. Not surprisingly, the theory of governance is intimately related to the emergence and evolution of the incomplete contracts paradigm.

A fundamental milestone in this evolution is the residual rights of control concept introduced by Grossman and Hart (1986). In a world of incomplete contracts, it is necessary to allocate the right to make *ex post* decisions in unspecified contingencies. This residual right is both meaningful and valuable. It is meaningful because it confers the discretion to make decisions *ex post*. It is valuable because this discretion can be used strategically in bargaining over the surplus.

Why Does Corporate Governance Matter?

By definition, corporate governance matters for distribution of rents, but to what extent does it matter for economic efficiency? There are three main channels through which the conditions that affect the division of quasi-rents also affect the total surplus produced. In presenting these channels I make a sharp distinction between *ex ante* (when specific investments need to be sunk) and *ex post* (when quasi-rents are divided) effects, as though the firm lasted just one period. Of course, this is not true in reality because *ex post* considerations of one period are mixed with *ex ante* considerations for the next period.

Ex Ante *Incentive Effects*

The process through which surplus is divided *ex post* affects the *ex ante* incentives to undertake some actions, which can create or destroy some value, in two main ways.

First, rational agents will not spend the optimal amount of resources in value- enhancing activities that are not properly rewarded by the governance system. In fact, one goal in designing a governance system is to motivate those investments that are not properly rewarded in the marketplace. The canonical example of how a change in the governance structure can change the incentives to make a value- enhancing relationship-specific investment is the Fisher Body case. In the early 1920s, Fisher Body (an auto body manufacturer) refused to locate its plants close to General Motors' plants in spite of the obvious efficiency improvement generated by such a move. Locating close to GM would have reduced Fisher Body's ability to supply other car manufacturers, which would have weakened its bargaining position *ex post* and possibly reduced its share of the quasi-rents generated by the relationship with GM (see Klein et al. 1978). A change in the governance system (the acquisition of Fisher Body by GM) eventually led to the efficient plant location decision. Another famous illustration of the same phenomenon is managerial shirking. A manager will shirk if her *ex post* bargaining payoff does not increase sufficiently with her effort and, therefore, fails to compensate her for the cost of this effort.

Second, rational agents will spend resources in inefficient activities whose only (or main) purpose is to alter the outcome of the *ex post* bargaining in their favour.

For example, a manager may specialize the firm in activities she is best at running because this increases her marginal contribution *ex post* and, thus, her share of the *ex post* rents (Shleifer and Vishny 1989). Interestingly, this problem is not limited to the top of the hierarchy, but is present throughout. Subordinates, who do not have much decision power, will waste resources trying to capture the benevolence of their powerful superiors (Milgrom 1988). Even the well-known tendency of managers to overinvest in growth can be interpreted as a manifestation of

this problem. Managers like to expand the size of their business because this makes them more important to the value of the firm and, thus, increases the payoff they can extract in the *ex pest* bargaining.

Of course, a governance system might promote or discourage these activities. For example, Chandler (1966) reports that, under the Durand reign, GM's capital allocation was highly politicized ('a sort of horse trading'). The move to a multidivisional structure, with the resulting increase in divisional managers' autonomy, reduced the managers' payoff from rent-seeking. Similarly, Milgrom and Roberts (1990) explain many organizational rules as a way to minimize influence costs. Finally, Rajan et al. (2000) argue that inefficient 'power-seeking' is more severe the more investment opportunities a firm's divisions have. Consistent with this claim, they find that the value of a diversified firm is negatively related to the diversity of the investment opportunities of its divisions.

Thus, a governance system affects the incentives to invest or seek power, altering the marginal payoffs that these actions have in *ex post* bargaining. For instance, for an independent Fisher Body, the marginal effect on the bargaining payoff of localizing its plants close to GM is negative (it reduces the value of its outside options), but is positive for Fisher Body as a unit of GM, which does not have the authority to supply other manufacturers without GM's consent (see Rajan and Zingales 1998). Thus, a different ownership structure alters the incentives to make specific investments.

Inefficient Bargaining

A second channel through which a governance system affects total value is by altering *ex post* bargaining efficiency. This is tantamount to saying that the governance system affects the degree to which the assumptions of the Coase theorem are violated. A governance system, therefore, can affect the degree of information asymmetry between the parties, the level of coordination costs, or the extent to which a party is liquidity constrained.

For example, if control rights are assigned to a large and dispersed set of claimants (like the shareholders of most publicly traded companies), free-rider problems may prevent an efficient action from being undertaken even if property rights are well defined and perfectly tradeable (Grossman and Hart 1980). Alternatively, the allocation of control rights can affect efficiency by determining the direction in which a compensating transfer must be made. The direction of the transfer matters when one of the parties to the *ex post* bargaining is liquidity constrained (Aghion and Bolton 1992) or when it faces a different opportunity to invest these resources productively rather than in power-seeking activities (Rajan and Zingales 1996). In both cases an efficient transaction may not be agreed upon – in the first case because the party that should compensate does not have the resources, in the second case because the transaction (while efficient *per se*) may generate such an increase in wasteful power-seeking as to more than offset its benefits.

To this standard list of imperfections, Hansmann (1996) adds the divergence of interests among the parties who have control rights. Citing the political economy literature, Hansmann argues that *ex post* inefficiency is increasing in the divergence of interests among control holders. For example, he argues that allocating control to workers is more costly when they differ in their professional skills, hierarchical position and tenure. While Hansmann does not provide a formal model of why this relation occurs, he does provide very compelling evidence that in practice control rights are rarely allocated to parties with conflicting Interests. His conjecture is intriguing because there is no well-established general theory of how different governance systems lead to different levels of *ex post* inefficiency. There is little doubt, however, that these inefficiencies exist and are important. For example, Wiggins and Libecap (1985) document that an excessively dispersed initial allocation of drilling rights leads to an inefficient method of extracting oil, with estimated losses as big as 50 per cent of the total value of the reservoir.

Risk Aversion

Finally, a governance system might affect the *ex ante* value of the total surplus by determining the level and the distribution of risk. If the different parties have different degrees of risk aversion (or different opportunities to diversify or hedge risk), then the efficiency of a governance system is also measured by how effectively it allocates risk to the most risk-tolerant party. This idea is the cornerstone of Fama and Jensen's (1983a; 1983b) analysis of organizational structure and corporate governance.

Different governance systems can also *generate* a different amount of risk. Suppose, for instance, that the total amount of surplus generated is constant. It is still possible that the payoff of each party is stochastic, if the governance structure generates a stochastic bargaining outcome. For example, a life insurance contract written in nominal dollars creates a pure gamble between the policy holders and the insurance company with respect to the future rate of inflation. This additional 'governance' risk (in this case created by the contract, in general created by the governance structure) reduces the value of the total surplus, if the parties are risk averse and cannot diversify away the risk.

In summary, the objectives of a corporate governance system should be: (*a*) to maximize the incentives for value-enhancing investments, while minimizing inefficient power seeking; (*b*) to minimize inefficiency in *ex post* bargaining; (*c*) to minimize any 'governance' risk and allocate the residual risk to the least risk averse parties.

Who Should Control the Firm?

To show the utility of the framework developed thus far, I will use it to address one of the most controversial issues in corporate governance: who should control the firm? In particular, I will analyse it with regard to the first of the three above objectives of a corporate governance system. For an analysis focused on the second objective the reader is referred to Hansmann (1996), and for an analysis focused on the third to Fama and Jensen (1983a, b).

As far as the first objective is concerned, the allocation of control is important because it affects the division of surplus. By controlling a firm's decisions, a party can ensure for itself of more and more valuable options without the collaboration of the other parties. This guarantees the controlling party a larger share of the surplus within the relationship. Thus, in the framework outlined above, the question of who should control the firm can be rephrased as: whose investments need more protection in the *ex post* bargaining? Again, the answer to this question is indissolubly linked to the underlying theory of the firm.

In the nexus of contracts view, the firm 'is just a legal fiction which serves as a focus for the complex process in which the conflicting objectives of individuals . . . are brought in equilibrium within a framework of contractual relationship' (Jensen and Meckling 1976, p. 312). Thus, according to this view each party is fully protected by its contract with the exception of the shareholders, who accept a residual payoff because they possess a comparative advantage in diversifying risk.

As a result, shareholders need the protection insured by control.

While widely popular, this explanation is unsatisfactory. The contractual protection provided to the parties involved in the nexus of contracts is complete only if contracts are complete. But if contracts are complete, then the statement that shareholders are in control is meaningless. In fact, in a world of complete contracts all the decisions are made *ex ante*, and thus shareholders are no more in control than are the workers: everything is contained in the initial grand contract. Furthermore, as I have already argued in Section 3, this conclusion is inconsistent with the existence of a debate on what a company should do.

Alternatively, if contracts are incomplete, then the argument that all other parties are fully protected by their contractual relationships does not automatically follow. In fact, in this context one should ask why shareholders need more protection than other parties to the nexus of contracts. I return to this issue below.

In the property rights view of the firm, the reason why shareholders should be in control is straightforward. Control is allocated so as to maximize the incentives to make human capital-specific investments. The owner of the firm will generally be the worker with the most expropriable investment. In other words, the property rights approach does not deal with outside shareholders and, thus, it applies only to entrepreneurial firms.

Outside of the GHM framework, the typical justification for why shareholders (or more generally the providers of finance) are in control is based on a combination of three arguments. Shareholders need more protection because: (a) their investment is more valuable; (*b*) other stakeholders can protect their investments better through contracts; (*c*) other stakeholders have other sources of power *ex post* that protect their investments. Of the three arguments, the first is clearly unfounded. Reviewing the empirical evidence on the return on specialized human capital, Blair (1995) estimates that the quasi-rents generated by specialized human capital are as big as accounting profits, which are likely to overestimate the quasi-rent generated by physical capital. Hence, there is no ground for dismissing human capital investments as second order to physical capital investments.

The second argument is harder to dismiss. Since we lack a fully satisfactory theory of why contracts are incomplete, we cannot easily argue which contracts are more incomplete. Nevertheless, it is hard to argue that human capital investments are easier to contract than physical capital investments. If there is one contingency that is easily verifiable, it is the provision of funds. Thus, it is not obvious why providers of funds are at a comparative disadvantage.

The most convincing argument is probably the third. As Williamson (1985) puts it,

> the suppliers of finance bear a unique relation to the firm: The whole of their investment in the firm is potentially placed at hazard. By contrast, the productive assets (plant and equipment; human capital) of suppliers of raw material, labor, intermediate product, electric power, and the like normally remains in the suppliers' possession.

Thus, the other stakeholders have a better outside option in the *ex post* bargaining, and they do not need the protection ensured via the residual rights of control.

Even this argument, however, is not fully satisfactory. In fact, it suggests only that the suppliers of finance should have some form of contractual protection – it does not necessarily imply that they should be protected via the residual rights of control.

A satisfactory explanation of why the residual right belongs to the shareholders can be obtained only in a theory of the firm that explicitly accounts for the existence of different stakeholders, and models the interaction between contractual (for example, ownership) and non-contractual (for example, unique human capital investments) sources of power. An attempt in this direction is made by Rajan and Zingales (1998).

To understand the argument, note that the residual right of control over an asset always increases the share of surplus captured by its owner (who has the opportunity to walk away with the asset), but it does not necessarily increase her marginal incentive to specialize. If, as is likely, a more specialized asset has less value outside the relationship for which it has been specialized, then specialization decreases the owner's outside opportunity and,; thus, her share of the quasi-rents. Owning a physical asset, then, makes an agent more reluctant to specialize it. As a result, the residual right of control is best allocated to a group of agents who need to protect their investment against *ex post* expropriation, but who have little control over how much the asset is specialized.

Consider now the different members of the specific investments nexus that makes up the firm. Most of the specific investments which form this nexus are in human capital and, therefore, can neither be contracted nor delegated *ex ante.* Granting the residual right to any of these members will have a negative effect on their incentive to specialize. By contrast, since the provision of funds is easily contractible, funds will be provided in the optimal amount as long as their providers receive sufficient surplus *ex post*. Thus, allocating the residual rights of control to the providers of funds has the positive effect of granting them enough surplus *ex post*, while avoiding the

negative effect of reducing their marginal incentives.

Once they have provided funds, however, financial investors might be reluctant to use these funds for very specialized projects, for fear of seeing their share of the return fall. Thus, it is optimal that, while retaining a residual right of control over the assets, the providers of funds delegate the right to specialize the assets to a third party, who does not internalize the opportunity loss generated by this specialization. This third party, thus, should not be in the position of a mere agent, who owes a duty of obedience to the principal, but should be granted the independence to act in the interest of the firm (that is, the whole body of members of the nexus of specific investments), and not only of the shareholders. Blair and Stout (1997) claim that this is the role American corporate law attributes to the board of directors.

In sum, a broader definition of the firm allows us to understand why the residual right of control is allocated to the providers of capital and why its use is mostly delegated to a board of directors.

Normative Analysis

An interesting, and largely unexplored, application of the incomplete contract approach to corporate governance is the analysis of its normative implications. In a world of complete contracts, such analysis has limited scope. A benevolent social planner would be unable to improve the *ex ante* allocation reached by private contracting, because this will achieve the constrained-efficient outcome. *Ex post*, the outcome might be inefficient, but that inefficiency is always part of the written contract and needs to be preserved to maintain *ex ante* future efficiency. By contrast, in a world of incomplete contracts, there is ample scope to analyse both *ex ante* and *ex post* efficiency.

First, a privately optimal governance system may not be socially efficient. In fact, a world of incomplete contracts generates some incentives to 'arbitrage power' through time. Consider an entrepreneur, who has immense bargaining power today, but anticipates losing it in the near future. If she could write all the contracts she could succeed in extracting all the present and future surplus arising from a relationship without any distortion. But, if some contracts cannot be written, then the entrepreneur has an incentive to distort her choices so as to transfer some of her bargaining power today into the future, enabling her to capture some of the future surplus as well. This is the idea underlying the choice of ownership in Zingales (1995a) and Bebchuk and Zingales (1996), and of the hierarchical structure in Rajan and Zingales (2001). It can also be used to provide a rationale for the existing mandatory rules (see Bebchuk and Zingales 1996).

Second, in a world of incomplete contracts one can discuss the welfare effects of different institutions. For example, in a world of complete contracts the type of legal system a country adopts is irrelevant, as long as private contracts are enforced. By contrast, it is at least conceivable that in an incomplete contract world it may have a significant effect. This is intriguing because empirically it has been shown that legal institutions have an effect on the appropriability of quasi-rents by outside investors (Zingales 1995b), on the way corporate governance is structured (La Porta et al. 1996), and on the amount of external finance raised (La Porta et al. 1997).

Finally, the incomplete contract approach generates a potential role for government intervention *ex post*. Unlike in the mechanism design approach, in an incomplete contract world *ex post* inefficiency is not necessarily desirable *ex ante.*

Thus, a selective intervention that eliminates *ex post* inefficiency, while preserving the distributional consequences sought *ex ante,* will improve welfare.

Limitations of the Incomplete Contract Approach

While the incomplete contracts approach to corporate governance has brought tremendous insights to the corporate governance debate, it has two weaknesses.

First, its predictions for the optimal allocation of ownership are extremely sensitive to what

contracts can be written. Consider, for instance, the plant localization problem discussed above. If no contracts can be written, then – according; to the property rights approach – Fisher Body (who makes the bigger specific investment) should own the asset. However, if General Motors could credibly commit through a contract to buy all its car bodies from Fisher Body (as it did), then giving ownership to Fisher Body will confer too much power on it, and, thus, it is optimal for General Motors to own the asset (Hart 1989), Thus, who should have the residual right of control depends crucially upon what the contractable rights are. But this is very difficult to argue on a priori grounds without a general theory of why contracts are incomplete (see Maskin and Tirole 1997).

Second, this approach relies heavily (as does the complete contract approach) on the agents anticipating all future possible contingencies (Hellwig 1997). This requirement can be reasonable when the subject of analysis is a small entrepreneurial firm, but it loses credibility when it is applied to large publicly held companies formed decades ago. Can we really interpret the capital structure of IBM today as the outcome of the design by Charles Flint (its founder) in 1911 attempting to allocate control optimally? Hart (1995) argues that the 'founding father' interpretation is simply a metaphor for the capital structure that a manager will choose under the pressure of the corporate control market. Yet Novaes and Zingales (1995) show that the two approaches lead to different predictions, not only about the level of debt but also about its sensitivity to the cost of financial distress and times. Thus, in the current state of knowledge, the *ex ante* approach to the capital structure of non- entrepreneurial companies lacks theoretical foundations.

Summary and Conclusions

In this article I have tried to summarize the results obtained by applying the incomplete contracts approach to corporate governance. In a world where all future observable contingencies can be costlessly contracted upon *ex ante*, there is no room for governance. By contrast, in an incomplete contracts world, corporate governance can be defined as the set of conditions that shapes the *ex post* bargaining over the quasi-rents generated by a firm. A governance system has efficiency effects both *ex ante*, through its impact on the incentive to make relationship-specific investments, and *ex post*, by altering the conditions under which bargaining takes place. A governance system also affects the level and the distribution of risk.

The incomplete contracts approach has been very successful in explaining the corporate governance of entrepreneurial firms. It can explain how ownership is allocated and how capital structure is chosen. By contrast, it is difficult for this approach to cope with the complexity of large publicly traded complies.

Nevertheless, recent contributions in the area are able to account for some important features of large corporations: allocation of ownership to the providers of capital who are dispersed, and the importance of internal organization.

Many aspects, however, remain to be investigated. First and foremost is the role of the board of directors. The second is the interaction between the different mechanisms of corporate governance. While we have many models that describe how each mechanism works in isolation, we know very little about how they interact. The effects are not obvious. For example, debt and takeovers are generally thought, in isolation, to be two instruments that reduce the amount of quasi-rents appropriated by management. But the use of debt may crowd out the effectiveness of takeovers, increasing rather than decreasing managerial rents (Novaes and Zingales 1995). Third, the normative implications of this approach deserve more attention. In a world of incomplete contracts, privately optimal governance can be inefficient *ex ante* and *ex post*. Of course, this is only a theoretical possibility, whose relevance needs to be assessed in the data. The most important contribution, however, will arise from a development of the underlying theory. Without a better understanding of why contracts are incomplete, all the results are merely provisional.

Corporate Law, Economic Analysis of

Robert Daines and Michael Klausner

Abstract

Economic analysis of corporate law largely focuses on (*a*) the efficiency of legal rules and the proper role of the law, (*b*) the ways in which legal rules affect shareholders' ability to monitor managers, and (*c*) the effect of limited liability on the relationship between the corporation and third parties. This article reviews the literature in each of these areas.

The economic analysis of corporate law focuses primarily on publicly held corporations. Following Coase (1937), the corporation is conceptualized as a nexus of contracts. Because corporate law focuses primarily on the authority of management and its obligations to shareholders, the primary 'contract' of interest is that between management and shareholders. The content of the manager–shareholder contract is conceptualized in terms of the agency-cost model of Jensen and Meckling (1976), with management viewed collectively as agent, and shareholders viewed collectively as principal. Ideally, the terms of the manager–shareholder contract minimize agency costs and thereby maximize the value of the firm.

Most of the economics-oriented corporate law literature can be divided into three areas, all of which focus on the United States. First, there are papers that analyse the economic forces by which corporate law is created by states and adopted by firms, and the proper role of corporate law in light of those forces. Second, there are papers that analyse particular monitoring mechanisms that law creates – shareholder voting, shareholder lawsuits, takeovers. A third set of papers analyses the basic features of a corporation, focusing on limited liability.

This review will discuss these three sets of papers. We do not address the substantial literature on law and finance that suggests that a country's corporate law rules may affect its financial markets and economic growth (see La Porta et al., 1997, 1998; and Rajan and Zingales, 1998). Nor do we address corporate governance strategies, such as CEO pay, that are largely independent of corporate law.

The Role of Corporate Law

Economics-oriented scholarship on the role of corporate law can be roughly divided into two generations. The first generation, which spanned the period from the late 1970s to the mid-1990s, tended to reach the conclusion that market forces would yield socially optimal corporate governance outcomes. The second generation spans the period from the mid-1990s to the present. This generation, which includes more empirical work than the first, has painted a less perfect picture of the relationship between market forces and socially optimal corporate governance (see Klausner, 2006).

First-Generation Scholarship

The central insight of the first generation of economics-oriented corporate law scholarship was the conceptualization of the public corporation as a contractual arrangement between

managers and shareholders. This insight has its origin in Coase (1937). It was developed within the agency cost framework in Jensen and Meckling (1976), and extended to the analysis of corporate law by Easterbrook and Fischel (1989, 1991). Although managers and shareholders do not negotiate governance arrangements, the price mechanism for a company's shares in an initial public offering (IPO) is expected to serve the same function, just as it does in other markets where buyers and sellers do not explicitly negotiate contracts. Consequently, the legally enforceable elements of the corporation's governance structure are viewed as the product of a market-mediated contracting process. Scholars writing in this framework therefore argue that firms' governance structures tend to minimize the agency costs associated with the separation of ownership and control, and thereby maximize the value of the corporation.

Legally enforceable governance commitments can take either of two forms. First, firms select the corporate law rules that govern the rights of shareholders and the obligations of management. Each of the 50 US states has enacted corporate law rules. Firms are free to elect to be governed by any of these rules, regardless of where they do business. To be governed by any state's legal rules, a firm need only incorporate in that state at the time of its IPO. Subsequent disputes between managers and shareholders will then by the decided according to the corporate law of that state. A firm cannot change its state of incorporation unless its board of directors and shareholders holding at least a majority of its shares agree. Second, pre-IPO manager/shareholders must draft a charter that will govern the corporation once it goes public. A charter begins as a blank slate and can include any governance arrangements that a firm's pre-IPO shareholders choose to adopt. To a substantial degree, the law allows a firm's charter to override provisions of corporate law. Thus, corporate law rules are often simply default rules that can be superseded by a corporation's charter terms.

Thus, one insight of this first generation was that corporate law was a product that states produce and firms consume. Winter (1977) was the first to argue that states are engaged in a 'race to the top' to produce corporate law that would tend to minimize agency costs. In order to obtain revenues from franchise fees and to create business for their local lawyers, states were expected to offer corporate law (that is, default rules) that would maximize the value of many firms and thereby save firms the trouble of customizing their own charter terms. Romano (1985) provided empirical evidence consistent with the proposition that a race to the top was occurring. She found, however, that Delaware had already achieved a substantial lead and questioned whether the race would actually make it to the top. The argument that market forces would produce legally enforceable governance commitments that would minimize agency costs stood in contrast to an earlier claim by Cary (1974) that states were engaged in a 'race to the bottom' to create legal rules that appeal to management at the expense of shareholders.

Second-Generation Scholarship

The second generation of scholarship has cast both empirical and theoretical doubt on the contractarian claims described above.

Empirical Findings

A central claim of the contractarian conception of the corporation and corporate law is that corporations are heterogeneous in their corporate governance needs – hence the value of atomistic contracting. Empirical studies have now shown, however, that there is a high degree of uniformity in firms' governance commitments at the time they go public.

Daines (2002) found that, between 1978 and 2002, 50 per cent of firms incorporated in Delaware, and that during the second half of this period over 70 per cent of firms incorporated in Delaware. More importantly, however, Daines found that, among firms that did not incorporate in Delaware, nearly all incorporated in the state in which they were headquartered – whatever that state happened to be. Bebchuk and Cohen (2003) and Kahan (2006) confirmed Daines's findings.

These findings regarding incorporation decisions have three implications. First, the decision to incorporate in one's home state (when no out-of-state firms incorporate there) cannot be motivated primarily by the content of a state's laws. Something else must be at work. Daines's findings suggest that this choice may be made by the firm's local lawyer, hoping to keep the firm's business following the IPO, or by management wanting access to the state legislature if it needs a law passed. Romano (1987) found that most state anti-takeover legislation enacted in the 1980s was initiated by in-state management seeking protection from hostile bids. Bebchuk and Cohen (2003) found that states seem to retain more home-state incorporations if they already have state anti-takeover statutes on their books, but Kahan (2006) refuted this finding. Kahan did find, however, that states with very low-quality corporate law retained fewer home-state incorporations than did other states.

Second, these findings imply a high degree of uniformity in the governance commitments reflected in a firm's incorporation decision. Firms that focus on the quality of corporate law choose Delaware law. This uniformity casts some doubt on the contractarian assumption that firms are heterogeneous in their governance needs. Alternatively, the findings may suggest that there is value in uniformity itself, a point addressed below. Either way, there is evidence that the choice of Delaware as a state of incorporation enhances firm value. Romano (1987) and Daines (2001) found evidence consistent with this conclusion. Subramanian (2004) argues that this is a small-firm effect.

Third, the findings on incorporation choices cast doubt on the proposition that states compete to attract incorporations – whether racing to the top or to the bottom, Delaware seems to be the only state competing. This is what Kahan and Kamar (2002) find in a study of states' efforts, or lack thereof, to attract incorporations and to earn revenues from them.

Empirical research has also revealed a high degree of uniformity in corporate charters. These supposed vehicles of customized contracting and innovation turn out to be fairly empty vessels. The only dimension on which they vary is in that of takeover defences (Klausner, 2006), and variability in that respect sits uneasily with the proposition that IPO charters maximize firm value. Three studies by Daines and Klausner (2001), Field and Karpoff (2002) and Coates (2001) have shown that firms commonly go public with charters providing for staggered boards, which are an effective anti-takeover defence that tends to reduce share value.

Theoretical Challenges to the Contractarian Framework

It is possible that the contractarians overstated their premise that firms are heterogeneous in their governance needs. When it comes to legally enforceable governance commitments, perhaps one size fits all.

There are theoretical reasons, however, to doubt that homogeneous governance needs explain the uniformity described above. The essentially complete absence of customization or innovation in corporate charters suggests there are market imperfections in the contracting process. There has been no lack of innovation in corporate governance since the mid-1980s. None, however, originated in a corporate charter. Innovation at the firm level has taken the form of unilateral adoption of governance structures – for instance, an independent board or separation of CEO and chair – with no legally binding commitment to maintain those structures. The absence of legally binding commitments suggests that the cost of legal enforcement plays some role in the relative emptiness of corporate charters. While there have been innovations in legally enforceable governance mechanisms, they have not occurred at the level of the individual firm charter or even state law, as the contractarian thesis predicts. Instead, they have occurred, for better or worse, through Securities and Exchange Commission (SEC) regulation and federal statute (Sarbanes–Oxley Act, described below).

Klausner (1995, 2006) and Kahan and Klausner (1996) posit that there are learning and network externalities associated with state corporate law and corporate charter terms. As a result of these externalities, commonly used governance

mechanisms have value independent of their intrinsic content; they tend to be better understood and less uncertain in their application than customized mechanisms. These externalities may thus explain the attraction of Delaware and the lack of customization or innovation in corporate charters.

In this context learning externalities take the form of judicial precedents interpreting and applying legal rules, and lawyers' familiarity with these precedents. Because many firms have been incorporated in Delaware, there is a large body of Delaware precedent. As a result, there is less uncertainty regarding how a legal rule will be applied. This may make Delaware valuable because firms have adopted it in the past.

Future judicial interpretations are valuable as well. The larger the number of firms that use the same legal rule or charter term over time, the more the rule or term will be litigated in the future, and the more frequently it will be interpreted. As Hansmann (2006) explains, the alternative would be periodic charter amendments, which could be difficult to accomplish because of the need to have a majority of shareholders and the company's board agree. Consequently, the market dynamic by which firms choose a state of incorporation can be expected to mirror that of product markets in network industries. The equilibrium in those industries can be socially suboptimal uniformity, which may be what is reflected in the attraction of Delaware incorporation and the 'plain vanilla' charter – that is, a charter with no customization that adopts essentially all default rules.

Kahan and Klausner (1996) offer two additional explanations of uniformity in charter terms and incorporation choices. One is that lawyers who draft charters on behalf of their corporate clients may be exhibit the same sort of individually rational herd behaviour that Scharfstein and Stein (1990) and Zwiebel (1995) model for agents such as money managers. These models are based on reputational payoffs to winning or losing with or without the herd. The second explanation relies on results in psychological experiments that reveal a 'status quo' bias, an 'anchoring' bias and a 'conformity' bias in other settings.

Law-Intensive Monitoring Mechanisms

Corporate law creates three monitoring mechanisms and influences a fourth. First, corporate law gives shareholders the right to vote for the board of directors and to approve certain major changes, such as a change to the firm's charter or a merger or sale of the firm. Second, corporate law specifies managers' duties to shareholders and provides a way for shareholders to collectively sue management for its failure to fulfil these obligations. Third, corporate law regulates the takeover process, which allows a poorly run firm to be acquired by a third party. Finally, US federal securities law imposes mandatory disclosure obligations on publicly held firms, which facilitates each of these monitoring mechanisms and enables non-legal monitoring mechanisms (such as the press).

Shareholder Voting

Corporate law gives control of the firm to the board of directors. Shareholder influence over managers comes from their right to elect the board and their implicit (or explicit) threat to vote out incumbent directors. Board elections are held annually and shareholders frequently have the ability to call interim elections. Today, voting is also the means by which control over firms changes hands in a takeover (Gilson and Schwartz, 2001).

Shareholders' ability to oust directors is thus an important check on managerial misbehaviour. The primary limitation on the effectiveness of the shareholder vote is economic rather than legal: shareholders' collective action problems. Individual shareholders with small stakes may not find it worthwhile to become informed and therefore typically either fail to vote or simply vote with management.

An important question is whether institutional investors, by virtue of their larger stakes, will solve the collective action problem and monitor managers more effectively. Money managers, pension funds, mutual funds, banks, insurance companies, and hedge funds all aggregate large pools of equity capital and may be more effective monitors. Rock (1991) and Romano (1993) give

some reason to be cautious about their impact, however. They point out that the interests of money managers sometimes conflict with those of other shareholders. Banks, pension funds and insurance companies may side with incumbent managers if doing so gives them other opportunities to profit by managing the firm's pension funds, making loans or selling other services. Index funds have different disincentives to monitor. They compete on cost, and activism would increase their costs. Public pension funds are frequently active in pressuring managers, but these funds are run by political appointees and may favour politically popular proposals unrelated to firm value. Thus, the empirical evidence suggests that institutional shareholder activism has had only weak effects on firm performance (see, for example, Romano, 2001).

Others, focusing on the rules that govern shareholder ownership and voting, are also cautious about the potential impact about institutional investors. Roe (1994) and Black (1992) argue that shareholder passivity and collective action problems are created not solely by economic forces but also by politically motivated legal constraints that limit the institutional shareholder's incentives and ability to check incumbent managers. In this political view of shareholder passivity, a variety of banking, insurance and financial regulations prevent institutional investors from owning larger stakes or from monitoring managers more closely.

More recently, hedge funds have begun to aggregate large blocks of stock and to use their voting power to influence firm policies. Some investigate whether hedge funds have interests that conflict with other shareholders, which would suggest that hedge fund activism should be regulated (see Kahan and Rock, 2007; and Hu and Black, 2006). The alternative view is that hedge funds' large stakes and relative freedom from regulatory restrictions allows them to overcome collective action problems and to monitor managers.

Shareholder Suits

The law provides mechanisms by which shareholders can collectively sue managers for mismanagement. As a means of controlling agency costs, however, shareholder suits are flawed. Because most shareholders will gain little from a successful lawsuit, shareholders often have no incentive to initiate or monitor these suits. Unless a major institutional shareholder is involved as lead plaintiff, lawyers initiate the suits, pay all costs, make litigation decisions, including settlement decisions, and collect a fee if the plaintiff class collects. To the extent the lawyer's interests diverge from the interests of the shareholders, agency costs are present on the plaintiffs' side of these lawsuits.

On the defendants' side, the familiar agency costs are present. Managers can use corporate funds to protect themselves – appropriately in some cases and inappropriately in others. They use corporate funds to purchase directors' and officers' liability insurance, which covers their personal liability and defence costs, unless they are proven to have engaged in deliberate fraud or the equivalent. Management can also use corporate funds to settle suits. Alexander (1991), Macey and Miller (1991), Coffee (1985, 1986), Romano (1991), Bohn and Choi (1996), among others, have argued that meritorious suits against management settle too easily, and that the prospect of settlement encourages frivolous suits.

The result of this battle of agents is nearly always a settlement in which the corporation and/or its directors' and officers' liability (D&O) insurer are the sole sources of payments. Consequently, payments go from shareholder to shareholder either directly or via insurance companies through premiums. Unless these suits deter mismanagement, the net winners are the lawyers on both sides. The shareholders in the aggregate are net losers (see Arlen and Carney, 1992; Langevoort, 1996; Mahoney, 1992; Easterbrook and Fischel, 1985).

Without commenting on the merits of these suits, Black, Cheffins and Klausner (2006) found only 13 cases, out of several thousand filed since 1980, in which outside directors have made personal payments. Inside managers bear personal liability more often, but settlement dynamics leave their assets untouched in all but a handful of cases per year (Alexander, 1991).

Consequently, there is a question whether these suits have a significant deterrent effect.

The Public Securities Litigation Reform Act of 1995 (PSLRA) created several mechanisms designed to deter the filing of non-meritorious suits and to deter early settlement of meritorious suits. For instance, the law empowered the courts to select a lead plaintiff to monitor the shareholders' lawyer, with a presumption favouring institutional shareholders with substantial shareholdings. The law also requires a court to dismiss a suit unless the plaintiffs have alleged particular facts that support a 'strong inference' that a violation of the securities laws was committed with the legally required intent. This requirement was directed at the reported practice by which lawyers would file suits simply because a company's shares took a sharp drop in price, and then force the company into an expensive discovery process.

Ever since its enactment, scholars have tried to assess the impact of the PSLRA on securities class actions. Event studies, on the whole, have indicated that the law had a positive impact on share prices (Spiess and Tkac, 1997; Johnson et al. 2000a; Johnson et al. 2000b). However, Ali and Kallapur (2001) found that the legislation had a negative impact on share prices. Studies have also tended to show that the PSLRA reduced the filing of non-meritorious suits (Johnson et al. 2000b; Bajaj et al. 2003). Others suggest, however, that some meritorious suits are deterred as well (Choi, 2007; Sale, 1998).

Choi et al. (2005), Thomas and Cox (2006) and Perino (2006) have shown that, while private institutional shareholders have not assumed the role of lead plaintiff, public pension plans have assumed that role to some extent. Perino (2006) found evidence consistent with monitoring by public pension plans.

Market for Corporate Control

The market for corporate control in the United States is regulated by state and federal law and is an important check on agency costs. If a firm is run poorly, either because managers are inattentive, consume too many perks or miss profitable merger opportunities, it may become the target of a takeover and its managers replaced. An active market in corporate control thus gives managers incentive to increase firm value (Manne, 1965).

In a 'hostile takeover' a buyer attempts to purchase a large block of stock, use its voting power to oust incumbent managers, purchase the remaining shares, and replace management. Alternatively, in the shadow of a hostile takeover, managers can agree to a 'friendly merger'. Both are associated with large gains to target shareholders. The evidence generally suggests that the premium comes from improvements in firm performance (see Andrade et al. 2001; Romano, 1992).

The law and economics literature has focused on three questions. First, what should managers do when the firm becomes the target of a hostile takeover? Easterbrook and Fischel (1982, 1991) argue that target management should remain passive and that the law should prohibit them from resisting a takeover. They argue that resistance will reduce bidder returns and thus bidders' incentive to engage in takeovers. This will in turn reduce the disciplinary threat of takeovers and increase agency costs generally. Gilson (1982) and Bebchuk (1982) argue that managers should resist a takeover attempt to the extent necessary to hold an auction, which will assure that the assets of the firm end up in their highest valued use.

A second question involves whether managers' negotiating over a potential merger should be allowed to grant termination fees or 'lock-ups' to favoured bidders. Such measures may discourage competition and affect the outcome of an auction, raising the risk that managers will favour particular bidders in exchange for private benefits, such as job security. Ayres (1990) and Fraidin and Hanson (1994) argue that termination fees and lock-ups will often not change the outcome of the auction and should therefore not be disfavoured. Kahan and Klausner (1996) examine how termination fees and lock-ups affect bidders' incentives to make a bid in the first place and their impact on agency costs generally. They explain that there is no reason for a target to grant a termination fee greater than a bidder's cost of making a bid.

Finally, a large literature examines whether, on average, takeover defences help or harm

shareholder wealth. The typical research strategy examines how a firm's stock price reacts to the adoption of a takeover defence (see, for example, Comment and Schwert, 1995). This strategy usually suffers from a fatal flaw: it ignores the fact that the most potent defence, the 'poison pill', is freely available to all firms even after a hostile bid is received. Therefore, in effect, all firms have a poison pill and most other takeover defences are relatively unimportant. To disable a poison pill, a hostile bidder must first wage a proxy fight to unseat incumbent managers, install new managers who can remove the poison pill, and then go forward with the merger. The only takeover defences that are relevant other than a poison pill are those that either prevent an acquirer from replacing a target board or delay an acquirer's effort to do so. The most common defence is a classified (or staggered) board, which prevents an acquirer from taking control of a target board for two annual election cycles (see, for example, Daines, 2006; Faleye, 2007; Coates and Subramanian, 2002). Dual class stock, which is rarely used, allows management to control the election of the board and can therefore prevent an acquisition altogether.

A related literature examines whether firm takeover defences and shareholder rights predict stock returns (see, for example, Gompers et al. 2003; Cremers and Nair, 2005).

Mandatory Disclosure

The monitoring mechanisms described above all depend, in part, on informed shareholders. Shareholder monitoring (of the kind contemplated by voting, law suits and the market for corporate control) is more effective when investors are informed. Thus, in many ways, the central regulatory event in US financial history was probably the 1933 and 1934 Acts, which created the Securities and Exchange Commission and required that publicly traded firms disclose detailed information about their historical performance and financial condition. These rules force firms both to disclose what they would otherwise prefer to keep private and to keep private information they might otherwise wish to disclose.

It is easy to see why disclosure might be valuable to investors. Accurate information allows investors to price securities and to monitor managers' performance. It is less easy to see why disclosure rules must be mandatory. Firms that fail to disclose will find it hard to raise money, as investors may take silence for bad news and refuse to invest (Ross, 1979; Grossman, 1981; Milgrom, 1981). Therefore, firms and entrepreneurs may find it in their own interest to disclose information, whether or not it is required by law.

However, firms would not always find full disclosure to be in their interest. Disclosure imposes direct costs as firms produce and verify the information, as well as indirect costs if competitors, customers and others can use the information to the firm's disadvantage. Moreover, the costs and benefits of disclosure are likely to vary between firms. Left to their own devices, therefore, firms will commit to varying levels of disclosure. Some therefore argue that markets can sort out the costs and benefits of disclosure and believe that uniform and mandatory disclosure requirements are unnecessary and even harmful (Romano, 2005; Mahoney, 1997; Choi and Guzman, 1997). Others believe that there are externalities from a firm's disclosures and that a mandatory rule may therefore be socially beneficial (Easterbrook and Fischel, 1991; Coffee, 1984; Dye, 1990; Admati and Pfleiderer, 2000).

Empirical evidence has not conclusively resolved this debate. Stigler (1964), Benston and Cohen (1969); Benston (1973) and Simon (1989), report evidence that mandatory disclosure did not improve investor welfare, but may have changed the characteristics of firms that go public. Recent evidence examines the effect of mandatory disclosure on firm returns and on asymmetric information (see Greenstone et al. 2006; Daines and Jones, 2007).

A related debate involves whether managers should be allowed to trade on non-public information. Some hold that trading by informed insiders reveals valuable information and reduces agency costs (Manne, 1966; Carlton and Fischel, 1983). Others argue that insider trading is inefficient (Cox, 1986; Kraakman, 1991) or reduces stock market liquidity (Goshen and

Parchomovsky, 2000). Beny (2007) reviews international evidence.

Creditors and the Corporation

Because the corporation is a legal entity, distinct from its shareholders and managers, shareholders in the firm have 'limited liability' in that they are generally not personally liable for the debts of the corporation. At worst, public shareholders can lose their equity in the firm if the firm becomes insolvent.

This separate legal status gives rise to two issues. First, because shareholders will reap the upside of the firm's successes but will not bear the full downside of its failures, managers may promote the interests of shareholders at the expense of creditors (Jensen and Meckling, 1976). The legal rule of 'veil piercing' developed to respond to this problem, though to a very limited extent. Under extreme circumstances in which a corporation is undercapitalized and other conditions are met, a court may impose liability on the corporation's shareholders. As a practical matter, however, this rule is not applied to public companies' shareholders, and in the private company context the courts' application of this rule is notoriously unpredictable (Thompson, 1991).

The rule of limited liability makes sense for contract creditors, who can negotiate their own protection from default or charge and interest rate that compensates for the risk. Tort creditors, however, are different. Those owed compensation for, say, a firm's pollution emissions, will not have had the opportunity to negotiate with the firm *ex ante* to address the possibility that it will not have sufficient net assets to pay them. Thus, to deter corporate management from externalizing costs in the form of accidents and other torts and to prevent excess investment in risky activities, Hansmann and Kraakman (1991) argue that it may be desirable, and practical, to hold public shareholders personally liable for a corporation's torts. Grundfest (1992) and Alexander (1992) disagree as to the practicality of this proposal.

A second issue involving limited liability is the use of the corporate form to 'partition' assets to create separate pools of assets to bond separate debts and other contractual commitments. Hansmann and Kraakman (2000) explain how the partitioning of assets to separately bond the commitments of the corporate entity, individual shareholders and corporate entities within a group of affiliated corporations can promote efficiencies in creditor monitoring.

Sarbanes–Oxley Act of 2002

The Sarbanes–Oxley Act of 2002 (SOX) introduced sweeping corporate governance mandates on firms whose shares trade on US securities exchanges. Until this legislation, legal rules regarding substantive corporate governance were the province of US state law, and federal law was limited primarily to disclosure requirements. SOX imposed a series of federal requirements on the board operation and structure. Event studies of various legislative events leading to the enactment of SOX yielded mixed results. Li et al. (2004), Jain and Rezaee (2006), and Chhaochhaira and Grinstein (2004) show a positive reaction, but Zhang (2005) shows a negative reaction. Litvak (2007) finds a negative reaction by comparing foreign cross-listed firms subject to SOX with cross-listed firm not subject to SOX. Aggarwal and Williamson (2006) found that six of the governance structures mandated by SOX (all related to board independence) had a positive impact on share value when adopted by firms voluntarily prior to SOX. Romano (2005), on the other hand, looked at other SOX requirements (loans to officers, executive certification of financials, auditors' provision of non-audit services, and audit committee independence) and reports that there is no evidence to support their value to shareholders. Linck et al. (2006) find that whatever the benefit of SOX, it increased the cost of boards, especially for small firms.

Corporations

Randall Morck

Abstract

A corporation is an artificial person with many of the rights of a biological one. The first business corporations pooled the savings of many individuals to permit ventures on a scale none could afford individually. Most large American and British corporations lack controlling shareholders; the consequent lack of monitoring and

control gives rise to corporate governance problems reflecting the private benefits of control. The view that corporations should be run to maximize shareholder conflicts in many countries with the actual legal duties of corporate officers, and collides with evidence that stock prices are sometimes set by investors with incomplete information.

A *corporation* is an artificial person, with many of the legal rights of a biological one. This modern legal and economic usage arose in the 16th century from the term's now archaic meaning of 'a group acting as one body' – encompassing municipal governments, businesses and other groups of individuals united towards a common goal. In that century and the next, trade with the Orient and the New World promised immense returns, but only after vast capital outlays on fleets of ships, networks of forts and private armies to defend them. The first business corporations, such as the Dutch East Indies Company, the British East India Company and the Hudson's Bay Company, were formed to pool the savings of many individuals and permit ventures on a scale none could afford individually. Each owner of a *share* of the corporation was periodically entitled to a *dividend* – a pro rata division of the corporation's free cash flow.

Polling all a corporation's shareholders for each business decision was impractical in an age of sailing ships and horse-drawn carriages. Instead, the shareholders elected *boards of governors* (later *directors*) – reputable men trusted by the majority of shareholders to direct the corporation's affairs.

This did not prevent all dispute. The Dutch East Indies Company (*Vereenigde Oostindische Compagnie* in Dutch) was formed as a limited time venture. When that limit drew near, the board boldly announced that the corporation would persist indefinitely. The shareholders sued to force a liquidating dividend – and lost! Fortunately, they found they could sell their shares to other investors for the value of a liquidating dividend – or even more (Frentrop 2002/3). Thus was born the first modern stock market, and the *alienability,* or unhindered sale, of shares became a defining characteristic of a corporation. Letting shareholders realize their investments by selling their shares, rather than liquidating the business, gave corporations a second defining characteristic: *indefinitely long lives.*

Boards occasionally betrayed their shareholders' trust and caused a corporation to contravene the law. Since individual shareholders were not consulted, holding them fully to account for the corporation's misdeeds seemed wrong. Since the corporation is a legal person, plaintiffs could sue it directly, and need not sue its shareholders personally. Thus, *limited liability* statutes came to shield individual shareholders from personal lawsuits for wrongs by corporations whose shares they own. Limited liability, a third defining characteristic of the modern business corporation, is an important innovation because it frees individuals to invest their savings in corporations run by strangers, undertaking risky ventures, or doing business in far off places. Vulnerability to personal lawsuits would otherwise make such investments seem indefensibly reckless to most savers.

Early corporations, like the Hudson's Bay Company, assigned one vote to each share in board elections. This essentially let the wealthiest shareholders appoint the board and, if they wished, run the corporation in their narrow interest rather than in the interests of all shareholders equally. For example, a large shareholder might force the corporation to do business with another corporation she controlled on disadvantageous terms. This sort of self-dealing, which (Johnson et al. 2000) dub 'tunneling', remains a widespread corporate governance concern where firms typically have dominant shareholders. Or a dominant shareholder might simply relish the perks, power and prestige of running the corporation, and

refuse to make way for more qualified managers – a corporate governance problem called 'entrenchment' (Morck et al. 1988). Entrenchment and tunnelling provide controlling shareholders with *private benefits of control* – returns not shared with small shareholders (Dyck and Zingales 2004). Distorted corporate governance associated with private benefits of control remains a first-order governance concern wherever corporations typically have a controlling shareholder. According to (La Porta et al. 1999), this includes the large corporate sectors of virtually all countries except Germany, Japan, the United Kingdom and the United States. Small and middle-sized corporations everywhere tend to have controlling shareholders.

In the 19th century, *democratic* corporate governance became associated with *one vote per shareholder,* rather than one vote per share (Dunlavy 2004). Echoes of this remain in the *voting caps* of modern Canadian and European corporations, which limit any single shareholder's voting power regardless of shares owned. However, large shareholders in many countries later turned deviations from one vote per share to their advantage by granting themselves special classes of common stock with many votes per share. In most countries, such *dual class shares* now virtually always magnify, rather than limit, the voting power of large shareholders, and so amplify, rather than dampen, problems associated with private benefits of control (Nenova 2003).

In the United States and the United Kingdom, however, one vote per share is the norm in shareholder meetings. Disclosure rules, regulatory oversight, officer and director liability, and other restraints on private benefits of control also seem more effective in America and Britain than elsewhere in curtailing private benefits of control (La Porta et al. 1999; Dyck and Zingales 2004). This makes being a large shareholder less attractive, especially if holding a diversified portfolio of small stakes in many firms reduces risk (Burkart et al. 2003). Unsurprisingly, most large American and British corporations now lack controlling shareholders (La Porta et al. 1999). They are run by professional managers who often own few shares (Morck et al. 1988).

A small shareholder who monitored and controlled these corporate top managers would bear all the investigative, legal and administrative costs involved, but the benefits of better governance would be spread across all shareholders. The cost therefore typically exceeds the benefit for any small shareholder acting alone (Grossman and Hart 1988). The consequent general lack of monitoring and control in corporations with no large shareholder gives rise to *other people's money* corporate governance problems. Adam Smith (1776) famously explains that, since corporate managers who own few or no shares are more

> the managers of other people's money than of their own, it cannot well be expected that they should watch over it with the same anxious vigilance with which partners in a private copartnery frequently watch over their own. Like the stewards of a rich man, they .. . . consider attention to small matters as not for their master's honour and very easily give themselves a dispensation from having it.

Unmonitored professional managers can thus enjoy the perks and privileges of running large corporations without any real concern for the returns they generate. Berle and Means (1932) argue that this sort of governance problem occurs in many large American corporations.

But in other countries, other people's money governance problems probably also afflict many corporations that, on first inspection, seem to have a controlling shareholder. This is because large corporations in most countries are not freestanding entities, but belong to *corporate groups* (La Porta et al. 1999). These are typically pyramidal structures, in which an apex shareholder, usually an extremely wealthy family, controls one or more listed corporations, which each control more listed corporations, which each control yet more listed corporations, *ad valorem et infinitum.* A family that controls 51 per cent of a listed corporation that controls 51 per cent of another that controls 51 per cent of yet another and so on actually owns only 0.51^n of the corporation n tiers down the in pyramid, with the remainder of each corporation financed by public or minority shareholders. Pyramids with a dozen or more layers are not uncommon, rendering the controlling shareholder's actual ownership of corporations at the

pyramid's base negligible. Pyramidal business groups thus permit controlling shareholders to extract private benefits of control from corporate empires financed largely from other people's money (Morck et al. 2000; Bebchuk et al. 2000). Pyramids were common in the United States until the 1930s (Berle and Means 1932; Bonbright and Means 1932), but were eliminated by various New Deal initiatives, including the double and multiple taxation of inter-corporate dividends (Morck 2005). British pyramids apparently withered under sustained attacks from institutional investors (Franks et al. 2005). However, the relevant unit of economic analysis for many purposes elsewhere in the world should often be the *business group,* not the corporation.

Jensen and Meckling (1976) show that *agency costs,* the present value of the costs of expected future governance shortfalls of any sort, are born by the corporation's initial shareholders. A corporation's founders receive less per share when they first sell shares to outside investors if worse corporate governance problems seem likely.

This gives rise to a *time inconsistency* problem in securities and corporations law. Investors and entrepreneurs selling shares to the public benefit from credible guarantees of good governance because these limit agency costs and so raise share prices. But top corporate decision makers in firms that have already issued shares, who foresee issuing no more, wish to maximize their utility (Baumol 1959, 1962; Williamson 1964) and understandably value the freedom to spend public shareholders' money as they like and to capture such private benefits of control as they can. Actual public policy probably reflects these groups' relative political lobbying power, which can change over time (Morck et al. 2000, 2005).

The normative view that a corporation *should* be run to maximize shareholder value derives from economists' assumption that firms maximize profits. In neoclassical economic theory, a firm that maximizes the present value of all its expected future economic profits necessarily maximizes the market value of its shares. This follows from modelling the corporation as a *nexus* of contracts, with the shareholders the *residual claimants* to the firm's cash flows (Fama and Jensen 1983a, b). Neoclassical theory further allows that profit maximization (value maximization in a multi-period setting) accords with economic efficiency under certain idealized conditions; see, for example, (Varian 1992) and (Malliaris and Brock 1983).

This normative view conflicts with the actual legal duties of corporate officers, directors and controlling shareholders in many countries. For example, many northern European countries and some US states impose a duty to balance shareholders' interests with those of *stakeholders,* especially employees. This is formalized in the German legal principle of *Mitbestimmung* (co-determination), which requires members of the *Aufsichtsrat* (supervisory board) of a large corporation to balance the interests of shareholders, employees and the state (Fohlin 2005). Common law legal systems assign officers and directors a duty to act *for the corporation.* In Britain and the United States, this is often interpreted as a duty to act for the corporation's owners, its shareholders. A duty to maximize share value seems implicit (Jensen and Meckling 1976; Black and Coffee 1997). However, the Canadian Supreme Court holds in *Peoples v. Wise* that the duty of the officers and directors of a corporation is not to shareholders, nor to any other stakeholders, but to the corporation per se. The social welfare implications of assigning different legal duties to corporate top decision makers are incompletely understood. Giving labour a voice in corporate decision making seems to impede risk taking and hamper growth (Faleye et al. 2006). Moreover, regardless of their assigned objective, if those entrusted to govern great corporations occasionally put their own interests ahead of their legal duties, agency costs must arise in some form.

The view that a corporation's top managers ought to maximize shareholder value also collides with evidence that stock prices are sometimes set by investors with incomplete information (Myers and Majluf 1984) or behavioural biases (Shleifer 2000). Coase (1937) argues that firms come about to alleviate information asymmetries and other

market imperfections, collectively denoted *transactions costs,* and that the boundaries of the firm correspond to an efficient solution to these problems. (Alchian and Demsetz 1972) argue that the critical market imperfections arise from people working in teams. (Williamson 1975) argues that interdependent assets are more generally important. Jensen (2004) calls for more research on normative theories about the boundaries of the corporation and the objective function of its top decision makers if stock prices are set by *noise traders,* that is, investors with behavioural biases. One approach holds that corporations actually exist primarily to lock the economy's capital into productive uses by isolating capital allocation decisions from maniac or panicked investors (Stout 2004). This view long dominated discussions of corporate management in Japan (for example, Aoki and Dore 1994) but appears to give rise to its own set of inefficiencies (see, for example, Morck and Nakamura 1999).

Corporatism

Joseph Halevi

Corporatism is a set of political doctrines aimed at organizing civil society on the basis of professional and occupational representation in chambers called Estates or Corporations. It maintains that class conflict is not inherent in the capitalist system of production and ownership relations. Corporatism has its ideological roots mainly in 19th-century French and Italian Catholic social thought, as well as in German romanticism and idealism. Corporative ideas can be found in eminent European thinkers. Hegel, in his *Philosophy of Right*, thought of a corporate structure in which the Estates constituted the link between civil society and the State (Hegel 1821). In France, Durkheim put forward a view of corporatism specifically related to the division of labour engendered by modern industry. According to Durkheim, the Corporations' task is to diversify at the level of each industry the general principles of industrial legislation formulated by the political assemblies (Durkheim 1893).

The Catholic strand appeared first as a response to the social cleavages stemming from the industrialization of Europe. It advocated a return to the corporate form of guild associations of the Middle Ages, which it romantically viewed as based on social harmony. In 1891 the papal encyclical Rerum Novarum took a more reformist approach. It rejected the notion that 'class is naturally hostile to class, and that the wealthy and the working men are intended by nature to live in mutual conflict' (Rerum Novarum 1891; in Camp 1969, p. 81). At the same time it recognized the legitimacy of independent worker's unions, although preference was given to the creation of a single organization embracing employers and employees. In practice the Catholic movement opted for the first variant, partly because the industrialists rejected the idea of a single organization and partly because of the strength of the Socialist-led unions.

Where politics were concerned, in countries like Italy and Germany, the Catholics gradually reconciled their corporative social views with parliamentarism. In other instances, the Catholic movement aimed at supplanting parliamentary institutions altogether. In Austria, for example, the alliance between the Social Christians and the fascist Heimwehr was the basis of the corporative Constitution passed before the assassination of Chancellor Dolfuss, in 1934.

Germany produced an important theoretician of corporatism: Karl Marlo. He wrote a comprehensive critique of liberalism in favour of Estate organizations (Marlo 1885). His views are a reaction to the radicalization of the working class, which led to the 1848 Revolution. In that year, Marlo proposed to the Frankfurt Parliament that it form a social chamber composed by the representatives of all occupations whose task would be to formulate the social legislation to be approved by the political chamber.

Modern corporatism begins with the idealist jurist and Italian nationalist Alfredo Rocco. In his conception corporatism was an instrument for fostering the productive power of the nation. He considered the Estates to be merely organs of the State.

Italian fascism absorbed Rocco's views from its inception, although it combined them with elements of Catholic corporatism as well as with aspects of the doctrine of revolutionary syndicalism held by Georges Sorel (Togliatti 1970). The syndicalist component was eliminated in 1926 when Rocco, who had become Mussolini's Minister of Justice, legally recognized the fascist unions only, banning all the others in existence. Under the pressure of the employers' association, Italian Confederation of Industry, shop floor committees, which the syndicalists wanted to retain, were also outlawed. The Italian corporative state was institutionalized when in 1927 a labour charter (Carta del Lavoro) was promulgated and, in 1934, a law was issued establishing 22 Estates. In 1939 their 500 delegates formed the Camera dei Fasci e delle Corporazioni, which replaced the Chamber of Deputies.

Italy's corporative state did not coordinate economic activity. Instead, it enabled the Government to control labour relations by making tutelage over the newly created labour unions legal. It enforced arbitration tribunals formed by a judge and two experts, thereby excluding any kind of worker representation even from the fascist unions (Salvemini 1936; Rossi 1955).

The rescue operations to save the Banca Commerciale which led to the formation in 1933 of the state-holding IRI (Institute for Industrial Reconstruction) are to be linked to the impact of the Depression on the endemic banking crisis in Italy rather than to any corporative economic programme. Already in 1922, Piero Sraffa pointed out that the frequent crises of Italy's banking system were caused by the fact that bank's activities were based on lending short while borrowing long. Sraffa showed that this was a structural characteristic of the Italian economy (Sraffa 1922). The Depression magnified the above tendencies and the Government found itself compelled to intervene on an unprecedented scale.

The corporative juridical structure only played an indirect economic role. It legalized, as part of the Estates, a very subordinate form of unionism, while allowing the employers to struggle – within the Estates – for the creation of Consortia which, once approved, become compulsory (Rossi 1955). Here there is both a similarity and a difference vis-à-vis the German case. The National Socialist regime pursued a policy of forced cartelization – an objective shared by many industrial groups well before 1933 – but not through a legal system of a syndicalist, corporative character. Workers were organized in a completely separate body called the Labour Front (Neumann 1944; Kuczynski 1945).

The juridically more complete nature of Italian corporatism became a reference for populist movements in South America. One important example is the Estado Novo established in Brazil under President Getulio Vargas in the years 1937–46. Following the Italian pattern a Labour Charter was issued. The decree-laws of 1939 legalized government prerogatives over labour unions, which were exercised by the Ministry of Labour.

Unlike Italy, Brazilian corporatism allowed the emergence of strong reformist demands. Although labour relations were governed by norms which prevented the formation of alliances between different groups of workers, the process leading to the corporative state marked also the appearance of formal unionism. Hence in Brazil during the liberal phase (1946–64) populist forces were capable of using institutions designed to control the working class for the purpose of giving political power to labour leaders (Erickson 1977). Yet the strengthening of corporatism came from the conservative forces themselves, which after the coup d'état of 1964 tightened the controls over labour organizations.

The main element of modern corporatism consists in a detailed network of technical and juridical norms, enforced by ministerial bodies, aimed at controlling the labour movement. A formal system of Estates had either an incidental character (Italy) or was never implemented.

The economic views of the main advocates of corporatism have never reached an analytical dimension. During the 1930s in Italy some discussion took place around the issue of home corporativus versus *homo oeconomicus* (Mancini et al. 1982).

Correspondence Principle

Federico Echenique

JEL Classifications

D5

The correspondence principle is the relation, which exists in certain economic models, between comparative statics of equilibria and the properties of out-of-equilibrium dynamics.

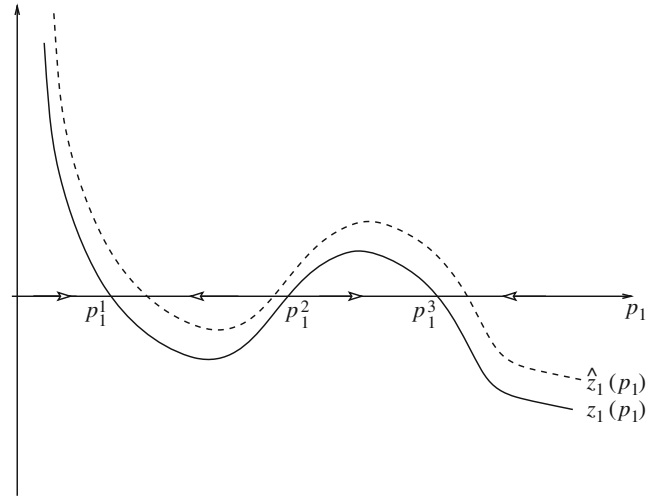
The correspondence principle (CP) implies that one obtains unambiguous comparative statics by selecting equilibria with desirable dynamic properties. Generally, the CP determines comparative statics in models with a one-dimensional endogenous variable, and in monotone multidimensional models. It does not determine comparative statics in general multidimensional models, such as Walrasian general equilibrium models with more than two goods.

One-Dimensional Models

The CP holds quite generally in one-dimensional models. Consider, for example, a two-good economy with excess-demand function for good 1 given by z_1, shown in Fig. 1. We fix the price of good 2; by Walras's Law the equilibrium prices are the zeroes of z_1: there are three equilibria, p_1^1, p_1^2 and p_1^3.

Now consider the comparative-statics exercise of shifting excess demand up to $\hat{z}_1$. What is the effect on equilibrium price? Locally, the price increases if the equilibrium is p_1^1 or p_1^3, but it decreases if it is p_1^2. The different comparative statics at p_1^1 and p_1^2 corresponds exactly to the different behavior of tâtonnement dynamics after a small perturbation: p_1^1 is stable while p_1^2 is unstable.

The difference between comparative statics at p_1^1 and at p_1^2 is easy to explain. The comparative statics at p_1^1 says: slightly larger prices than p_1^1 are reached by increasing excess demand, and smaller prices are reached by decreasing excess demand. Since excess demand is zero at p_1^1, there must be *positive* excess demand at slightly larger prices and *negative* excess demand at slightly smaller prices. Hence, tâtonnement dynamics, which respond to the sign of excess demand, converges to p_1^1 after a small perturbation from p_1^1. On the other hand, at p_1^2 larger prices result from a decrease in excess demand; hence excess demand is positive at larger prices. Similarly, excess



Correspondence Principle, Fig. 1 Two-good economy

demand is negative at smaller prices. As a result, tâtonnement dynamics will not approach p_1^2 after a small perturbation from p_1^2.

If the economy is subject to sporadic shocks, one should not observe p_1^2, the unstable equilibrium. Hence, as a consequence of the correspondence between comparative statics and dynamics, one should expect an increase in excess demand to produce an increase in equilibrium price.

I shall give a general statement of the correspondence principle for the one-dimensional case. Consider a model where the endogenous variable takes values in [0, 1] and equilibria are determined as the fixed points of $f(\cdot, t)$: $[0, 1] \to [0, 1]$; $t \in T \subseteq R$ is an exogenous parameter. Assume that T is convex and that f is C^1.

A *selection of equilibria* is a function $e : T \to [0,1]$ such that $e(t) = f(e(t), t)$ for all $t \in T$. Say that a fixed point $x \in [0, 1]$ is *stable* if there is a neighbourhood V of x such that any sequence x_n satisfying $x_0 \in V$ and $x_{n+1} = f(x_n)$ for $n \geq 1$, converges to x. Say that $x \in [0, 1]$ is *unstable* if, for any neighbourhood V of x, there is a neighbourhood W of x such that all sequences defined as above eventually lie in the complement of W.

Proposition 1 *Let f be monotone increasing in t. If e is a continuous selection of equilibria that is strictly decreasing over some interval $[\underline{t}, \overline{t}]$, then for all $t \in (\underline{t}, \overline{t})$, $e(t)$ is unstable.*

Multidimensional Models

The one-dimensional CP is a relation between the sign of the comparative-statics change in prices, and the sign of excess demand for smaller and larger prices. When more than one price is determined, this relation does not need to exist. Still, the CP holds for monotone models – models where the different dimensions of the endogenous variables are in some sense complements. Monotone economic models stem mainly from game theoretic models with strategic complementarities.

I proceed to give a statement of the CP. Consider a model where the endogenous variable takes values in a compact rectangle $X \subseteq R^n$, and equilibria are determined as the fixed points of $f(\cdot, t) : X \to X; t \in T \subseteq R$ is a parameter and T is convex.

Proposition 2 *Let f be monotone increasing in (x, t) and let e be a continuous selection of equilibria.*

- *If e is strictly decreasing over $[\underline{t}, \overline{t}] \subseteq T$, then for all $t \in (\underline{t}, \overline{t})$, $e(t)$, is unstable.*

- *If e is strictly increasing over $[\underline{t}, \overline{t}]$, then for all $t \in (\underline{t}, \overline{t})$, if $e(t)$ is locally isolated, it is stable.*

Literature

The CP was formulated by Paul Samuelson (1941, 1942, 1947), who also coined the term (though Hicks 1939, stated the CP informally). Samuelson formulated the onedimensional CP. The version in Proposition 1 is taken from Echenique (2000).

Bassett et al. (1968) study the scope of the CP. Arrow and Hahn (1971) present a critical discussion of the CP, and, because it fails in economies with more than two goods, conclude that 'very few useful propositions are derivable from this principle'. The monotone multidimensional CP is from Echenique (2002), who presents a general version of Proposition 2. Echenique (2004) presents a CP that does not rely on continuous selections of equilibria. The CP is also effective in dynamic optimization models (Brock 1983; Burmeister and Long 1977; Magill and Sheinkman 1979) and in models of international trade (Bhagwati et al. 1987).

Correspondences

M. Ali Khan

Abstract

Correspondences are versatile mathematical objects for which a rich theory can be developed. They arise naturally in many diverse areas of applied mathematics, including economic theory. For example, an individual consumer's demand correspondence associates with each price system the set of utility maximizing consumption plans. Similarly, an individual producer's supply correspondence associates with each price system the set of profit-maximizing production plans. These individual responses are correspondences rather than functions because of the constancy of marginal rates of substitution in consumption and in production over a range of commodity bundles.

Keywords

Berge's maximum theorem; Brouwer's fixed point theorem; Correspondences; Functions; Kakutani's fixed point theorem; Lyapunov's theorem

A correspondence Q from a domain set X to a range set Y associates with each element x in X, a non-empty subset of Y, $Q(x)$. A *function* is a correspondence such that $Q(x)$ is a singleton for each x in X. It is for this reason that a correspondence is also termed a *multi-valued function* or, more simply, a *multi-function*. Another name for a correspondence is a *set-valued mapping*.

Correspondences arise naturally in economic theory. One may think of an individual consumer's demand correspondence, which associates with each price system the set of utility maximizing consumption plans; see, for example, Hildenbrand (1974, p. 92). An equally pervasive example is an individual producer's supply correspondence which associates with each price system the set of profit- maximizing production plans (see, for example, Arrow and Hahn 1971, pp. 54–5). The fact that these individual responses are correspondences rather than functions is simply a consequence of 'flats' in the underlying indifference surfaces and isoquants or, more precisely, of the constancy of marginal rates of substitution in consumption and in production over a range of commodity bundles. Indeed, the association of these marginal rates with the point at which they are evaluated is another example of a correspondence that arises naturally in economic theory, particularly in the study of marginal cost pricing equilibria in economies with increasing returns to scale (for example, Brown et al. 1986). The fact that there is no unique rate of substitution is simply a consequence of 'kinks' in the underlying function. In the case of a convex function, such a correspondence is termed the *subdifferential* correspondence, and, for more general functions, it is *Clarke's generalized derivative*.

If the domain and range of a correspondence are *topological spaces*, one can formulate various notions of continuity of a correspondence. Recall that (X, τ_X) is a topological space if X is a set and τ_X is a collection of subsets of X that contains X and the empty set ø and is closed under finite intersection and arbitrary union. We can now present one formalization of the intuitive idea of continuity of a correspondence. A correspondence $Q : X \to Y$, X, Y, both topological spaces, is said to be upper *semicontinuous* (u.s.c.) if for any V in τ_Y, the set $\{x \in X : Q(x) \subset V\}$ is in τ_X. Q is said to be lower *semicontinuous* (l.s.c.) if for any V in τ_Y, the set $\{x \in X : Q(x) \cap V \neq \text{ø}\}$ is in τ_X. It is easy to convince oneself that a correspondence may be u.s.c. without being l.s.c. and vice versa. It is also easy to show that, if Y is a compact space, a correspondence Q is u.s.c. if and only if its graph, $\text{Gr}Q$, $\text{Gr}Q = \{(x, y) \in X \times Y : y \in Q(x)\}$, is such that its complement belongs to $\tau_X \times \tau_Y$. A correspondence is said to be *continuous* if it is both u.s.c. and l.s.c.

A very useful result for establishing u.s.c. of correspondences arising from maximization is Berge's *maximum theorem*. This states, in particular, that for any continuous correspondence Q from a topological space X to a topological space Y and any continuous function f from $X \times Y$ into the reals, the associated correspondence $\mu : X \to Y$ given by $\mu(x) = \{y \in Q(x) : f(y, x) \geq f(y', x)$ for all $y' \in Q(x)\}$ is u.s.c. This theorem is used to show u.s.c. of the demand and supply correspondences in the theory of the consumer and of the producer.

A result which plays a significant role in the proof of the existence of a competitive equilibrium is Kakutani's *fixed point theorem* for convex valued, u.s.c. correspondences which take a non-empty convex compact subset of an Euclidean space to itself. The theorem states that such correspondences Q have a fixed point, that is, an element x such that $x \in Q(x)$. Kakutani's theorem yields as an immediate corollary Brouwer's fixed point theorem and generalizes, word for word, to locally convex spaces as has been shown by Glicksberg and Ky Fan (see, for example, Berge 1963, p. 251).

It is of interest to know of conditions under which a correspondence $Q : X \to Y$ yields a *continuous selection*, that is, a continuous function $f : X \to Y$ such that $f(x) \in Q(x)$ for all x in X. The celebrated selection theorems of Michael (see, for example, Bessaga and Pelczynski 1975, ch. II.7) give a variety of sufficient conditions for this. One of these requires X to be a paracompact topological space, Y to be a separable Banach space and

Q to be convex valued and l.s.c. This theorem has been used by Gale and Mas-Colell (1974) to show the existence of competitive equilibrium for economies in which consumer preferences need neither be complete nor transitive. If Q is u.s.c. rather than l.s.c., recent work of Cellina gives sufficient conditions under which one may obtain an *approximate continuous selection*.

So far in this exposition we have been considering results on correspondences whose domain and range are both topological spaces. An alternative setting is one where the range is a topological space but the domain is a *measurable space*. $(T, \sum)$ is a measurable space if T is a set and Σ is a family of subsets that includes T and is closed under complementation and countable unions, that is, Σ is a σ-*algebra*. Such correspondences arise naturally in the study of economies in which the set of agents is modelled as a measurable space. An obvious example of such a correspondence is one which associates with every agent his/her set of utility maximizing consumption plans under a given price system.

One can develop concepts analogous to continuity for correspondences from a measurable space to a topological space. A correspondence $Q : T \to Y$ is said to be *measurable* if, for any set V in τ_Y, the set $\{t \in T : Q(t) \cap V \neq \varnothing\}$ is an element of Σ. Variants of this definition have been presented in the literature along with conditions under which these variants are all equivalent. One particularly fruitful variant requires the measure space to be *complete* and the correspondence to have a *measurable graph*, that is, GrQ is a subset of $\sum \bigotimes \mathscr{B}(Y)$, the smallest σ-algebra generated by the sets in $\sum \times \mathscr{B}(Y)$ and where $\mathscr{B}(Y)$ is the smallest σ-algebra generated by sets τ_Y.

We can now state a measure-theoretic analogue of Berge's theorem. Let Q be a correspondence with a measurable graph and f a $\sum \bigotimes \mathscr{B}(Y)$ measurable function. From $T \times Y$ into the reals. Then a result due to the collective efforts of Debreu and Castaing–Valadier states that under a mild restriction on Y, namely Souslin, the correspondence $\mu : T \to X$, $\mu(t) = \{x \in Q(t) : f(t, x) \geq f(t, x')$ for all x' in $Q(t)\}$, has a measurable graph.

We have developed enough terminology to state a fundamental theorem due to the collective efforts of von Neumann, Aumann and St. Beuve. This states that under a restriction on the range space Y, namely, Souslin, every correspondence Q with a measurable graph yields a *measurable selection*, that is, a measurable function $f : T \to Y$ such that $f(t) \in Q(t)$ for all t in T.

Once we have a measurable selection theorem, we are in a position to formulate a satisfactory notion of an integral of a correspondence, a notion which may also be seen as a formalization of a sum of an infinite number of sets. However, one preliminary notion that still needs to be stated is that of a *measure* μ on $(T, \sum)$. A measure μ is a set-valued function from Σ into (say) Euclidean space R^n such that

$$\mu(A) \geq 0, \mu\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} \mu(A_i)$$

for all A, A_i in Σ and such that A_i are mutually disjoint. Now let us assume we know how to integrate a function with respect to μ and can therefore specify a function $f : T \to R^n$ to be an *integrable function* if its integral (Lebesgue integral) is finite. Following Aumann, we can define the integral of a correspondence, Q, $\int_T Q(t)\mathrm{d}\mu$ to be the set $\{\int_T f(t)\mathrm{d}t : f$, an integrable function which is a measurable selection from $Q\}$. It is now clear that $\int_T Q(t)\mathrm{d}\mu$ is non-empty if Q has a measurable graph and if there exists an integrable function g with non-negative values and such that $|x| \leq g(t)$ for all $x \in Q(t)$ and for all $t \in T$.

Finally, we can state a consequence of Lyapunov's theorem on the range of an *atomless measure* that has played a fundamental role in the development of the theory of economies with a continuum of agents. A measure μ on a measurable space $(T, \sum)$ is atomless if $(T, \sum, \mu)$ has no *atoms*, that is $A \in \Sigma$ such that $\mu(A) > 0$ and $B \in \sum, B \subset A$ implies $\mu(B) = \mu(A)$ or $\mu(B) = 0$. The Lyapunov–Richter theorem states that the integral of a correspondence $Q : T \to R^n$ is convex if μ is an atomless measure on (T, Σ).

In summary, a correspondence is a versatile mathematical object for which a deep and rich theory can be developed and which arises naturally in many diverse areas of applied

mathematics, including economic theory. For an introduction to this theory and to its applications, the reader is referred to the following references which also contain all the concepts and results not referenced in this entry.

Corruption and Economic Growth

Niloy Bose

Abstract

Theory is divided over the effects of corruption on economic growth. However, the growing consensus based on the empirical literature is that corruption is associated with negative growth outcomes. This relationship is not necessarily linear, and causality between corruption and economic growth can run in both directions.

Keywords

Corruption; Economic growth; Multiple equilibria; Threshold effects; Two-way causality

Corruption can take many forms. Broadly defined, it is the use of public office to promote personal gain (Jain 2001). In recent years, various international development agencies have taken an unequivocal stand that corruption is 'the single greatest obstacle to economic and social development' (www.worldbank.org/oublicsector/anticorrupt). The literature on corruption, however, offers two equally plausible yet opposing views.

Two Opposing Theoretical Views

One view argues that corruption can enhance efficiency and raise growth in the presence of cumbersome bureaucratic regulations. Bribes for instance are sometimes accepted in exchange for overcoming institutional rigidities that raise inefficiencies (Leff 1964; Huntington 1968; Leys 1970). More recent expositions of this view can be found in Acemoglou and Verdier (1998, 2000), who argue that some corruption may be optimal in the presence of incomplete contracts or market failures. Others (Lui 1985; Beck and Maher 1986), without relying on pre-existing institutional rigidities, have argued that corruption introduces competition for government resources and helps to provide services more efficiently. Despite finding abundant support in the day-to-day experiences in many developing countries, this efficiency-enhancing or 'grease the wheel' view has been challenged on the grounds that the regulations and red tape that corruption helps to

circumvent are not exogenous, but are put in place to maximize income from corrupt practices in the first place (Myrdal 1968; Bardhan 1997; Rose-Ackerman 1978).

The other view advocates that corruption lowers the volume and efficiency of private and public investment and therefore is detrimental to economic growth. Theory and anecdotal evidence suggest various channels through which these effects could materialize. For example, corruption could lower resources available for productive public investments (Blackburn et al. 2010) and could divert funds to where bribes are easiest to collect, imparting a bias towards low-productivity projects (Wade 1985; Hardin 1993). Others suggest that corruption changes incentives, prices and opportunities in such a way that allocation of talent, technology and capital move away from their socially most productive use. For example, opportunities to seek rent through corrupt practices could divert investment from human to political capital (Murphy et al. 1991; Ehrlich and Lui 1999); rent-seeking by public officials through the imposition of excessive regulation and bureaucracy could discourage innovation (e.g. Murphy et al. 1993) and encourage informal and inefficient sectors (Sarte 2000).

Empirical Evidence

A number of organizations – most notably Business International Corporation, Political Risk Services Inc., and Transparency International – provide cross-country measures of corruption which are constructed on the basis of subjective evaluations of experts, and surveys sent to a network of correspondents around the world. While they differ in various aspects (including their coverage, methodology and availability) and are susceptible to the usual caveats associated with survey data, these measures are highly correlated, suggesting that they do in fact contain relevant information. The advent of these corruption measures has sparked a flurry of empirical investigations into the relationship between corruption and economic growth. The major findings from these investigations are as follows.

First, there is overwhelming evidence from cross-country analysis that corruption hurts economic growth in various ways: by lowering investment (Mauro 1995; Knack and Keefer 1995), creating obstacles to doing business and encouraging unofficial sectors (e.g. Johnson et al. 1997), reducing inflows of foreign capital (Wei 2000) and decreasing the quality of public investment through a misallocation of public expenditure (Tanzi and Davoodi 1997; Mauro 1998). A number of micro studies (see Svensson 2005 for details) have also yielded insights about the long-run cost of corruption. Despite finding a weak direct association between corruption and the growth rate of GDP, these studies have helped solidify the view that corruption hurts growth through its adverse effect on key determinants of growth. In contrast, there is little evidence to support the efficiency-enhancing view even in countries that are reportedly mired with regulations. Using firm-level survey data, Kaufmann and Wei (1999) in fact find that firms that pay more bribes are likely to spend more time with bureaucrats negotiating regulations, and accordingly face a higher cost of capital.

Second, cross-country differences in the incidence of corruption owe much to cross-country differences in the level of prosperity. According to Treisman (2000), a significant proportion – as much as 50 to 73 per cent – of the variation in corruption indices can be explained by the variation in per-capita income. Other studies (Paldam 2002) have confirmed this relationship.

Third, there is evidence that the growth effect of corruption could be nonlinear. Mendez and Sepulveda (2006) and Bose et al. (2008) provide evidence for multiple regimes – one in which the incidence of corruption is high, and its effect on the quality of public infrastructure is strongly negative, and one for relatively low levels of corruption, where its effect is neutral or perhaps even slightly positive. There could be many reasons for such nonlinearities. For example, corruption could have a smaller (negative) impact where it is more 'predictable' (Campos et al. 1999) and where institutional quality is low (Aidt et al. 2008). Alternatively, these nonlinearities could arise through informational frictions in the public procurement process (Bose et al. 2008): when firms earn

economic profits due to market conditions, some of these profits can be extracted in the form of bribes without affecting the provision of public goods. However, when corruption exceeds a certain threshold, this will no longer continue to hold true.

Finally, there is evidence for multiple equilibria in the corruption–economic growth nexus, leading to the notion that some countries may be drawn into a vicious cycle of low growth and high corruption (Bardhan 1997). Haque and Kneller (2009) provide a formal account of such persistence in the data by identifying corruption-development 'clubs' where countries appear to become trapped in highcorruption–low-development or low-corruption–high-development patterns. At micro-level, explanation for persistence of corruption is typically obtained by appealing to the notion of strategic complementarities, where an individual's incentive to be corrupt depends on the behavior of the others (Andvig and Moene 1990; Murphy et al. 1993). These theories are useful in explaining persistence when corruption has already taken a firm grip on a society. From a practical perspective, what one would, however, like to know is how an economy might settle in one equilibrium rather than another as a result of the interplay between the fundamental determinants of corruption and growth. Some progress (Blackburn et al. 2006; Mauro 2004; Blackburn et al. 2010; Aidt et al. 2008) has been made in addressing this concern. Generally, these papers present a framework where a feedback loop from growth to corruption is combined with standard mechanisms through which corruption reduces growth. This gives rise to a self-enforcing dynamic that provides an explanation why corruption and poverty are often not transient phenomena, but an integral part of the fabric of society.

There is now a large body of evidence supporting the view that corruption is detrimental to economic growth. This evidence, however, is based on perceived indices of corruption – that is, data that do not measure corruption itself, but only capture opinions about its prevalence. Recently, researchers have turned their attention to corruption data that are constructed on the basis of actual experience. (For details, see www.transparency.org/policy research/surveysindices/gcb and http://info.worldbank.org/governance/wbes/.) While still in their state of infancy, investigations (Treisman 2007) based on new data have begun to show promise in advancing our understanding of the corruption–growth relationship. At the same time, there is now wider recognition among researchers that corruption is a multifaceted phenomenon with roots in political, cultural and moral aspects of society. A better understanding of how these factors interact with economic fundamentals and shape incentives for corruption could shed further insights into the corruption–growth nexus.

Cossa, Luigi (1831–1896)

G. De Vivo

Born in Milan, Cossa was Professor of Political Economy at the University of Pavia from 1858 to his death. He was influential both through his works and, perhaps even more, through his many pupils: Pantaleoni (who was not one of them) wrote in 1909 (p. 755) that Cossa was one of the 'three men [who] have been the direct teachers of all Italian economists' (the others being F. Ferrara and A. Messedaglia). Cossa is generally regarded as one of the Italian 'Socialists of the Chair', and as such he was attacked by Ferrara, who accused the 'Germanists' of being 'socialists, and corrupters of the Italian youth' (thus Cossa himself summarized Ferrara's onslaught: Cossa 1876, p. 226).

Cossa had studied in Germany with Roscher and had been strongly influenced by him. The German influence is mainly revealed in his acceptance of the idea of the historical relativity of economic laws. He also maintained that a system of protection 'at certain times and under certain conditions... has given notable advantages to industrial organisation and progress' (Cossa 1876, p. 124). (All this, of course, sounded like blasphemy to Ferrara, a great admirer of Bastiat.) He was far from regarding the German economists as faultless, and never denied the importance, for some parts of political economy, of the deductive

method. A good account of Cossa's position is that given by Edgeworth, who described him as 'hold [ing] the balance between the claims of historical observation and deductive reasoning with great fairness' (Edgeworth 1892, p. 685).

Cossa did not go deeply into economic theory, keeping to a rather superficial eclecticism. But Pantaleoni wrote of him that he had the capacity of perfectly understanding books that he would have never been able to write (Pantaleoni 1898, p. 250).

Cossa's fame is mostly due to the bibliographical essays he published, especially his 1876 *Guida allo Studio dell'Economia Politica*, the 2nd edition of which was translated into English, and published by Macmillan, with a preface by Jevons, in 1880 (a new, greatly enlarged, edition issued in 1892, under the title *Introduzione allo Studio dell'Economia Politica* and translated into English, was also very successful). The *Guida*, like most of Cossa's works, mainly consisted of a 'Historical Part', containing an annotated bibliography of political economy. Another book which also attained some fame, and was translated into many languages (including even Japanese, if we can trust Loria 1896, p. 488) was *Primi Elementi di Economia Politica* (1875).

Cossa's bibliographies can still be instructive for a modern reader, especially the parts on Italian, and on French and German, economics. More interesting than those in his books are however those published in many instalments in the *Giornale degli Economisti*, from 1891 to 1900. These have only recently been reprinted in a single volume (L. Cossa, *Saggi bibliografici di economia politica*, con Prefazione di L. Dal Pane 1963), but have not been translated into English. Cossa's scholarship could be exaggerated (Einaudi spoke of him as '*onnisciente*'). For instance, he attributed to Edward Gibbon Wakefield the 1804 *Essay upon Political Economy* (see p. 245 of the volume just quoted) which had been written by his uncle Daniel (in 1804, E.G. Wakefield was only 9 years old). It must however be said that his standards (especially when compared with those of many of his contemporaries) were generally of a fairly high level.

Cost and Supply Curves

James C. Moore

In microeconomic theory we usually suppose that an individual firm has a production technology which can be characterized by a production function $\phi : \Re_+^n \to \Re_+$; where the quantity $\phi : (v)$, for $\in \Re_+^n$, is interpreted as the maximum quantity of output which can be produced, given the vector of quantities of inputs, v. Using the generic notation 'x' to denote the quantity of output, we also suppose that the firm's revenue and cost are described by functions $R : \Re_+ \times P \to \Re_+$ and $K : \Re_+^n \times \Omega \to \Re_+$, where:

$R(x, \rho)$ is the revenue obtained by selling output $x \in \Re_+$, given the market conditions for its

output represented by $\rho \in P$; where ρ is assumed to be outside the firm's control, and

P is the space of possible output market conditions,

$K(\upsilon, w)$ is the cost incurred by the firm in employing the vector of input quantities $\upsilon \in \Re^n_+$, given the input market conditions $\omega \in \Omega$; where ω is assumed to be outside the firm's control, and

Ω is the space of possible input market conditions.

The usual behavioural assumption made is that the firm chooses υ in such a way as to maximise profits; that is, given $(\overline{\rho},\overline{\omega}) \in P \times \Omega$, the firm chooses $\upsilon^* \in \Re^n_+$ so as to satisfy:

$$\text{for all } \upsilon \in \Re^n_+, R[\phi(\upsilon), \overline{\rho}] - K(\upsilon,\overline{\omega}) \underline{\leq} R[\phi(\upsilon^*), \overline{\rho}] - K(\upsilon^*,\overline{\omega}). \quad (1)$$

In what follows, we shall say that v* maximizes profits for ϕ, given $(\overline{\rho},\overline{\omega})$, iff υ* satisfies (1).

Define

$$\Re_{++} = \{x \in \Re | x > 0\}$$

and

$$\Re^n_{++} = \{\mathrm{w} \in \Re^n | \mathrm{w}_i > 0 \quad \text{for } i = 1, \ldots . n\}.$$

In this essay we shall assume that P and Ω are non-empty subsets of

$$P^* = \{\rho | \rho : \Re_+ \to \Re_{++}\} \text{ and } \Omega^* = \{\omega | \omega : \Re^n_+ \to \Re^n_{++}\},$$

respectively; and that R and K take the form

$$R(x, \rho) = \rho(x) \cdot x \quad \text{for } (x, \rho) \in \Re_+ \times P, \quad (2)$$

and

$$K(\upsilon, \omega) - \omega(\upsilon) \cdot \upsilon + C_0 \quad \text{for} (\upsilon, \omega) \in \Re^n_+ \times \Omega, \quad (3)$$

where $C_0 \geqq 0$ is the firm's fixed cost. Thus ρ and ω are, essentially, inverse demand (for output) and supply price functions for inputs, respectively.

The basic idea of this representation, as it applies to demand functions, is as follows. Under the usual assumptions of microeconomic theory, the demand function for x can be written as:

$$x = d(p_x, p, m, \alpha),$$

where

p_x = the price of good x,

$p = (p_1, \ldots p_l)$ is the vector of prices of other commodities in the economy,

$m = (m_1, \ldots m_k)$ is the vector of consumer incomes,

α is a parameter representing 'taste',

If, for each (p, m, α), $d(\cdot, p, m, \alpha)$ is strictly decreasing in p_x, we can invert the function to write

$$p_x = D(x, p, m, \alpha)$$

Each specification of (p, m, α) then determines a function $\rho : \Re_+ \to \Re_+$ defined by:

$$\rho(x) = D(x, p, m, \alpha) \quad \text{for } x \in \Re_+.$$

It is this sort of interpretation we have in mind by representing output market conditions by $\rho \in P^*$ and similar considerations apply to $\omega \in \Omega^*$. In accordance with this interpretation, we shall refer to elements of P* and Ω* as *output price* and *input supply price functions*, respectively.

Of particular importance to the analysis, however, is the case wherein the firm does not, by its own actions, change the market prices of the inputs which it uses; or the manager of the firm behaves as if this were the case (and thus is a 'price-taker' in input markets). In our formulation, this amounts to the assumption that

$$\Omega = \Omega^c, \quad (4)$$

where Ω^c is that subset of Ω* consisting of all constant functions (*constant supply price functions*) on $\Re^n_+$. In this situation $\omega \in \Omega^c$ corresponds to a unique value of $w \in \Re^n_{++}$ (and conversely);

and thus by a slight abuse of our notation, we can write the cost function (3) in the form:

$$K(\upsilon, w) = w \cdot \upsilon + C_0 \quad \text{for} (\upsilon, w) \in \Re^n_+ \times \Re^n_{++}. \tag{5}$$

Since our principal concern will be with the theory of pure competition, we shall assume throughout our discussion of the behaviour of the individual firm that (4) and (5) hold. However, the more general specification of K will be useful when we turn to the discussion of competitive equilibrium for an industry.

When (4) and (5) hold, it is useful to break the firm's profit-maximization problem down into two parts, as follows.

1. Defining $X \subseteq \Re_+$, the firm's *producible set*, by:

$$X = \left\{x \in \Re_+ | \left(\exists \upsilon \in \Re^n_+\right) : \phi(\upsilon) \geqq x\right\}, \tag{6}$$

we find, for each $(\mathrm{x}, \mathrm{w}) \in X \times \Re^n_{++}$, $c(\mathrm{x}, \mathrm{w})$, the minimum (variable) cost of producing x, given w. That is, given $(\mathrm{x}^*, \mathrm{w}^*) \in X \times \Re^n_{++}$, we find $\upsilon^* \in \Re^n_+$ satisfying:

$$\phi(\upsilon^*) \geqq x^* \text{ and } w^* \cdot \upsilon^* \leqq w^* \cdot \upsilon \text{ for all } \upsilon \in \Re^n_+ \text{ such that } \phi(\upsilon) \geqq x^* \tag{7}$$

Variable cost and total cost at (x*, w*), $c(x^*, w^*)$ and $c(x^*, w^*)$, respectively, are then given by:

$$c(x^*, w^*) = w^* \cdot v^*,$$

and

$$C(x^*, w^*) = c(x^*, w^*) + C_0$$

2. Given the function C, and $\rho \in P$, *we* then find $x^* \in X$ satisfying

$$\text{for all } x \in X, R(x, \rho) - C(x, w) \leqq R(x^*, \rho) - C(x^*, w^*); \tag{8}$$

or equivalently,

$$\text{for all } x \in X, R(x, \rho) - c(x, w) \leqq R(x^*, \rho) - c(x^*, w^*); \tag{8'}$$

Because of the equivalance of (8) and (8'), we shall hereafter concern ourselves only with the variable cost function, c, and we shall refer to it as simply the 'cost function'. Similarly we define the firm's (gross) *profit function*, $\pi : X \times P \times \Re^n_{++} \to R$ by

$$\pi(x, \rho, w) = R(x, \rho) - c(x, w); \tag{9}$$

and we shall say that $x^* \in X$ maximizes the profit function $\pi(\cdot, \rho, w)$ if, and only if, it satisfies(8′)

It can be shown that if $R(\cdot, \rho)$ is non-decreasing in x on X, and υ* maximizes profits for ϕ, given (ρ, w), then

$$w \cdot \upsilon^* = c[\phi(\upsilon^*), w], \tag{10}$$

and $x^* \equiv (\upsilon^*)$ satisfies (8′). Conversely, if $x^* \in X$ satisfies (8′), and υ* satisfies (7), then υ* maximizes profits for ϕ, given (ρ, w). Thus, if $R(\cdot, \rho)$ is non-decreasing on X; the two procedures are logically equivalent. If $R(\cdot, \rho)$ is decreasing on a portion of X (the case of inelastic demand), the two-step procedure is not necessarily equivalent to maximizing profits for ϕ, given (ρ, w). However, in the situation we will be examining in detail, $R(\cdot, \rho)$ will always be non-decreasing on X.

One advantage of the two-step analysis of profit maximization is that the problem of maximizing the profit function, π, is much simpler, both conceptually and operationally, than the problem of finding $\upsilon^* \in \Re^n_+$ which maximizes profits for ϕ. However, a much more significant advantage of the two-step analysis is that the analysis of the cost function itself is applicable whatever the form of the revenue function, R. In particular, the relationship between a firm's production and cost functions, the examination of which will be our next order of business, is of interest whatever the (output) market structure under investigation.

In order to formally analyse the relationship between production and cost, let us say that a function $\phi : \Re^n_+ \to \Re_+$ is a *production function* if, and only if, $\phi(\cdot)$ satisfies the following three properties:

P.1 $\phi(0) = 0$ and for some, $\upsilon^{T} \in \Re^{n}_{+}$, $\phi(\upsilon^{T}) > 0$.
P.2 ϕ is non-decreasing on $\Re^{n}_{+}$, i.e.,
for each $\upsilon, \upsilon' \in \Re^{n}_{+}$, if $\upsilon \geqq \upsilon'$, then $\phi(\upsilon) \geqq \phi(\upsilon')$.
P.3 ϕ is upper semi-continuous on $\Re^{n}_{+}$.

In the following treatment, we shall also define:

$$X_{+} = \{x \in X | x > 0\} = \left\{x \in \Re_{+} | \left(\exists \upsilon \in \Re^{n}_{+}\right) : 0 < x \leqq \phi(\upsilon)\right\}$$

and

$$\Re^{n}_{++} = \left\{w \in \Re^{n}_{+} | w_i > 0 \quad \text{for } i = 1, ..., n\right\}.$$

The above conditions are generally fairly standard, and probably require no discussion, except perhaps the assumption that ϕ is upper semi-continuous. Generally speaking, continuity is *not* an empirically meaningful condition; that is, in investigating an actual production process we can do no better than to observe a finite collection of input vectors $\{v^1, \ldots, v^\tau\}$, together with the associated values of output $\{x^1, \ldots, x^\tau\}$. If these observations are consistent with the hypothesis that there exists a function $\phi : \Re^{n}_{+} \to \Re_{+}$ such that

$$x^t = \phi(x^t) \quad \text{for } t = 1, \ldots, \tau; \tag{11}$$

then they are also consistent with the additional assumption that ϕ is continuous. Consequently, one might very legitimately ask why I have not simply made the more familiar assumption that ϕ is continuous. My reason for not doing so is that there are situations in which we may want to interpret the quantity of output as a stock, rather than a flow. In some situations where this is the case (e.g., 'finite production runs'), it is likely to be appropriate to assume that ϕ is discrete-valued; and while it is possible for a function $\phi : \Re^{n}_{+} \to \Re_{+}$ to be both upper semi-continuous and discrete-valued (an example is presented later in the text), it is not possible for such a function to be both discrete-valued and continuous. As it turns out, most of the analysis to follow requires only that ϕ be upper semi-continuous, and thus is applicable with either a stock or a flow interpretation of output quantities.

Turning now to the derivation of the cost function, let $(x^*, w^*) \in X \times \Re^{n}_{++}$. Since ϕ is upper semi-continuous, it can be shown that there exists $\upsilon^* \in \Re^{n}_{+}$ such that υ^* satisfies (7) for $x = x^*$ and $w = w^*$. Thus it follows that if ϕ is a production function, by our definition, then the (variable) cost function $c : X \times \Re^{n}_{++} \to \Re_{+}$ is well-defined. In fact, it is fairly easy to show that the cost function $c(\cdot)$ corresponding to a given production function, $\phi(\cdot)$, will satisfy the following conditions. (Most of these properties are established in McFadden, 1978, and those which are not are proved in Moore, 1986.)

C.1. X, the producible set for ϕ, is a sub-interval of $\Re_{+}$, and either
  a. there exists $\overline{x} > 0$ such that $X = [0, \overline{x}]$, or
  b. for each $w \in \Re^{n}_{++}$, $c(\cdot, w)$ is unbounded on X.
C.2. for each $w \in \Re^{n}_{++}$:
  a. $c(\cdot, w)$ is non-decreasing in x,
  b. $c(0, w) = 0$,
  c. $c(x, w) > 0$ for each $x \in X_{+}$,
  d. $c(\cdot, w)$ is lower semi-continuous on X.
C.3. for each $x \in X_{+}$, $c(x, \cdot)$ is:
  a. increasing in w.
  b. positively homogeneous of degree one in w.
  c. concave in w.
  d. continuous in w.

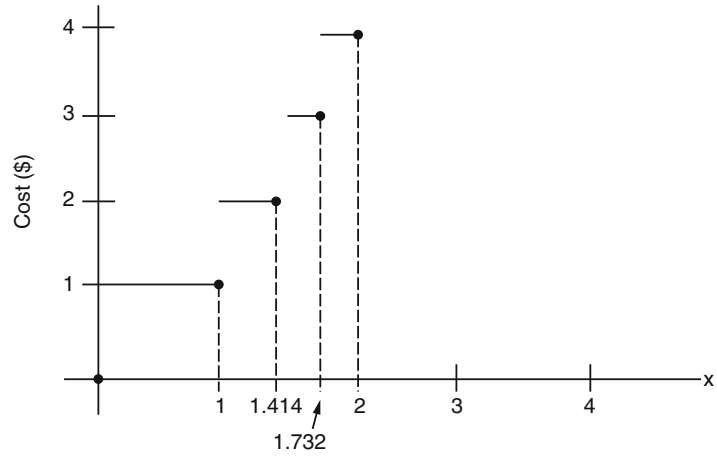
Since $C(\cdot)$, the *total cost function for* ϕ is defined by

$$C(w) = c(w) + K_0 \quad \text{for } (w) \in \Re^{n}_{++}, \tag{12}$$

it follows at once that C also satisfies all of the above properties *except* C.2.b and C.3.b. We can also define the *average variable cost*, and *average cost* functions on $X_{+} \times \Re^{n}_{++}$ by:

$$a(w) = c(w)/x \quad \text{for}(w) \in X_{+} \times \Re^{n}_{++}, \tag{13}$$

Cost and Supply Curves, Fig. 1



and

$$A(\mathrm{x},\mathrm{w}) = C(\mathrm{x},\mathrm{w})/w \quad \text{for}(\mathrm{x},\mathrm{w}) \in X_+ \times \Re^{n}_{++}, \tag{14}$$

respectively. However, under the assumptions we have been employing to this point, the marginal cost function, $c_x(\cdot, w)$, will not necessarily be well-defined. ['$c_x(x, w)$' denotes the partial derivative of c with respect to x, evaluated at (x, w)]. In fact, under the assumptions which we have been employing, a cost function may look rather unlike those used in traditional intermediate theory diagrams, as will be seen from the following example.

For each $x \in \Re$, define $\lfloor x \rfloor$ and $\lceil x \rceil$ by:

$\lfloor x \rfloor$ = that unique integer, n, satisfying $\mathrm{n} \leqq \mathrm{x} < \mathrm{n} < +1$,

and

$\lceil x \rceil$ = that unique integer, n', satisfying:

$$\mathrm{n}' - 1 < \mathrm{x} \leqq \mathrm{n}'.$$

If we let $\alpha > 0$ be a positive real number, and define $\phi : \Re_+ \to \Re_+$ by

$$\phi(x) = \alpha\sqrt{\lfloor \upsilon \rfloor}, \quad \text{for } \upsilon \in \Re_+,$$

it can be shown that ϕ is a production function. Moreover, it is easy to see that the producible set for ϕ is given by:

$$X = \Re_+,$$

and that the cost function for ϕ is given by:

$$c(x, w) = w\left\lceil (x/\alpha)^2 \right\rceil \quad \text{for } x \in X \quad \text{and} \quad w \in \Re_{++}.$$

The graph of $c(\cdot)$ for $\alpha = w = 1$ is shown in Fig. 1, below.

Obviously, the marginal cost function is not defined in this example.

Suppose now that the firm sells its output in a competitive market; that is, that the firm is a 'price-taker' in its output market. In terms of our formulation, this means that P is the set of all constant functions (*constant output price functions*); and by considerations similar to those used in our development of the cost function, we can write the firm's revenue function as:

$$\mathrm{R}(\mathrm{x}, p) = \mathrm{p} \cdot \mathrm{x} \quad \text{for } (\mathrm{x},\mathrm{p}) \in X \times \Re_{++}. \tag{15}$$

Thus we are interested in whether or when, given $(p, w) \in \Re_{++} \times \Re^{n}_{++}$, there exists $x^* \in X$ satisfying

$$\begin{aligned} &\text{for all } x \in X, \\ &p \cdot x - c(x, w) \leqq p \cdot x^* - c(x^*, w). \end{aligned} \tag{16}$$

If, for each $(p, w) \in \Re_{++} \times \Re^{n}_{++}$, there exists a unique $x^* \in X$ satisfying (16), then there exists a function $s : \Re_+ \times \Re^{n}_{++} \to X$ such that for each

(p, w), $s(p, w)$ is that unique value of x, x^*, satisfying (16). This function is the firm's *supply function*; its value at each (p, w) is the firm's competitive (profit-maximizing) output, given the output, price, p, and the vector of input prices, w. We shall briefly examine the conditions under which this function will exist, and its relationship to the firm's cost curve.

Suppose for the moment that the cost function is differentiable in x, and let '$c_x(x, w)$' denote the partial derivative of c with respect to x, evaluated at $(\mathrm{x}, \mathrm{w}) \in X \times \Re^n_{++}$. The function $c_x(\cdot)$ is called the firm's *marginal cost function*, and it is customary in intermediate microtheory texts to state that the firm's supply curve is 'that portion of the marginal cost curve lying above the average variable cost curve'. Clearly the situation is a bit more complicated than this; and these complications, while perhaps not critical in the analysis of the individual competitive firm, become troublesome when we turn to the analysis of supply in a competitive industry.

In examining this problem, we shall restrict our attention to the case in which the text book treatment mentioned above is most nearly correct (or at least the most favorable case I can come up with); namely, that in which the firm's cost function satisfies the following condition.

C.4. Defining $\chi = \sup X$ (χ may, of course, be equal to $+\infty$), c is continuously differentiable in x on $[0, \chi[\times \Re^n_{++}$; and, for each $w \in \Re^n_{++}$, $c_x(\cdot)$ is strictly increasing on $[0, \chi[$. [By '$c_x(0, w)$' we mean the right hand partial derivative.

We shall not attempt to develop conditions on the firm's production function sufficient to ensure that c satisfies C.4. However, it is easy to show that if ϕ is strictly concave, then $c(\cdot, w)$ will be strictly convex in x, for each $w \in \Re^n_{++}$. If in this case c is differentiable as well, then $c_x(\cdot, w)$ will be strictly increasing in x on $[0, \chi[$, for each $w \in \Re^n_{++}$. Moreover, it follows from recent results on duality relationships between production and cost-functions that, given any cost function, c, satisfying (C.1–C.3 and) C.4, there exists a unique concave production function for which c is the corresponding cost function. (For an excellent survey of duality, see Diewert, 1982.)

Suppose, then, that c satisfies C.4. It is easy to see that, for each $\mathrm{w} \in \Re^n_{++}$,

$$\lim_{x \to \chi} c_x(x, w)$$

exists, although it may be equal to $+\infty$. Furthermore, if for each $w \in \Re^n_{++}$, we define $a(w)$ and $b(w)$ by

$$a(w) = c_x(0, w) \quad b(w) = \lim_{x \to \chi} c_x(x, w);$$

it follows from C.4 that for each $p \in [a(w), b(w)]$, there exists a unique $x \in [0, \chi]$ such that

$$p = c_x(x, w).$$

Consequently, $c_x(\cdot, w)$ is invertible (in x) on the set π^0 defined by

$$\pi^0 = \{(\mathrm{p}, \mathrm{w}) \in \Re_{++} \times \Re^n_{++} \mid p \in [a(\mathrm{w}), b(\mathrm{w})]\};$$

that is, there exists a function $\sigma : \pi^0 \to [0, \chi] \subseteq X$ satisfying:

$$\text{for each } (p, w) \in \pi^0, \quad c_x[\sigma(p, w), w] = p, \tag{17}$$

and

$$\text{for each } (\mathrm{x}, \mathrm{w}) \in [0, \chi[\times \Re^n_{++}, \ \sigma[c_x(\mathrm{x}, \mathrm{w}), \mathrm{w}] = x \tag{18}$$

If we define π as the set of all $(\mathrm{p}, \mathrm{w}) \in \Re_{++} \times \Re_{++}$ such that there exists $x^* \in X$ satisfying (16), the interested reader should have no great difficulty in proving the following.

S.1. $\pi^0 \subseteq \pi$

S.2. For each $(p, w) \in \pi$, the profit-maximizing output is unique; thus the firm's supply function has domain π, and is given by:

$$s(p, w) = \left\{ \begin{array}{ll} 0 & \text{if } 0 < \mathrm{p} \leqq a(\mathrm{w}) \\ \sigma(\mathrm{p}, \mathrm{w}) & \text{if } p \in]\mathrm{a}(\mathrm{w}), \mathrm{b}(\mathrm{w})[\\ \chi & \text{if } p \geqq b(w) \end{array} \right\} \text{for} (\mathrm{p}, \mathrm{w}) \in \pi \tag{19}$$

S.3. For each $w \in \mathfrak{R}^n_{++}$, $s(\cdot, w)$, is continuous and non-decreasing in p; and is strictly increasing in p on $]a(w), b(w)[$.

While, as already indicated, I shall leave the proof of the above result to the 'interested reader'; one or two explanatory comments seem to be in order. First, if c satisfies C.4, then marginal cost is always at least as large as average variable cost, i.e.,

$$\text{for each } (\mathrm{x}, \mathrm{w}) \in X_+ \times \mathfrak{R}^n_{++}, \quad c_x(\mathrm{x}, \mathrm{w}) > c(\mathrm{x}, \mathrm{w})/x \tag{20}$$

(this is easily established by the use of the mean value theorem). Secondly, the condition $p \geqq b(w)$ and $(p, w) \in \pi$ is a bit misleading. The fact of the matter is, these two conditions can hold simultaneously only if X is of the form $X = [0, \chi]$, with χ finite (and positive. In this case also $\pi = \mathfrak{R}_{++} \times \mathfrak{R}^n_{++}$.) If this is not the case, then by C.1 we see that two other cases are possible.

Case 1: $X =]0, \chi[$ with χ finite. Here we have by C.1 that $c(\cdot, w)$ is unbounded in X, and this fact can be used to show that $b(w) = +\infty$, for each $w \in \mathfrak{R}^n_{++}$. Thus in this case, $\pi = \mathfrak{R}_{++} \times \mathfrak{R}^n_{++}$, but we cannot have $p \geq b(w)$.

Case 2: $X = \mathfrak{R}_+$. Here it is possible that $b(w)$ is finite. However, if this is the case, and (p, w) is such that $p \geqq b(w)$, then no profit-maximizing solution exists. For example, consider the homothetic cost function

$$c(x, w) = f(x)\gamma(w), \tag{21}$$

where γ can be any function satisfying C.3, and f is given by:

$$f(x) = \alpha x + \left(x^2 + \beta^2\right)^{1/2} - \beta, \quad \text{with } \alpha, \beta > 0. \tag{22}$$

Here it is easily shown that c satisfies C.1–C.4, and that

$$a(w) = c_x(0, w) = f'(x)\gamma(w) = a\gamma(w), \tag{23}$$

While

$$\begin{aligned} b(w) &= \lim_{\chi \to +\infty} c_x(x, w) = \gamma(w) \lim_{x \to +\infty} f'(x) \\ &= (\alpha + 1)\gamma(w). \end{aligned} \tag{24}$$

Here $b(w)$ is finite, but if $p \geqq b(w)$, then no profit-maximizing output exists.

Turning our attention to suppy conditions for a competitive industry, suppose there are m firms producing a single (homogeneous) commodity, and let the ith firm's production function, cost function, and producible set be denoted by ϕ^i, c^i, and X_i, respectively. We shall use the generic notation x_i and v^i to denote the ith firm's output and vector of inputs employed, respectively; and we define the *producible set for the industry*, X, by

$$X = \sum_{i=1}^{m} X_i.$$

We assume that the market is competitive, so that each firm is a price-taker in both output and input markets; and we shall be interested in the competitive equilibria of the market (or industry), defined as follows.

We shall say that $\left(\overline{v}^i, \ldots, \overline{v}^m; \overline{\rho}, \overline{\omega}\right)$ is a *competitive equilibrium for the industry* iff.

1. $\overline{v}^i \in \mathfrak{R}^n_+$ for $i = 1, \ldots, m$,
2. $\overline{\rho} \in P^*, \overline{\omega} \in \Omega^*$, and
3. defining $\overline{p} = \overline{\rho}\left[\sum_{i=1}^{m} \phi^i\left(\overline{v}^i\right)\right]$ and $\overline{w} = \overline{\omega}\left(\sum_{i=1}^{m} \overline{v}^i\right)$,

the following condition holds: for each $i (i = 1, \ldots, m)$, $\overline{v}^i$ satisfies

$$\text{for all } v^i \in \mathfrak{R}^n_+, \overline{p} \cdot \phi^i(v^i) - \overline{w} \cdot v^i \underline{\leq} \overline{p} \cdot \phi^i\left(\overline{v}^i\right) - \overline{w} \cdot \overline{v}^i \tag{25}$$

We shall also be interested in aggregate competitive equilibria for the industry, defined as follows.

We shall say that $(\overline{x},\overline{v},\overline{p},\overline{w}) \in X \times \mathfrak{R}^n_+ \times P^* \times \Omega^*$ is an *aggregate competitive equilibrium for the industry* iff there exist $\overline{v}^i \in \mathfrak{R}^n_+$ for $i = i, \ldots, m$ such that

$$\overline{v} = \sum_{i=1}^{m} \overline{v}^i, \quad \overline{x} = \sum_{i=1}^{m} \phi^i(\overline{v}^i),$$

and $(\overline{v}^1, \ldots, \overline{v}^m; \overline{p}, \overline{\omega})$ is a competitive equilibrium for the industry. We shall say that $(\overline{x},\overline{p},\overline{\omega}) \in X \times P^* \times \Omega^*$ is an aggregate output equilibrium for the industry iff there exists $\overline{v} \in \mathfrak{R}^n_+$ such that $(\overline{x},\overline{v},\overline{p},\overline{\omega})$ is an aggregate competitive equilibrium for the industry.

The first question I would like to consider is whether we can characterize the aggregate output equilibria as the set of points where supply equals demand, if by 'supply' we mean the summation of the supply functions of the individual firms. I don't believe that it will be necessary to go into a lot of detail to convince the reader of the truth of the following two assertions.

1. We cannot obtain the set of output equilibria for the industry by summing the individual supply curves and then finding the set of points at which this summation function equals demand unless we restrict our attention to cases in which $\omega \in \Omega^c$. This is a fairly serious difficulty, since this assumes that all m firms in the industry can simultaneously expand or contract input usage without appreciably affecting input prices, an assumption which is much more restrictive than assuming that each firm behaves as if its individual actions have no appreciable effect on input prices.
2. Even if we restrict our attention to the case where $\Omega = \Omega^c$, the analysis of the form of the summation supply function will be a very messy business. Suppose, for example, that each cost function c^i satisfies C.4, and denote the ith firm's supply function by s^i and its domain by π^i. Then the summation (industry) supply function will be defined on

$$\pi = \bigcap_{i=1}^{m} \pi_i,$$

and will be given by

$$s(p,w) = \sum_{i=1}^{m} s^i(p,w) \quad \text{for } (p,w) \in \pi.$$

Given $\overline{w} \in \mathfrak{R}^n_{++}$ and $\rho \in P^*$, $(\overline{x},\overline{p},\overline{\omega})$ will be an aggregate output equilibrium for the industry in this case if, and only if,

$$[\overline{p}(\overline{x}), \overline{w}] \in \pi \quad \text{and} \quad x = s[\overline{p}(\overline{x}), \overline{w}]. \tag{26}$$

In this case, therefore one can obtain the industry supply function by summing the supply functions of the individual firms, and this industry supply function can be conveniently utilized to obtain the aggregate output equilibria for the industry. However, if the reader will re-examine condition S.2, above [and particularly equation (19)], I am sure you will have no difficulty convincing yourself that the characterization of the form of π and $s(\cdot)$ will be a very messy business; even under the somewhat restrictive assumption that each c^i satisfies C.4. In fact, this is a fairly substantive problem, for suppose one wishes to estimate the supply function for a purely competitive industry. Given our present estimation techniques, this means that one needs to specify, a functional form for $s(\cdot)$ (actually, a parametric family, the individual elements of which are determined by a finite set of parameters), whose parameters can be estimated from data on aggregate output equilibria for the market. The question is, what sort of functional form is appropriate? Once again, a glance back at condition S.2 and equation (19) will suffice to convince the reader that the only practical means of deriving the form $s(\cdot)$ from assumptions about the functional form of the individual cost functions, c^i, is to assume that all of the individual firms have the same cost function; an assumption with which it is difficult to be comfortable.

Fortunately, there is a way of circumventing both of these difficulties, at least to a great extent. The relationships we shall develop to facilitate this alternative analysis are in some sense 'well known', but for some reason they do not seem to have found their way into microeconomic theory textbooks. We begin by considering the following problem, for an arbitrary $v \in \mathfrak{R}^n_+$:

C

$$\text{Maximize} \sum_{i=1}^{m} \phi^i(v^i), \text{subject to} \sum_{i=1}^{m} v^i \leqq v \text{ and } v^i \in \Re_+^n \text{ for } i = 1, .., m. \tag{27}$$

Since each ϕ^i is upper semi-continuous, the function

$$F(v^1, \ldots, v^m) \equiv \sum_{i=1}^{m} \phi^i(v^i)$$

is also upper semi-continuous; and, for each $v \in \Re_+^n$, the set

$$V(v) = \left\{ (v^1, \ldots, v^m) \in \Re^{mn} \middle| \sum_{i=1}^{m} v^i \leqq v \right\}$$

is compact. Therefore, for each $v \in \Re_+^n$, the problem (27) has a solution, the value of which we shall denote by '$\phi(v)$', that is,

$$\phi(v) = \max \left\{ \sum_{i=1}^{m} \phi^i(v^i) \mid (v^1, \ldots, v^m) \in V(v) \right\}. \tag{28}$$

We shall refer to the function ϕ as the *Industry production function*; and for each $v \in \Re_+^n$ we shall denote the solution set of (27) by '$V^*(v)$', that is,

$$V^*(v) = \left\{ (v^1, \ldots, v^m) \in V(v) \middle| \sum_{i=1}^{m} \phi^i(v^i) = \phi(v) \right\}. \tag{29}$$

It can be shown that ϕ is a production function; that is, it satisfies P.1–P.3. The industry production function does not necessarily retain other properties of the individual production functions, ϕ^i; for example, it may be the case that all the ϕ^i are quasi-concave but that ϕ is not quasi-concave. On the other hand, if all the ϕ^i are concave, or are all positively homogeneous of degree $r > 0$, then ϕ is a production function, and thus has a cost function satisfying C.1–C.3. We can show that the set of aggregate competitive equilibria for the industry are the solutions of the following problem

Given a production function, ϕ, and $(\overline{p}, \overline{\omega}) \in P^* \times \Omega^*$, we shall say that $\overline{v} \in \Re_+^n$ *myopically maximizes profits for* ϕ, *given* $(\overline{p}, \overline{\omega})$ if $\overline{v}$ satisfies:

$$\text{for all } v \in \Re_+^n, \overline{p} \cdot \phi(v) - \overline{w} \cdot v \leqq \overline{p} \cdot \phi(\overline{v}) - \overline{w} \cdot \overline{v}, \tag{30}$$

where $\overline{p} = \overline{p}[\phi(\overline{v})]$ and $\overline{w} = \overline{\omega}(\overline{v})$.

One can then prove the following result; although, in the interest of brevity, I shall not do so here (a proof is included in Moore, 1986).

Proposition 1 If $\overline{v} \in \Re_+^n$ myopically maximizes profits for ϕ (the industry production function), given $(\overline{p}, \overline{\omega}) \in P^* \times \Omega^*$, then $[\phi(\overline{v}), \overline{v}, \overline{p}, \overline{\omega}]$ is an aggregate competitive equilibrium for the industry [in fact, in this situation $(\overline{v}^1, \ldots, \overline{v}^m; \overline{p}, \overline{\omega})$ is a competitive equilibrium for the industry, for any $(\overline{v}^1, \ldots, \overline{v}^m) \in V^*(\overline{v})$]. Conversely, if $(\widehat{v}^1, \ldots, \widehat{v}^m; \widehat{\rho}, \widehat{\omega})$ is a competitive equilibrium for the industry, and we define

$$\widehat{v} = \sum_{i=1}^{m}, \widehat{v}^i,$$

then

$$\phi(\widehat{v}) = \sum_{i=1}^{m} \phi^i(\widehat{v}^i),$$

and $\widehat{v}$ myopically maximizes profits for ϕ, given $(\widehat{\rho}, \widehat{\omega})$.

There are a number of points which appear to be worth making with regard to the implications of the above result.

1. Given $(\overline{p}, \overline{\omega}) \in P^* \times \Omega^*$, one can find all aggregate competitive output and input equilibria corresponding to $(\overline{p}, \overline{\omega})$ by finding the set of v which myopically maximize ϕ, given $(\overline{p}, \overline{\omega})$. If there is a unique maximizing value of v, then there is correspondingly a unique aggregate competitive equilibrium for the industry. (This uniqueness question is explored in Moore, 1986).
2. One can estimate the industry production function, ϕ, from observations on aggregate output

and input usage associated with competitive equilibria for the industry; since if $(\overline{v}^1, \ldots, \overline{v}^m; \overline{p}, \overline{\omega})$ is a competitive equilibrium, for the industry, then

$$\sum_{i=1}^{m} \phi^i(\overline{v}^i) = \phi\left(\sum_{i=1}^{m} \overline{v}^i\right).$$

Similarly if one also has data on the values of w associated with each such competitive equilibrium, one can also estimate $\overline{\omega}$.

There is a complication connected with this last point, however. The situation I have been describing is one in which we have a series of competitive equilibria for the industry;

$$(x^t, v^t, \rho^t, \omega^t) \quad \text{for } t = 1, \ldots, T; \tag{31}$$

and we have observed

$$(x^t, v^t, w^t) \quad \text{for } t = 1, \ldots, T, \tag{32}$$

where

$$w^t = \omega^t(v^t) \quad \text{for } t = 1, \ldots, T. \tag{33}$$

Under the assumption that the individual production functions, ϕ^i, are unchanged over the period, then we can clearly estimate the industry production function from the relation

$$x^t = \phi(v^t) \quad \text{for } t = 1, \ldots, T, \tag{34}$$

where (34) holds by virtue of the fact that

$$x^t = \sum_{i=1}^{m} \phi^i(v^{it}), \quad v^t = \sum_{i=1}^{m} v^{it},$$

and

$$\sum_{i=1}^{m} \phi^i(v^{it}) = \phi\left(\sum_{i=1}^{m} v^{it}\right).$$

Assuming that there exists $\overline{w} \in \Omega^*$ such that

$$\omega^t = \overline{\omega} \quad \text{for } t = 1, \ldots T; \tag{35}$$

we can equally well estimate $\overline{w}$ from the relationship

$$w^t = \omega^t(v^t) = \overline{\omega}(v^t) \quad \text{for } t = 1, \ldots, T. \tag{36}$$

However, here it is well to keep in mind a point raised by Joan Robinson in her famous article 'Rising Supply Price' (1941): if the industry output price function changes from, say, ρ^1 to ρ^2, there will generally be a corresponding change in the input supply price function as well (in our framework, a change from some ω^1 to $w^2 \in \Omega^*$). In the situation under consideration here, and under the assumption that the ϕ^i's are unchanged, we must have $\rho^t \neq \rho^{t'}$ if $(x^t, v^t) \neq (x^t, v^t)$. Thus we have to allow for the possibility that $\omega^t \neq w^{r'}$ as well (unless, of course, $\omega^t = \omega^{r'}$ for all $t, t' = 1, \ldots, T$). This is essentially, an identification problem, and can be handled by methods similar to those used in conventional demand and supply estimation [on this, see, e.g., Fisher (1966)].

Robinson's point is also pertinent to the predictive use of the methods we have discussed here, however. Suppose we know, or have estimated, both the industry production function, ϕ, and the prevailing input supply price function $\overline{\omega}$; and we wish to predict the aggregate competitive equilibrium associated with $\widehat{\rho} \in P^*$. It follows from Proposition *1* that we can find $(\overline{x}, \overline{v}, \widehat{\rho}, \overline{\omega})$ by finding $\overline{v} \in \Re^n_+$ such that $\overline{v}$ myopically maximizes profits for ϕ, given $(\widehat{\rho}, \overline{\omega})$. The problem here, of course, is that if demand conditions change to $\widehat{\rho}$, there may be a corresponding change to a new input supply price function, $\widehat{\omega}$. While I have no suggestions regarding a way of circumventing this difficulty, one suspects that there are many more situations in which it is safe to assume that industry supply conditions remain unchanged for 'small' changes in ρ, than there are in which input prices themselves remain fixed for such changes in ρ.

3. Let us call the cost function, c, corresponding to the industry production function, ϕ, the *industry cost function*. It can be shown that if

$(\overline{v}^1, \ldots, \overline{v}^m; \overline{p}, \overline{\omega})$ is a competitive equilibrium for the industry, and we define

$$\overline{w} = \overline{\omega}\left(\sum_{i=1}^{m} \overline{v}^i\right), \quad \text{and} \quad \overline{x}_i = \phi^i\left(\overline{v}^i\right) \text{for } i = 1, \ldots, m,$$

then

$$\sum_{i=1}^{m} \overline{w} \cdot v^i = c(\overline{x}, \overline{w}), \quad \text{where} \quad \overline{x} = \sum_{i=1}^{m} \overline{x}_i.$$

Thus one can estimate the industry cost function by observations on aggregate industry output, total industry factor cost, and $\overline{w}$. This fact is of particular interest in connection with our next point.

4. In the constant input supply price case $(\Omega = \Omega^c)$, our analysis yields a simplified approach to obtaining (and analyzing the properties of) the industry supply function. From Proposition *1* and our discussion of profit maximization by the individual firm, we can see that if we derive the function s: $\pi \rightarrow X$ from the industry cost function from its cost function (see the derivation of S.1–S.3 above), we can find the aggregate output equilibrium for the industry, given $(\overline{p}, \overline{w})$, by finding $\overline{x} \in X$ satisfying

$$\overline{x} = s\left[\overline{p}(\overline{x}), \overline{w}\right).$$

In other words, it is legitimate to approach the problem of estimating a supply curve for an industry by specifying a production function (or cost function) for the industry were a as an aggregate, and proceeding as if the industry were a single profit-maximizing entity.

The perceptive reader may, however, have detected a problem with the above procedure. We have shown that if each firm in a competitive industry has an individual production function (by the definition used here), then there is an associated total product function for the industry which is also a production function. The question remains, however, whether *any* production function could serve to describe industry output relationships in this manner. Insofar as I am aware, the answer to this general question is unknown, and deserves investigation. However, any *concave* production function can play such a role, as is shown by the following.

Proposition 2 Let: $\phi : \Re_+^n \rightarrow \Re_+$ be a concave production function, and let m be a positive integer. Then there exist concave production functions: $\phi^i : \Re_+^n \rightarrow \Re_+$ for $i = 1, \ldots, m$, such that ϕ is the industry production function associated with the ϕ^i.

While I shall not provide a complete proof of Proposition *2* here, it can be established by showing that if ϕ is a concave production function, and one defines $\phi = (i = 1, \ldots, m)$ by

$$\phi^i(v^i) = (1/m)\phi(mv^i) \quad \text{for } v^i \in \Re_+^n;$$

then ϕ^i is a concave production function, and ϕ is the industry production function associated with $(\phi^i, \ldots, \phi^m)$. (Cf. Stigum 1986).

Introduction

Cost and expenditure functions are widely used in both theoretical and applied economics. Cost functions are often used in econometric studies which describe the technology of firms or industries while their consumer theory counterparts, expenditure functions, are frequently used to describe the preferences of consumers.

Cost and expenditure functions also play an important role in many theoretical investigations. This is due to the fact that a cost function embodies the consequences of cost minimizing behaviour on the part of a consumer or producer and so it is not necessary to spell out the details of the primal minimization problem that defined the cost function. This may seem like a very minor advantage, but when one is dealing with, say, the comparative statics of a general equilibrium problem, the use of cost functions leads to the analysis of a much smaller system of equations and hence the structure of the problem can be more easily understood.

Sections "Properties of Cost Functions," "Duality Between Cost and Production Functions," "The Derivative Property of the Cost Function," and "The Comparative Statics Properties of Cost Functions" below develop the theoretical properties of cost functions while sections "Functional Forms for Cost Functions," "Applications to the Estimation of Consumer Preferences," and "Cost Functions and Measures of Welfare Gain" are devoted to empirical applications of cost functions in the producer and consumer contexts.

Properties of Cost Functions

One of the fundamental paradigms in economics is the one which has a producer competitively minimizing costs subject to his technological constraints. Competitive means that the producer takes input prices as fixed during the given period of time irrespective of the producer's demand for those inputs.

We assume that only one output can be produced using N inputs and that the producer's technology can be summarized by a *production function* $F : y = F(x)$ where $y \geq 0$ is the maximal amount of output that can be produced during a period, given the non-negative vector of inputs $x \equiv (x_1, \ldots, x_N) \geq 0_N$. We further assume that the cost of purchasing one unit of input i is $p_i > 0$, $i = 1, \ldots, N$ and that the positive vector of input prices that the producer faces is $p \equiv (p_1, \ldots, p_N) \gg 0_N$.

For $y \geq 0$, $p \gg 0_N$, the producer's *cost function* C is defined as the solution to the following constrained minimization problem:

$$C(y,p) \equiv \min_x \{p.x : F(x) \geq y, x \geq 0_N\} \qquad (1)$$

where $p \cdot x \equiv \sum_{n=1}^{N} p_n x_n$. Thus $C(y, p)$ is the minimum input cost of producing at least the output level y, given that the producer faces the input price vector p.

The minimization problem (1) can also be given a consumer theory interpretation: let F be a consumer's preference or *utility function,* let y be a utility or welfare level, let x be a vector of commodity purchases (rentals in the case of consumer durables), and let p be a vector of commodity (rental) prices. In this case, the consumer attempts to minimize the cost of achieving at least the target welfare level indexed by y, and the solution to (1) defines the consumer's *expenditure function.*

Unfortunately, the minimum (1) may not exist in general. However, if we impose the following very weak regularity condition on F, it can be shown that C will be well defined as a minimum: *Assumption* 1 *on F: F* is continuous from above.

Assumption 1 means that for every y in the range of F, the *upper level set* $L(y) \equiv \{x : F(x) \geq y, x \geq 0_N\}$ is a closed set. The assumption is a technical one of minimal economic interest. It is also a very weak condition from an empirical point of view, since it cannot be contradicted by a finite set of data on the inputs and output of a producer.

If we assume that the production function F satisfies Assumption 1, it turns out that the cost function C has the following properties: *Property 1: C* is a non-negative function; that is, $C(y, p) \geq 0$; *Property 2: C* is *linearly homogeneous* in input prices p for each fixed output level y; that is, $C(y^1, p) \geq C(y^2, p)$ for $y^1 \geq y^2 \geq 0$ and $p \gg 0_N$; *Property 3: C* is *nondecreasing* in p for fixed y; that is,

$C(y, p^1) \geq C(y, p^2)$ for $y \geq 0$, $p^1 \geq p^2 \gg 0_N$; *Property 4*: *C* is *concave* in p for fixed y;

that is, $C(y, \lambda p^1 + (1 - \lambda)p^2) \geq \lambda C(y, p^1) + (1 - \lambda)C(y, p^2)$ for $y \geq 0$, $0 \leq \lambda \leq 1$, $p^1 \gg 0_N$ and $p^2 \gg 0_N$; *Property 5: C* is *nondecreasing* in y for fixed p; that is, *Property 6: C* is *continuous from below* in y for fixed p; that is $\{y : C(y, p) \leq \alpha\}$ is a closed set for every α and $p \gg 0_N$.

Properties 1–4 for C were derived by Shephard (1953) under stronger regularity conditions on F and Properties 4, 5, and 6 were obtained by McKenzie (1957), Uzawa (1964) and Shephard (1970) respectively.

From the viewpoint of economies, all of the properties of C are intuitively obvious except Properties 4 and 6. Property 6 on C is the technical counterpart to Assumption 1 on F and is of minimal economic interest. However, Property 4 has some significant economic implications as we shall see in section "The Comparative Statics Properties of Cost Functions" below.

We can already draw some useful empirical implications from the fact that a cost function must satisfy Properties 1–6 above. For example, in industrial organization and applied econometrics, it is quite common to assume that the true functional form for a firm's or industry's cost function has the following functional form:

$$C(y,p) \equiv \alpha + \beta \cdot p + \gamma y \tag{2}$$

where α , $\beta \equiv (\beta_1, \ \ldots \ , \beta_N)$ and γ are unknown parameters. However, Property 2 implies that α and γ must be zero in order for the cost function to be linearly homogeneous in input prices. But then $C(y, p) = \beta \cdot p$ does not depend on the output level y, which is very implausible.

Duality Between Cost and Production Functions

It is easy to see that the family of upper level sets, $L(y) \equiv \{x : F(x) \geq y, x \geq 0_N\}$, completely determines the production function F. Furthermore, the cost function C may be defined in terms of the production function by (1) or equivalently, in terms of the family of upper level sets as follows:

$$C(y,p) = \min_x \{p \cdot x : x \text{ belongs to } L(y)\}. \tag{3}$$

Thus given the production function F or the family of level sets $L(y)$, the cost function C is determined.

We now ask the following question: given a cost function C which has Properties 1 to 6, can we use C to define the underlying production function F?

For a given output level y and input price vector $p \gg 0_N$, define the corresponding isocost plane by $\{x : p \cdot x = C(y, p)\}$.From the definitions of $C(y, p)$ and $L(y)$, it is obvious that the set $L(y)$ must lie above this isocost plane and be

tangent to it; that is, $L(y)$ must be a subset of the set $\{x : p \cdot x \geq C(y, p)\}$ and this conclusion must be true for every positive input price vector p. Thus $L(y)$ must be a subset of the intersection of all these sets which we denote by $M(y)$:

$$M(y) \equiv \bigcap_{p \gg 0}^{N} \{x : p \cdot x \geq C(y,p)\}. \quad (4)$$

The set $M(y)$ is called the *disposal, convex hull of* $L(y)$; see McFadden (1966).

Each set $\{x : p \cdot x \geq C(y, p)\}$ is a halfspace and is a convex set. A set S *is convex* if and only if x^1 and x^2 belong to S and $0 \leq \lambda \leq 1$ implies $\lambda x^1 + (1 - \lambda)x^2$ also belongs to S. Since $M(y)$ is the intersection of a family of convex sets, $M(y)$ is also a convex set. $M(y)$ also has the following *free disposal* property:

$$x^1 \text{ belongs to } M(y), x^1 \leq x^2, \text{ then } x^2 \text{ belongs to } M(y). \quad (5)$$

We know $L(y)$ must be a subset of $M(y)$. If we want $L(y)$ to coincide with $M(y)$, then $L(y)$ must also be a convex set with the free disposal property. It can be shown that $L(y)$ will have these last two properties for every output level y if and only if the production function F has the following two properties: *Assumption 2 on F: F* is *quasiconcave* function: that is, for every y belonging to the range of F, $L(y) \equiv \{x : F(x) \geq y\}$ is a convex set. *Assumption 3 on F: F* is *nondecreasing;* that is, if $x^2 \geq x^1 \geq 0_N$, then $F(x^2) \geq F(x^1)$.

We may now answer our earlier question about whether a cost function C can completely determine the production function F: the answer is yes if the production satisfies Assumptions 1–3.

More precisely, we have the following result: given a cost function C which satisfies Properties 1–6, then the production function F defined by

$$F(x) \equiv \max_y \{y : C(y,p) \leq p \cdot x \text{ for every } p \gg 0_N\}, x \geq 0_N \quad (6)$$

satisfies Assumptions 1–3. Moreover, if we define the cost function C^* which corresponds to the F defined by (6) in the usual way [recall (1)], then $C^* = C$; that is, this derived cost function C^* coincides with the original cost function C. Thus there is a *duality* between production functions F satisfying Assumptions 1–3 and cost functions C having Properties 1–6: each function completely determines the other under these regularity conditions.

Duality theorems similar to the above results have been established under various regularity conditions by Shephard (1953, 1970), Uzawa (1964), McFadden (1966, 1978a) and Diewert (1971, 1982).

The Derivative Property of the Cost Function

The following result is the basis for most of the theoretical and empirical applications of cost functions.

Suppose the cost function C satisfies Properties 1–6 listed in section "Properties of Cost Functions" and in addition, C is differentiable with respect to the components of p at the point (y^*, p^*). Then the solution $x^* \equiv (x_1^*, \ldots, x_N^*)$ to the cost minimization problem $\min_y \{P^* \cdot x : F(x) \geq y^*, x \geq 0_N\}$ is unique and

$$x_i^* = \partial C(y^*, p^*)/\partial_{pi}, i = 1, \ldots, N; \quad (7)$$

that is, the cost minimizing demand for the ith input is equal to the partial derivative of the cost function with respect to the ith input price.

The result (7) is known as the derivative property of the cost function (see McFadden, 1978a) or Shephard's Lemma, since Shephard (1953) was the first to obtain the result. It should be noted that Hicks (1946) and Samuelson (1947) obtained the result (7) earlier, but under different hypotheses: they assumed the existence of a utility or production function F and deduced (7) by analysing the comparative statics properties of the cost minimization problem (1). On the other hand, Shephard (1953, 1970) assumed only the existence of a cost function satisfying the appropriate regularity conditions.

C

A very elegant proof of (7) using the hypotheses of Hicks and Samuelson is due to Karlin (1959) and Gorman (1976). Their proof proceeds as follows.

Let x^* be a solution to $\min_x\{p^* \cdot x : F(x) \geq y^*, x \geq 0_N\} = C(y^*, p^*)$. Then for every $p \gg 0_N$, x^* is feasible for the cost minimization problem defined by $C(y^*, p) = \min_x\{p \cdot x : F(x) \geq y^*, x \geq 0_N\}$ but it is not necessarily optimal. Thus for every $p \gg 0_N$, we have the following inequality:

$$p \cdot x^* \geq C(y^*, p). \tag{8}$$

We also have

$$p^* \cdot x^* = C(y^*, p^*). \tag{9}$$

For $p \gg 0_N$, define the function $g(p) \equiv p \cdot x^* - C(y^*, p)$. From (8), $g(p) \geq 0$ for all $p \gg 0_N$, and from (9), $g(p^*) = 0$. Thus $g(p)$ attains a global minimum at $p = p^*$. Since g is differentiable, the first-order necessary conditions for a minimum must be satisfied at p^*:

$$\nabla_p g(p^*) = x^* - \nabla_p C(y^*, p^*) = 0_N \tag{10}$$

Where $\nabla_p g(p^*) \equiv [\partial g(p^*)/\partial p_1, \ldots, \partial g(p^*)/\partial p_N]$ denotes the vector of first-order partial derivatives of g with respect to the components of p evaluated at p^* and $\nabla_p C(y^*, p^*)$ denotes the vector of first-order partial derivatives of C with respect to the components of p evaluated at (y^*, p^*). The second set of equalities in (10) can be rearranged to yield (7).

From an econometric point of view, Shephard's Lemma is a very useful result. In order to obtain a valid system of cost minimizing input demand functions, $x(y,p) \equiv [x_1(y,p), \ldots, x_N(y,p)]$ all we have to do is postulate a functional form for C which satisfies Properties 1–6 and then differentiate C with respect to the components of the input price vector p; that is, $x(y, p) = \nabla_p C(y, p)$. It is not necessary to compute the production function F that corresponds to C via the Shephard Duality Theorem nor is it necessary to undertake the often complex algebra involved in deriving the input demand functions using the production function and Lagrangian techniques. In section "Functional Forms for Cost Functions" below, we shall consider several functional forms for C that have been suggested for their econometric convenience.

The Comparative Statics Properties of Cost Functions

Suppose that we are given a cost function C satisfying Properties 1–6 that is also twice continuously differentiable at (y^*, p^*) where $y^* > 0$ and $p^* \gg 0_N$. Applying Shephard's Lemma (7), the above differentiability assumption ensures that the cost minimizing input demand functions $x_i(y, p)$ exist and are once continuously differentiable at (y^*, p^*).

Define $[\partial x_i/\partial p_j] \equiv [\partial x_i(y^*, p^*)/\partial p_j]$ to be the N by N matrix of partial derivatives of the N demand functions $x_i(y^*, p^*)$ with respect to the N prices p_j, $i,j = 1,\ldots, N$. From (7), it follows that

$$\begin{aligned}[\partial x_i/\partial p_j] &= [\partial^2 C(y^*, p^*)/\partial p_i \partial p_j] \\ &\equiv \nabla^2_{pp} C(y^*, p^*)\end{aligned} \tag{11}$$

where $\nabla^2_{pp} C(y^*, p^*)$ is the matrix of second-order partial derivatives of the cost function with respect to the components of the input price vector evaluated at (y^*, p^*). The twice continuous differentiability property of C implies by Young's Theorem in calculus that $\nabla^2_{pp} C(y^*, p^*)$ is asymmetric N by N matrix. Thus using (11), we have

$$[\partial x_i/\partial p_j] = [\partial x_i/\partial p_j]^{\mathrm{T}} = [\partial x_i/\partial p_i] \tag{12}$$

where A^{T} denotes the transpose of the Matrix A. Thus we have established the Hicks (1946) and Samuelson (1947) *symmetry restrictions* on input-demand functions, $\partial x_i(y^*, p^*)/\partial p_j = \partial x_j(y^*, p^*)/\partial p_i$ for all i and j.

Since C is concave in p and is twice continuously differentiable with respect to the components of p at the point (y^*, p^*), it follows from a characterization of concave functions that $\nabla^2_{pp} C(y^*, p^*)$ is a negative semidefinite matrix. Thus by (11),

$$z^{T}[\partial x_i/\partial p_j]z \leq 0 \text{ for all vectors } z. \quad (13)$$

In particular, letting $z = e_i$, the ith unit vector, (13) implies

$$\partial x_i(y^*, p^*)/\partial p_i \leq 0 \text{ for } i = 1, \ldots, N; \quad (14)$$

that is, the ith cost minimizing input demand function cannot slope upwards with respect to the ith input price for $i = 1,..., N$.

Since C is linearly homogeneous in p, we have $C(y^*, \lambda p^*) = \lambda C(y^*, p^*)$ for all $\lambda > 0$. Partially differentiating this equation with respect to p_i for λ close to 1 yields the equation $C_i(y^*, \lambda p^*)\lambda = \lambda C_i(y^*, p^*)$ where $C_i(y^*, p^*) \equiv \partial C(y^*, p^*)/\partial p_i$. Thus $C_i(y^*, \lambda p^*) = C_i(y^*, p^*)$ and differentiation of this last equation with respect to λ yields when $\lambda = 1$:

$$\sum_{j=1}^{N} p_j^* \partial^2 C(y^*, p^*)/\partial p_i \partial p_j = 0 \quad \text{for } i = 1, \ldots, N. \quad (15)$$

Equations (11) and (15) imply that the input-demand functions $x_i(y^*, p^*)$ satisfy the following N restrictions:

$$\sum_{j=1}^{N} p_j^* \partial x_i(y^*, p^*)/\partial p_j = 0 \quad \text{for } i = 1, \ldots, N. \quad (16)$$

A final general restriction on the derivatives of the input-demand functions may be obtained as follows: for λ near 1 differentiate both sides of $C(y^*, \lambda p^*) = \lambda C(y^*, p^*)$ with respect to y and then differentiate the resulting equation with respect to λ. When $\lambda = 1$, the last equation becomes:

$$\sum_{j=1}^{N} p_j^* \partial^2 C(y^*, p^*)/\partial y \partial p_j = \partial C(y^*, p^*)/\partial y. \quad (17)$$

The twice continuous differentiability of C at (y^*, p^*) and (7) imply:

$$\partial^2 C(y^*, p^*)/\partial y \partial p_j = \partial^2 C(y^*, p^*)/\partial p_j \partial y = \partial x_j(y^*, p^*)/\partial y. \quad (18)$$

Property 5 for cost functions implies that

$$\partial C(y^*, p^*)/\partial y^* \geq 0. \quad (19)$$

Using (18) and (19), (17) is equivalent to:

$$\sum_{j=1}^{N} p_j^* \partial x_j(y^*, p^*)/\partial y \geq 0. \quad (20)$$

Thus for at least one j, we must have $\partial x_j(y^*, p^*)/\partial y \geq 0$; that is, as output increases, not every input demand can decrease.

We have shown that the assumption of cost minimizing behaviour implies a number of restrictions on input demand functions that are potentially testable. Hicks (1946) and Samuelson (1947) obtained the restrictions (12), (13), and (16) using the first-order conditions for the primal cost minimization problem (1) and the properties of determinants of bordered Hessian matrices; Samuelson also obtained (20). Our derivation of the restrictions on input-demand functions using the dual approach is due to McKenzie (1957), Karlin (1959) and McFadden (1978a).

Hicks (1946) also showed that when $N = 2$, so that there are only two inputs, then (12), (13), and (16) imply that

$$\partial x_1(y^*, p_1^*, p_2^*)/\partial p_2 = \partial x_2(y^*, p_1^*, p_2^*)/\partial p_1 \geq 0. \quad (21)$$

Hicks (1946) called two distinct goods i and j *substitutes* if and only if $\partial x_i(y, p)/\partial p_j \geq 0$ and *complements* if and only if $\partial x_i(y, p)/\partial p_j < 0$. Thus in the two input case, the two goods must be substitutes. Hicks also showed that in the three input case, at least two of the three pairs of goods must be substitutes.

We turn now to empirical applications of cost functions.

C

Functional Forms for Cost Functions

Shephard's Lemma (7) provides a convenient method for generating systems of cost minimizing input demand functions: simply postulate a functional form for $C(y, p)$ and then partially differentiate C with respect to each input price. Below, we present three examples to illustrate the technique.

Our first example is the *translog cost function* due to Christensen et al. (1971, 1973). The logarithm of the cost function is defined as follows:

$$\begin{aligned}\ln C(y,p) &\equiv \alpha_0 + \sum_{i=1}^{N} a_i \ln p_i \\ &= (1/2) \times \sum_{i=1}^{N}\sum_{j=1}^{N} a_{ij} \ln p_i \ln p_j \\ &\quad + \sum_{i=1}^{N} a_{ij} \ln p_i \ln y + a_y \ln y \\ &\quad + (1/2) a_{yy} \ln y \ln y \end{aligned} \tag{22}$$

where the a_i, a_{ij}, $= a_{ij}$, a_i, a_y and a_{yy} are $1 + N + (1/2)N \quad (N + 1) + N + 2 = 3 + 2N +$ $(1/2)N(N + 1)$ parameters determined by the technology of the firm or industry. Differentiating both sides of (22) with respect to the logarithm of the ith input price, $\ln p_i$ for $i = 1, \ldots, N$ yields the following system of equations:

$$s_i = a_i + \sum_{j=1}^{N} a_{ij} \ln p_j + a_{iy} \ln y, \quad i = 1, \ldots, N \tag{23}$$

where the ith input cost share is defined as $s_i \equiv [p_i \partial C(y, p)/\partial p_i]/C(y, p) = p_i x_i(y, p)/C(y, p)$ where the last equality follows using (7).

By Property 2 for cost functions, $C(y, p)$ must be linearly homogeneous in input prices. This property will be satisfied by the translog cost function cost function if and only if the following N+2 linear restrictions on the parameters hold:

$$\sum_{i=1}^{N} a_i = 1, \sum_{i=1}^{N} a_{iy} = 0 \text{ and } \sum_{j=1}^{N}$$

$$a_{ij} = 0 \text{ for } i = 1, \ldots, N. \tag{24}$$

It is possible to append errors to equations (22) and N–1 of the equations (23) and econometrically estimate the unknown parameters, given data on inputs, input prices and output. The symmetry restrictions $a_{ij} = a_{ij}$ and the restrictions (24) may be imposed or one can test for their validity. If these restrictions are imposed, then the resulting translog cost function will have $1 + N + (1/2)$ $N(N + 1)$ free parameters.

What considerations are relevant in choosing a functional form for a cost function? The following four properties are desirable: (i) *flexibility*; that is, the functional form for C should have a sufficient number of free parameters to be able to provide a second-order approximation to an arbitrary twice continuously differentiable function with the appropriate theoretical properties, (ii) *parsimony*; that is, the functional form for C should have the minimal number of free parameters required to have the flexibility property, (iii) *linearity*; that is, the unknown parameters of C should appear in the system of estimating equations in a linear fashion in order to facilitate econometric estimation, and (iv) *consistency*; that is, the functional form for C should be consistent with Properties 1–6 for cost functions. These considerations were first suggested by Diewert (1971) in an informal manner; the term parsimony is due to Fuss et al. (1978) and the term flexible is due to Diewert (1974). The equivalence of various definitions of the flexibility property is discussed by Barnett (1983).

How satisfactory is the translog cost function in the light of the above considerations? We consider the flexibility property first. In order to be able to approximate a function of $1 + N$ variables to the second order, we require $1 + (1 + N) + (1 + N)^2$ free parameters. However, if we assume that the cost functions are twice continuously differentiable, then we can reduce the number by $N(N + 1)/2$ due to the symmetry property of the second-order partial derivatives. The linear homogeneity property of the cost function, Property 2, yields an additional N+1 restriction on the first and second derivatives of C, (15) and (17), plus the

following restriction (which follows using Euler's Theorem on homogeneous functions):

$$C(y,p) = \sum_{i=1}^{N} p_i \partial C(y,p)/\partial p_i. \qquad (25)$$

Thus a flexible functional form for a cost function should have $1 + (1 + N) + (1 + N)^2 - [(1/2)N(N + 1) + N + 1 + 1] = 1 + N + (1/2)N(N + 1)$ free parameters, which is precisely the number the translog cost function has when the restrictions (24) are imposed. It can be shown that the translog cost function is indeed flexible and we have just shown that it is also parsimonious.

As can be seen by inspecting (22) and (23), the estimating equations are linear in the unknown parameters, so the linearity property is also satisfied.

If the restrictions (24) are imposed, Property 2 will be satisfied. In practice, the other properties that a cost function must have will be satisfied with the exception of Property 4, the concavity in prices property. If all of the a_{ij} and a_{iy} parameters are zero, then the translog cost function reduces to a Cobb–Douglas cost function which satisfies the concavity property globally. However, in the general case, the best we can hope for is that the concavity property is satisfied locally for a range of input prices.

If a production function is linearly homogeneous (that is, $F(\lambda x) = \lambda F(x)$ for $\lambda \geq 0$ and $x \geq 0_N$) so that the technology is subject to constant returns to scale, then the corresponding cost function has the following property:

$$C(y,p) = yC(1,p); \qquad (26)$$

that is, total cost is equal to the output level y times the cost of producing one unit of output, $C(1, p) \equiv c(p)$, the *unit cost function.*

If C is twice continuously differentiable and satisfies (26), then one can show that the following $2 + N$ restrictions on the first and second derivatives of C must hold:

$$C(y,p) = y\partial C(y,p)\partial y; \qquad (27)$$

$$\partial^2 C(y,p)/\partial y^2 = 0; \qquad (28)$$

$$\partial C(y,p)/\partial p_i = y\partial^2 C(y,p)/\partial y \partial p_i, \quad i = 1, \ldots, N. \qquad (29)$$

However, in view of (25), it can be seen that only N–1 of the restrictions (29) are new. Thus the assumption of a constant returns to scale technology imposes new restrictions on the derivatives of the cost function C.

It can be shown that necessary and sufficient conditions for the translog cost function defined by (22) and (24) to satisfy (26) are the following N+1 restrictions:

$$a_y = 1, a_{yy} = 1 \text{ and } a_{iy} = 0 \text{ for } i = 1, \ldots, N-1. \qquad (30)$$

Of course (30) and (24) imply that a_{Ny}=0 as well.

It can be shown that if the restrictions (24) and (30) are imposed on the parameters of the translog cost function defined by (22), then the resulting functional form is flexible in the class of cost functions that satisfy the constant returns to scale property (26). Note that we can test for the validity of the constant returns to scale property by testing whether the N+1 linear restrictions (30) hold.

For our second example, consider the following functional form for a cost function:

$$C(y,p) \equiv c(p)y + \sum_{i=1}^{N} b_i p_i + b_{yy}\left(\sum_{i=1}^{N} \beta_i p_i\right) y^2; \qquad (31)$$

$$c(p) \equiv \sum_{i=1}^{N}\sum_{j=1}^{N} b_{ij} p_i^{1/2} p_j^{1/2} \qquad (32)$$

where the b_{yy}, b_i, $b_{ij} = b_{ji}$ and β_i are parameters which characterize the technology. If $b_i = 0$ for $i = 1, \ldots, N$ and $b_{yy} = 0$, then (31) reduces to the *Generalized Leontief cost function* defined by Diewert (1971). If in addition, $b_{ij} = 0$ for all $i \neq j$, then (31) reduces to the cost function $\sum_{i=1}^{N}$

$b_{ii}p_iy$, which is dual to the Leontief (no substitution) production function, $F(x_i, \ldots, x_N) \equiv \min \{x_i/b_{ii} : i = 1, \ldots, N\}$.

In order for the cost function defined by (31) and (32) to satisfy the parsimony property, it is necessary for the empirical investigator to prespecify the β_i parameters; for example, one could set β_i equal to 1 or to the average input quantity x_i observed in the sample of data. Under these conditions, the Generalized Leontief cost function has $(1/2)N(N + 1) + N + 1$ free parameters, which is just the required number for the flexibility property. In fact, Diewert and Wales (1987) show that this cost function is flexible and parsimonious when the β_i are predetermined.

Applying (7), the input-demand functions that correspond to (31) and (32) are:

$$x_i(y,p) = \sum_{j=1}^{N} b_{ij}p_i^{-1/2}p_j^{1/2}y + b_i + b_{yy}\beta_i y^2.i = 1, \ldots, N \tag{33}$$

For the purpose of econometric estimation, errors can be appended to the N Eq. 33. If the βi are predetermined, it can be seen that the system of estimating equations is linear in the unknown parameters.

If we wish to test for a constant returns to scale technology, then the following $1+N$ linear restrictions on the parameters are necessary and sufficient for this property:

$$b_{yy} = 0 \text{ and } b_i = 0 \text{ for } i = 1, \ldots, N. \tag{34}$$

Note that the linear homogeneity in prices property is satisfied by the Generalized Leontief cost function. The other properties for cost functions will also be satisfied in practice with the exception of Property 4, the concavity in prices property. If all $b_{ij} \geq 0$ for $i \neq j$, then the concavity property will be globally satisfied, but this assumption rules out complementary pairs of inputs (recall the discussion about substitutes and complements at the end of the previous section). Thus in general, one can only hope that the concavity property will be satisfied locally, as was the case with the translog cost function.

For our third and final example, consider the following *normalized quadratic cost function* defined by (31) but now $c(p)$ is defined as follows:

$$c(p) \equiv \sum_{i=1}^{N} b_{ii}p_i + (1/2)\sum_{i=1}^{N} \times \sum_{j=1}^{N} a_{ij}p_ip_j/\left(\sum_{n=1}^{N}\alpha_n p_n\right) \tag{35}$$

where the N by N matrix $A \equiv [a_{ij}]$ is symmetric and satisfies the following restriction for some input price vector $p^* \gg 0_N$;

$$Ap^* = 0_N. \tag{36}$$

This functional form is due to Diewert and Wales (1987); its generalizes some functional forms due to Fuss (1977) and McFadden (1978b). The functional form has Nb_{ii} parameters, $(1/2)N(N - 1)$ free a_{ij} parameters taking into consideration (36), N b_i parameters, 1 b_{yy}, N β_i and $N\alpha_n$ parameters or $1 + 3N + (1/2)N(N + 1)$ free parameters in all. In order for this functional form to have the parsimony property, it is necessary for the empirical investigator to prespecify the β_i and α_n parameters; we assume that this has been done and these parameters are non-negative and not identically equal to zero. Under these conditions, Diewert and Wales (1987) show that this cost function is parsimonious and flexible at the point (y^*, p^*) where p^* is the price vector which appears in (36).

Applying (7), the system of input demand functions divided by the output y is:

$$x_i(y,p)/y = b_{ii} + \sum_{j=1}^{N} a_{ij}p_j\left(\sum_{n=1}^{N}\alpha_n p_n\right)^{-1} - \left(\sum_{j=1}^{N}\sum_{k=1}^{N} a_{jk}p_jp_k\right) \times \left(\sum_{n=1}^{N}\alpha_n p_n\right)^{-2}\alpha_i + b_i y^{-1} + b_{yy}\beta_i y, i = 1, \ldots, N. \tag{37}$$

Errors can be appended to (37) and we obtain a system of estimating equations which is linear in

the unknown parameters, provided that the α_n and β_i are prespecified.

If we wish to test for a constant returns to scale technology, then again the $1 + N$ linear restrictions (34) are necessary and sufficient for this property.

The normalized quadratic cost function with prespecified α_n and β_i is flexible, parsimonious and has linear estimating equations. As was the case with our first two examples, our third example has no problem in satisfying Properties 1, 2, 3, 5 and 6 for cost functions. It also turns out that our third example has no problem in satisfying Property 4: Diewert and Wales (1986) using some results due to Lau (1978), show that the normalized quadratic cost function is globally concave if and only if the A matrix is negative semidefinite. They also indicate how this negative semidefiniteness property can be imposed if necessary without destroying the flexibility of the functional form; simply set $A = -SS^{T}$ where S is a lower triangular N by N matrix and S^{T} is its transpose. However, in this latter case, nonlinear regression techniques must be used in order to estimate the unknown parameters.

The extensive empirical literature on estimating cost functions is nicely reviewed by Jorgenson (1984).

Applications to the Estimation of Consumer Preferences

The cost function techniques described in the previous section can be used to obtain empirical descriptions of technologies. Those techniques can also be adapted to obtain empirical descriptions of consumer preferences.

As was noted in section "Properties of Cost Functions," y may be interpreted as a household's welfare level, F as a utility or preference function, p as a vector of commodity prices and $C(y, p)$ as the minimum cost of achieving at least the welfare level y.

However, the econometric techniques described in the previous section cannot be utilized immediately in the consumer context because utility cannot be observed whereas output can. We acknowledge this difference by using u, the consumer's utility or welfare level, in place of y in what follows.

The theory outlined in the previous sections is still valid: given a differentiable functional form for the cost function $C(u, p)$ that satisfies Properties 1 to 6, we may form the consumer's system of *constant real income or Hicksian demand functions* $x(u, p) \equiv [x_1(u, p), \ldots, x_N(u, p)]$ by differentiating the cost function with respect to each commodity price p_i [recall (7)]:

$$x_i(u,p) = \partial C(u,p)/\partial p_i, i = 1, \ldots, N. \quad (38)$$

We determine u as a function of the prices p and the consumer's observed expenditure on commodities during the period Y, say, by equating the minimum cost of achieving the welfare level u to the observed expenditure; that is, we solve the following equation for u:

$$C(u,p) = Y. \quad (39)$$

The solution function g where $u = g(Y, p)$ is known as the consumer's *indirect utility function.* Now replace u in the right-hand side of (38) by $g(Y, p)$ and obtain the consumer's system of *market demand functions:*

$$x_i = \partial C(g(Y,p),p)/\partial p_i, i = 1, \ldots, N. \quad (40)$$

If we multiply equation i in (40) by p_i, sum the resulting equations and use (7), (25) and (39), then we obtain the identity $\sum_{i=1}^{N} p_i x_i = Y$, so only N–1 of the N equations in (40) are independent. Thus for econometric estimation purposes, we may add errors to N–1 of the equations in (40), and given a functional form for C, we may use these equations to estimate the unknown parameters in C. We shall discuss this technique in more detail shortly, but first, we must discuss the problems involved in cardinalizing utility.

The scaling of utility is irrelevant in describing a consumer's preferences. However, when we postulate a functional form for a cost function, we are implicitly imposing a cardinalization of the consumer's utility. Hence, we might as well

impose a convenient cardinalization: *money metric scaling of utility* (the term is due to Samuelson 1974). This involves setting utility u equal to 'income' Y, holding prices constant at some specified price vector p^*, that is, we have

$$Y = g(Y, p^*) \quad \text{for all } Y > 0. \tag{41}$$

In terms of the cost function, (41) may be rewritten as

$$u = C(u, p^*) \text{ for all } u > 0. \tag{42}$$

In examples 2 and 3 in the previous section, the cost function had the following form:

$$C(u,p) = c(p)u + \sum_{i=1}^{N} b_i p_i + b_{yy}\left(\sum_{i=1}^{N} \beta_i p_i\right) u^2. \tag{43}$$

In order to make (43) consistent with money metric scaling, (42), the following three restrictions on the parameters of C must be satisfied:

$$c(p^*) = 1, \sum_{i=1}^{N} b_i p_i^* = 0 \text{ and } b_{yy} = 0. \tag{44}$$

Using $b_{yy} = 0$ we find that the indirect utility function that corresponds to the C defined by (43) is

$$g(Y,p) = \left(Y - \sum_{i=1}^{N} b_i p_i\right)/c(p). \tag{45}$$

Substitution of (45) into (40) yields the following system of consumer demand functions:

$$x_i = b_i + [\partial c(p)/\partial p_i]\left(Y - \sum_{i=1}^{N} b_i p_i\right)/c(p). \quad i = 1, \ldots, N. \tag{46}$$

Now add errors to N–1 of the Eq. 46, calculate the partial derivatives of the $c(p)$ defined by (32) or (35), impose the normalizations (44) and we have a system of nonlinear estimating equations. An empirical example of this technique for estimating consumer preferences may be found in Diewert and Wales (1986).

Finally, we note that cost functions of the type defined by (43) with $b_{yy} = 0$ have very convenient aggregation over consumers' properties; see Gorman (1953) and Deaton and Muellbauer (1980).

Cost Functions and Measures of Welfare Gain

Consider a consumer whose preferences can be represented by the differentiable cost function, $C(u, p)$. Suppose we can observe the consumer's choices x^1 and x^2 during periods 1 and 2 when prices p^1 and p^2 prevail. Let u^1 and u^2 be the welfare levels attained during those two periods. Then by (7),

$$x^i = \nabla_p C(u^i, p^i), i = 1, 2. \tag{47}$$

For many purposes in applied welfare economics, it is useful to evaluate the *ex post* welfare change of the consumer. Two natural measures, suggested originally by Hicks (1942), are his *equivalent* and *compensating variations* which we denote by $V(p^1)$ and $V(p^2)$:

$$V(p^1) \equiv C(u^2, p^1) - C(u^1, p^1); V(p^2) \equiv C(u^2, p^2) - C(u^1, p^2). \tag{48}$$

From (47) and (25), $C(u^1, p^1) = p^1 \cdot x^1$ and $C(u^2, p^2) = p^2 \cdot x^2$. However, the costs $C(u^2, p^1)$ and $C(u^1, p^2)$ are not observable. Hence the following question arises: can we form approximations to $V(p^i)$ that use only observable data?

Linear approximations to $C(u^i, p^j)$ may be obtained using Taylor's Theorem. Thus we have:

$$V(p^1) \cong [C(u^2, p^2) + \nabla_p C(u^2, p^2) \cdot (p^1 - p^2)] - C(u^1, p^1) = [p^2 \cdot x^2 + x^2 \cdot (p^1 - p^2)] - p^1 \cdot x^1 \text{ using (47)} = p^1 \cdot (x^2 - x^1) \tag{49}$$

and

$$
\begin{aligned}
V(p^2) &\cong C(u^2,p^2) \\
&- \left[C(u^1,p^1) + \nabla_p C(u^1,p^1)\cdot(p^2-p^1)\right] \\
&= p^2\cdot x^2 - \left[p^1\cdot x^2 + x^1\cdot(p^2-p^1)\right] \text{ using (47)} \\
&= p^2\cdot(x^2-x^1).
\end{aligned}
\tag{50}
$$

The first-order approximations (49) and (50) are essentially due to Hicks (1942, 1946).

To obtain a second-order approximation result, we proceed indirectly. Suppose the consumer's cost function is defined by

$$
C(u,p) \equiv c(p) + \sum_{i=1}^{N} b_i p_i u \tag{51}
$$

where $c(p)$ is the normalized quadrative unit cost function defined by (35) for some prespecified $\alpha \equiv (\alpha_1, \ldots, \alpha_n) > 0_N$.

It can be shown that the cost function defined by (51) can provide a second- order approximation to an arbitrary twice continuously differentiable cost function that satisfies the money metric scaling of utility property (42).

Now use the parameters vector α which occurred in the definition of $c(p)$ in order to define the *normalized prices* v^i

$$
v^i \equiv p^i/(p^i\cdot\alpha), \quad i=1,2. \tag{52}
$$

Straightforward calculations show that if C is defined by (51), then the following identity holds *exactly*:

$$
\begin{aligned}
&(1/2)V(v^1) + (1/2)V(v^2) \\
&\quad = (1/2)(v^1+v^2)\cdot(x^2-x^1)
\end{aligned}
\tag{53}
$$

where $V(v^1)$ and $V(v^2)$ are equivalent and compensating variations evaluated using the normalized prices v^i in place of the commodity price vectors p^i. Thus (53) says that an average of the Hicksian variations using normalized prices is exactly equal to the average of the normalized prices inner producted with the vector of quantity differences, x^2–x^1, provided that preferences are defined by the cost function (51). Note that the right-hand side of (53) can be evaluated using observable price and quantity data. Since the formula on the right-hand side is exact for preferences which have a second-order approximation property, we could call it a *superlative welfare gain measure* in analogy to the terminology used in index number theory. The term gain measure is due to King (1983).

Consider the following standard problem in the theory of demand: Find $x^* \geq 0$ so as to max $u(x)$ subject to $\langle x, p\rangle \leq \omega$ where $\langle x, p\rangle$ is the inner product of the n-dimensional commodity and price vectors, and $\omega > 0$ and u are the consumer's income and utility function respectively; this problem is here labelled $max(p, \omega)$.

The functional dependence of the *value* $v^*[\equiv u(x^*)]$ of this nonlinear programming problem on its parameters (p, ω) is denoted by $v(p, \omega)$, where v is the *indirect* utility function. The similar dependence of the *solution* x^* of max (p, ω) is written $f(p, \omega)$, where f is the *ordinary* (or *Marshallian*) demand function (or correspondence). If v^* does not exist then neither do v, x^* or f. Important though they are such non-existence problems are irrelevant here, so without further ado assume that every optimization problem has a solution.

Consider next a problem whose form is similar to that of max (p, ω) but whose objective is different, that is, cost minimization rather than utility maximization. Specifically, find $x^{**} \geq 0$ so as to minmin $\langle x, p\rangle$ subject to $u(x) \geq \tau$ where x, p and u are as before and τ is a *target* level of utility; this new problem is labelled $\min(p, \tau)$. The functional dependence of the value $\mu^{**}(\equiv\langle x^{**}, p\rangle)$ of $\min(p, \tau)$ on its parameters (p, τ) is denoted $c(p,$

τ), where c is the *cost* (or *expenditure*) function. The similar dependence of x^{**} on (p, τ) is written $h(p, \tau)$, where h is the *compensated* (or *Hicksian*) demand function (or correspondence).

Suppose now that $\max(p, \omega)$ is solved and its value v^* is inserted into the second optimization problem, thus creating the problem $\min(p, v^*)$. Is each solution x^* of $\max(p, \omega)$ necessarily also a solution of $\min(p, v^*)$? Call this Question I. A similar question can be asked of the reverse situation, which is: For arbitrary (p, τ) solve $\min(p, \tau)$, obtain it value μ^{**} and then solve the resulting max problem, (p, μ^{**}). Question II is then: Is each solution x^{**} of $\min(p, \tau)$ necessarily also a solution of $\max(p, \mu^{**})$?

Problem $\min(p, v^*)$ has often been called the *dual* of $\max(p, \omega)$, from as far back as Arrow and Debreu (1954, pp. 285–6) to Deaton and Muellbauer (1980, pp. 37 ff.) and beyond. Indeed, this usage is now so common that for most economists $\min(p, v^*)$ seems to be *the* leading species of the genus *dual problem*.

One can see why. It appears to be quite analogous to dual problems in linear programming (lp), with max becoming min, and objective and constraint functions becoming constraint and objective functions, respectively. However, the analogy with duals in lp is misleading, for each solution x^{**} of the alleged 'dual' $\min(p, v^*)$ is located in the *same* space as each solution x^* of its 'primal' $\max(p, \omega)$, whereas in lp the solutions to the dual all lie in the *dual* space. As Deaton and Muellbauer justly remark: 'The essential feature of the duality approach is a *change of variables*' (1980, p. 47, their italics). So a new term for the relation that $\min(p, v^*)$ bears to $\max(p, \omega)$ is needed in order to distinguish it from genuine duality; the 'mirrored' (or 'reflected') problem is suggested in Newman (1982).

In demand theory it is sometimes recognized explicitly that Question I needs an answer (for example, Samuelson 1947, p. 103; McKenzie 1957, p. 186) but more often not, probably because the usual assumptions on preferences are quite sufficient for coincidence of x^{**} with x^*. An explicit treatment appears unnecessary: '... clearly, the vector of commodities must in both cases be the same' (Deaton and Muellbauer 1980, p. 37). In welfare economics, however, it has long been recognized that a suitably generalized form of Question I, simple as it is, has importance for the first fundamental theorem of welfare economics, namely that every competitive allocation is (strongly) Pareto-optimal.

Question II has always been considered more delicate than Question I. Indeed, it was not even put until Arrow (1951, pp. 527–8) exhibited his famous 'exceptional case' (now often known as the Arrow Corner) in which it receives a negative answer. Its relevance for proofs of existence of competitive equilibrium was fully grasped by Arrow and Debreu (1954, sections 4 and 5), and later Debreu (1959, pp. 67–71), for essentially this reason, devoted four pages of his terse classic to a detailed examination of both Questions.

It is interesting that although the second Question is economically more subtle than the first, from a sufficiently abstract point of view the two are logically isomorphic (see Newman 1982, where in both Theorem (c) and Theorem (c′) the assertion 'iff' is wrong and should be replaced by 'if'). While such extreme abstraction is irrelevant here, both $\max(p, \omega)$ and $\min(p, \tau)$ do need to be put into a form suitable for general equilibrium theory.

The Setting

The consumer is now endowed, not with an exogenous positive income, but with a nonzero bundle x^0, whose worth $\langle x^0, p\rangle$ may be zero. For simplicity (and only that), free disposal is assumed.

Assumptions About Preferences

The consumer has two disjoint binary relations $\succ$ ('preference') and $\sim$ ('indifference') each defined on some non-empty $S \subset R^n$; the union of $\succ$ and $\sim$ is denoted $\succsim$. Indifference is reflexive and symmetric (so that preference is irreflexive) and the

statements $x^1 \succ x^3$ and $x^2 \sim x^3$ together imply $x^1 \succ x^3$. Neither completeness nor transitivity of preference is assumed, so a utility function need not exist.

The generalized version of max(p, ω) is then: Find $x^* \in S$ for which $\langle x^{**} p\rangle \leq \langle x^0, p\rangle$ and such that $x \succ x^*$ implies $\langle x, p\rangle > \langle x^0, p\rangle$. In words, '$x^*$ is feasible and anything preferred to it is unaffordable'. This problem is labelled max(p, x^0).

The generalized version of min(p, τ) is: Find $x^{**} \in S$ for which $x^{**} \gtrsim t$ and such that $x \gtrsim t$ implies $\langle x, p\rangle \geq \langle x^{**}, p\rangle$. In words, 'anything at least as good as the target bundle $t \in S$ costs at least as much as x^{**}'. This problem is labelled min(p, t).

Note that in the absence of a utility function max(p, x^0) can have a solution but not a value, while min(p, t) can have both value and solution, just as before.

Some Definitions

Any bundle $x^{\#}$ to which no $x \in S$ is preferred is called *bliss*, while a bundle $x_{\#}$ for which at prices p there is no cheaper $x \in S$ is called *p-minimal*. Preferences are *locally nonsatiated* at x^1 if *any* neighbourhood $N(x^1)$ contains $x \succ x^1$, while $x^2 \in S$ has *locally cheaper points* at p (a term apparently due to McKenzie 1957) if *any* neighbourhood $N(x^2)$ contains a bundle $x \in S$ which at prices p is cheaper than x^2. If $x^{\#}$ is bliss it cannot be locally nonsatiated, and if $x_{\#}$. is p-minimal it has no locally cheaper points at p.

Following Bergstrom et al. (1976), preferences are said to have *open upper sections* if $x' \succ x^2$ implies the existence of a neighbourhood $N(x^1) \subset S$ for which $x \succ x^2$ for every x in it.

The following simple result answers both Questions satisfactorily and generalizes easily to a wide class of infinite-dimensional commodity spaces.

Theorem

(i) Assume (a) that if $x \in S$ is not bliss it is locally nonsatiated, and (b) that the solution x^* of max(p, x^0) is not bliss. Then x^* also solves min(p, x^*). Moreover, the value μ^{**} of min(p, x^{**}) equals $\langle x^0, p\rangle$.

(ii) Assume (c) that preferences have open upper sections, (d) that if $x \in S$ is not p-minimal it has locally cheaper points at p, and (e) that the solution x^{**} of min(p, t) is not p-minimal. Then x^{**} also solves max(p, μ^{**}), where $\mu^{**} = \langle x^{**}, p\rangle$.

Proof

(i) Suppose the result false, so there exists $x^1 \gtrsim x^*$ such that $\langle x^1, p\rangle < \langle x^*, p\rangle$ Now $x^1 \gtrsim x^*$ cannot occur because if it did $\langle x^1, p\rangle < \langle x^*, p\rangle \leq \langle x^0, p\rangle$ would imply that x^* does not solve max(p, x^0), contrary to hypothesis. So $x^1 \sim x^*$.

Since the vector p represents a continuous linear function (al) there is a neighbourhood $N(x^1)$ all of whose points are cheaper at prices p than x^*. From (b) there exists $x \succ x^*$, and this and the symmetry of $\sim$ imply that $x \succ x^1$ as well, so that x^1, is not bliss either. Hence from (a) at least one member of $N(x^1)$, say x^2, is such that $x^2 \succ x^1$. Because $x^1 \succ x^*$ this leads to $x^2 \succ x^*$, which again contradicts the hypothesis. Thus x^* solves min(p, x^*), which implies $\mu^{**} = \langle x^*, p\rangle$.

Suppose $\langle x^*, p\rangle < \langle x^0, p\rangle$. By the continuity of p there exists $N(x^*)$ all of whose points are cheaper at prices p than is x^0, while from (b) and (a) at least one of them, say x^3, is such that $x^3 \succ x^*$. Yet again, this contradicts the hypothesis. So $\langle x^*, p\rangle = \langle x^0, p\rangle$.

(ii) By assumption $x^{**} \gtrsim t$ Suppose $x^{**} \succ t$. From (c) there exists $N(x^{**})$ such that $x \succ t$ for every x in it. From (e) and (d) x^{**} has locally cheaper points at p, so at least one x in $N(x^{**})$, say x^1, is cheaper than x^{**} at p. Since $x^1 \succ t$, this contradicts the hypothesis that x^{**} solves min(p, t). Hence $x^{**} \sim t$.

Suppose now that x^{**} does not solve max(p, μ^{**}), so there is an x^2 such that $x^2 \succ x^{**}$ and $\langle x^2, p\rangle \leq \langle x^{**}, p\rangle$. Hence $x^2 \succ t$. If x^2 were cheaper at p than x^{**} that would again contradict the hypothesis. So $\langle x^2, p\rangle \leq \langle x^{**}, p\rangle$.

From (e) there is an $x \in S$ cheaper at p than x^{**}, hence cheaper than x^2, so x^2 is not p-minimal either. Since $x^2 \succ t$, from (c) there exists $N(x^2)$ such that $x \succ t$ for every x in it and from (d) at least one of these must be cheaper than x^2 at p, and so cheaper than x^{**}, which again contradicts the hypothesis. Q.E.D.

One sees just how few and how weak are the assumptions on preferences that enable Questions I and II to be answered, as distinct (for ex) from those needed to guarantee the *existence* of solutions x^* and x^{**}. Note that two assumptions are used for Question I and three for II, an inequality which occurs because the constraint in $\max(p, x^0)$ is linear and hence continuous, whereas in the problem $\min(p, t)$ some continuity in the (nonlinear) constraint has to be *imposed* by means of the 'extra' assumption (c). This asymmetry disappears in a more abstract treatment, with more general constraints.

The intuitions behind the proof help to see why Question II is a serious problem for general equilibrium theory. In the proof of (i) the bundle x^1 that is cheaper than x^* is made a little bigger, in effect increasing satisfaction by increasing expenditure, until a bundle is reached that is still affordable at income $\langle x^0, p \rangle$ but which is better than x^*; that expenditure can always be thus 'traded' for satisfaction is assured by local non-satiation. In the proof of (ii) the bundle x^1 that is better than x^{**} is made a little smaller, lessening satisfaction in return for less cost, until a bundle is reached that is still as good as t but which costs less than x^{**}; such 'trading' of satisfaction for expenditure is guaranteed by the existence of locally cheaper points. However, if the expenditure on x^{**} at prices p is already least possible (that is, if x^{**} is p-minimal) then 'trading' in *that* direction cannot occur – one cannot go below least cost.

Of the five assumptions of the Theorem the only one whose meaning is not transparent and whose restriction is not 'reasonable' is (e), so that it comes as no surprise that the main thing wrong at the Arrow Corner is that (e) does not hold there. For further discussion of this Slater-like assumption and its role in general equilibrium theory, see consumption sets.

Cost of Production

John Eatwell

Adam Smith argued that competition would tend to establish the 'natural prices' of commodities produced, i.e. the prices at which 'the price of any commodity is neither more nor less than what is sufficient to pay the rent of land, the wages of labour, and the profit of stock employed. . .according to their natural rates' (Smith 1776, p. 65). In other words, the price of any produced commodity will, under the pressure of competition, be equal to its cost of production.

Ricardo was later to use the term 'cost of production' as a synonym for the 'value' of a commodity, where by value is meant, in the *Essay on Profits*, the difficulty or facility of production of the commodity, and in the *Principles*, the relative

quantity of labour necessary for the production of the commodity. The expression is used to represent the value of the commodity as manifest in terms of the standard of values used in the market. Ricardo dismissed the attempt by Malthus to draw a distinction between value and cost:

> Mr. Malthus appears to think that it is part of my doctrine, that the cost and value of a thing should be the same; – it is, if he means by cost, 'cost of production', including profits (1817, p. 47n).

Ricardo's identification of cost and value has led some authors to the belief that the classical theory of value is a 'cost of production' theory, which may be contrasted with the 'supply and demand' theory of neoclassical economics – an idea that was perhaps reinforced by Marshall's claim that classical theory was 'one-sided', was only one blade of the scissors:

> we might as reasonably dispute whether it is the upper or the under blade of a pair of scissors that cuts a piece of paper, as whether value is governed by utility or cost of production (1890, p. 548).

Walras, too, seems to suggest that 'cost of production' and demand are independent forces in the mutual determination of price.

In fact the condition that the cost of production of produced commodities is equal to their price is simply a definition of competitive equilibrium. The proposition that price is equal to cost is thus common to all theories of competitive value. The fact is not trivial, but is the outcome of competitive mobility. The meaningful question for any theory of value is what determines that cost and price.

The classical theory of value and distribution takes as data the size and composition of social output, the conditions of reproduction, and the real wage (Sraffa 1960; Garegnani 1984). In a model which contains only circulating capital these data may be formed into the following price equations:

$$Ap(1+r) = p \tag{1}$$

where A is the $n \times n$ input–output matrix, p the price vector and r the rate of profit. Wage goods are incorporated in the input coefficients. There is no presumption that A is invariant to changes in output.

Given that A is connected (all commodities are basic) then the equations may be solved for unique positive values of r and p. Although in (1) price is equal to cost of production, cost of production is not independent of price. Since A is connected the price of every commodity depends as much on its *own price* as on the price of other commodities (Sraffa 1960, ch. 2).

The neoclassical theory of value takes as its data the preferences of individuals, the technology, and the endowment of factor services. In equilibrium the price of each produced commodity will equal the sum of the rentals of the factor services used in its production, i.e. its cost of production:

$$Bw = p \tag{2}$$

where B is the $n \times m$ matrix of input coefficients of factor services, w is the vector of factor rentals, and p the vector of prices of commodities produced. In this case it might appear at first glance that cost of production is independent of price since prices on the left hand side of (2) do not appear on the right hand side. But the appearance is deceptive. The rentals which clear the markets for factor services are determined by the endowments of factor services and the demands for them, which are in turn functions of the prices of final products. Hence the prices of produced commodities are not 'determined' by their costs of production, but are determined simultaneously with their costs of production.

Cost–Benefit Analysis

David L. Weimer

Abstract

Cost–benefit analysis (CBA) is a collection of methods and rules for assessing the social costs and benefits of alternative public policies. It promotes efficiency by identifying the set of feasible projects that would yield the largest positive net benefits to society. The willingness of people to pay to gain or avoid policy impacts is the guiding principle for measuring benefits. Opportunity cost is the guiding principle for measuring costs. CBA requires that appropriate shadow prices be derived when policies have effects beyond those that can be taken into account as changes of prices or quantities in undistorted markets.

Public policies, such as infrastructure projects, social welfare programmes, tax laws and regulations, typically have diverse effects in the sense that people would be willing to pay something to obtain effects they view as desirable and would require compensation to accept voluntarily effects they view as undesirable. If, across all members of society, the total amount willing to be paid by those who enjoy desirable effects (benefits) exceeds the total amount needed to compensate those who suffer undesirable effects (costs), then adopting the policy would make it potentially possible to achieve a Pareto improvement on the status quo. If the benefits do not exceed the costs, then adopting the policy does not offer a potential Pareto improvement. How should such costs and benefits be determined? Cost–benefit analysis (CBA) is the collection of generally accepted methods and rules for assessing the social costs and benefits of alternative public policies.

The US Flood Control Act of 1936 appears to be the first call for CBA to be systematically used to inform public policy (Steiner 1974); it became embedded within modern welfare economics with articles by John R. Hicks (1939) and Nicholas Kaldor (1940) that set out the efficiency rationale for requiring policies to have positive net benefits. Two forces have contributed to the increased use of CBA since the 1960s. First, budget pressures and the desire to avoid inefficient regulations have led many governments to promote, or even require, the subjection of certain types of policies to CBA. Its use in the United States, particularly in the area of economic regulation, has been mandated by a series of Executive Orders (Hahn and Sunstein 2002). Her Majesty's Treasury in the United Kingdom publishes the *Green Book* to help public sector organizations apply CBA to ensure that 'public funds are spent on activities that provide the greatest benefits to society, and that they are spent in the most efficient way' (HM Treasury 2002: v). Second, economists have shown ingenuity in finding ways to value goods not traded in efficient markets, thereby expanding the range of policies to which CBA can be reasonably applied. For example, the travel-cost method provides a way to value recreational facilities that charge an administratively

determined entry fee (Clawson and Knetsch 1966); hedonic pricing models facilitate valuation of spatially varying local public goods (Smith and Huang 1995); and the development of the contingent valuation survey method, propelled by environmental damage assessment suits in US courts, permits the valuation of public goods, such as existence value, that lack readily observable behavioural traces needed for revealed preference estimation (David 1963; Bateman and Willis 2000).

CBA promotes efficiency by identifying the set of feasible projects that would yield the largest positive net benefits. Three conceptual criticisms can be made against this proposition. First, because those who suffer costs from a policy are almost never fully compensated, CBA in any particular application generally will not guarantee a Pareto improvement. The counter-argument is that, if CBA is consistently used to select policies offering the largest net benefits and there are no consistent losers, then it is likely that overall everyone will actually be made better off. Second, the CBA techniques for measuring net benefits cannot guarantee a coherent social ordering of policy alternatives. For example, it is possible to identify situations in which moving from one policy to another offers positive net benefits as does moving back to the original policy (Scitovsky 1941; Blackorby and Donaldson 1990). As no fair social choice rule can guarantee a transitive social ordering (Arrow 1963), this result is not surprising and is of minor consequence compared with the practical difficulties encountered in applying CBA. Third, and most important, only a few economists argue that public policies should be selected solely to promote the goal of efficiency. Other goals, such as equity and preservation of human dignity, are often legitimately viewed as relevant to policy choice, so that CBA is inappropriate as a decision rule. Nonetheless, as efficiency is almost always one of the relevant goals of public policy, CBA remains useful as a method for assessing efficiency in the context of a broader multi-goal analysis.

Social Perspective

CBA assesses social costs and benefits, which distinguishes it from the self- regarding calculus of individual economic actors. The meaning of 'social' in this context is twofold. First, it involves the definition of the relevant society; that is, it requires a determination of whose costs and benefits have standing (Whittington and MacRae 1986). Economists generally argue for national standing, recognizing that those in a particular country live under the same political contract, or constitution, and share a common economy with its own fiscal and monetary policy. In practice, however, sub-national governments often base their decisions only on their own costs and benefits and therefore demand CBA with standing restricted to those under their jurisdictions. Even when geographic standing is resolved, issues remain as to whether the costs and benefits of all residents – citizens, legal aliens, illegal aliens, those with legally proscribed preferences – should count (Zerbe 1998).

Second, it requires comprehensive assessment of the valued effects of policies on those with standing. The effects are commonly divided into the categories of active and passive use. Policies affect active use by changing the observable quantities of goods consumed, such as day care or fishing. Passive use includes all those effects that cannot be readily identified with observable changes in behaviour: existence value, or the willingness to pay for some good, such as wilderness, that one never expects to consume actively (Krutilla 1967); option value, or the willingness to pay for some good that one may wish to consume actively in the future (Weisbrod 1964); donor value, or the willingness to pay for redistributions of goods to others (Hochman and Rogers 1969). The absence of observable behaviour precludes valuation of passive use through the revealed preference methods most favoured by economists. Stated preference methods, such as contingent value surveys, are thus necessary for undertaking comprehensive assessments of policies with effects on passive use.

Social Benefits: Willingness to Pay

A common metric for policy effects is required if these effects are to be aggregated across individuals within the relevant society. If more than one policy alternative is to be compared with the status quo, then this metric must have ordinal properties. Further, if it is to be compared with the resource costs of implementing the policy, then it must be measured in the monetary unit of the society. Equivalent variation (*EV*) satisfies these conditions (McKenzie 1983). Consider the expenditure, or cost- utility, function C(U,P), where *C* is the amount of money needed to achieve utility *U* with price vector *P*. If U_1 is the person's utility under the price vector P_1 that would result from the policy change and P_0 is the price vector that would result under the status quo, then the equivalent variation of the policy change is given by

$$EV = C(U_1, P_0) - C(U_1, P_1)$$

the difference between the expenditure needed to achieve U_1 without the policy and with it. The EV is the amount of money that one would have to give to the person instead of implementing the policy so that the person is as well off as he or she would have been had the policy been implemented. A negative EV indicates that the person finds the net effects of the policy undesirable.

In its actual use, CBA almost always evaluates policy effects with willingness to pay, which differs conceptually from EV. Willingness to pay answers the question: how much money could be taken away from a person in conjunction with the policy so that he or she has the same utility with the policy as without it? Rather than corresponding to EV, which holds utility constant at a level with the policy, willingness to pay corresponds to compensating variation, which holds utility constant at the pre-policy level. Although compensating variation is more intuitively appealing, it does not provide a fully satisfactory money metric like EV.

The equivalent or compensating variation of a price change in a single market can be calculated as the change in social surplus as measured under the appropriate Hicksian, or utility-compensated, demand schedule. In practice, however, analysts typically work with econometrically derived demand curves that do not hold utility constant. Changes in consumer surplus measured with these Marshallian demand curves only approximate the compensating variation, with differences driven by income effects that can be large for either large income elasticities or large price changes. Some progress has been made to put bounds on the differences between the Marshallian and Hicksian measures (Willig 1976; Seade 1978), but these bounds are rarely applied in practice.

The interpretation of Marshallian consumer surplus as willingness to pay becomes even more complicated when policies have secondary effects in the markets of complements and substitutes of the goods primarily affected by policies. Although a general equilibrium model would be most appropriate for taking account of these secondary market effects, common practice is to approximate the combined effect of the primary and secondary markets by measuring surplus changes with the use of an estimated demand schedule for the primary market that does not hold the prices of substitutes and complements constant (Sugden and Williams 1978; Gramlich 1990; Boardman et al. 2006). In such cases, analysts need not account for price changes in undistorted secondary markets. Indeed, doing so would likely result in double counting of benefits.

Social Costs: Opportunity Costs

Public policies generally require the use of real resources to produce their effects. The guiding principle for monetizing the forgone value of these resources is opportunity cost: what is the value of the resources in their next-best use? That is, what is the value forgone by using the resources for the project? When factor markets are undistorted and the additional demand created by the project does not increase price, the opportunity cost of the resource just equals its market value,

which, if the resource is obtained by purchase, just equals the expenditure on the resource. When factor markets are undistorted but the additional demand induced by the policy drives up price, then the opportunity cost of the resource equals the sum of expenditure and the change in social surplus, the algebraic sum of the change in consumer surplus and the change in rents usually measured as change in producer surplus based on the short-run supply schedule (Mishan 1968). For example, if supply and demand curves are linear, then the opportunity cost equals the average of the pre- and post-purchase prices of the resource times the quantity purchased.

If markets are distorted, then even if price does not change the opportunity cost does not necessarily equal the expenditure required to secure supply. For example, a common factor-market distortion is involuntary unemployment resulting from minimum wages imposed by either law or custom. The expenditures needed to hire workers from a market with involuntary unemployment for a project clearly overestimate the opportunity cost of this labour. Nonetheless, the opportunity cost is almost certainly not zero, as sometimes argued by policy advocates, because the time of the workers hired by the project has an opportunity cost in terms of forgone leisure and household production.

Accommodating Uncertainty

CBA requires prediction of the effects of adopting a policy. Predictions are inherently uncertain. In addition to uncertainty about such parameters as price elasticities required for predictions of changes in social surplus, CBA often requires analysts to confront fundamental uncertainty about future states of the world. For example, preparing a vaccine to guard against a potential pandemic is costly but offers large benefits in the event that a pandemic actually materializes. CBA requires analysts to convert these uncertainties into risks by specifying representative states of the world and assigning probabilities to these states. Common practice is to model the policy choice as a decision analysis problem, or game against nature, and to choose the policy that maximizes the expected value of social surplus.

A more conceptually valid measure of the benefits of a project with certain costs in the face of risk about the future state of the world is option price (Graham 1981). Option price answers that question: what is the maximum certain payment that an individual would be willing to make to obtain the project? The sum of these certain payments for all those with standing can then be compared with the certain cost of implementing the policy. In general, however, option price does not equal the expected value of an individual's surplus over the possible states of the world; it differs from expected surplus by the option value of the policy for the individual. Although contingent valuation surveys seek to elicit individuals' option prices directly, more commonly analysts estimate benefits as expected surpluses, and consider option value as an excluded value. Some progress has been made in signing option value (Larson and Flacco 1992), but analysts rarely have enough information for confidently including it as a monetized correction to expected surplus.

Discounting for Time

Policies typically have effects that extend far into the future. Infrastructure projects in particular are usually characterized by large initial investments followed by beneficial use over years or even scores of years. CBA requires that costs and benefits accruing in the future be converted into their present value equivalents. On the assumption that future costs and benefits are predicted in real dollars, then a dollar of cost or benefit occurring t periods beyond the present equals in present value terms

$$1/(1+d)^t$$

where d is the real discount rate for the period length. In practice, discounting is usually done on an annual basis. As valid comparison of projects requires that they be assessed over the same time horizon, it is often necessary to convert present

values to equivalent perpetual streams of constant values through the use of an annuity factor.

The appropriate value for the real discount rate remains controversial. One approach is to set the discount rate equal to the marginal rate of pure time preference, the rate at which consumers are indifferent between exchanging current for future consumption. Another approach is to set the discount rate equal to the opportunity cost of capital, the marginal rate of return on private investment. In an ideal capital market these two rates would be equal. In the presence of transaction costs and taxes, however, these rates differ substantially. For example, an estimate of the marginal rate of pure time preference based on the after-tax real rate of return on US treasury bonds is 1.5%, while an estimate of the opportunity cost of capital based on the expected real yield on AAA corporate bonds is 4.5% (Moore et al. 2004).

If all costs and benefits correspond to changes in consumption, then the marginal rate of pure time preference is the appropriate discount rate. Instead, if all costs and benefits correspond to changes in private investment, then the marginal rate of return on private investment is the appropriate discount rate. However, most projects involve changes in both consumption and investment. The shadow price of capital approach involves expressing all costs and benefits in terms of consumption changes so that the marginal rate of pure time preference can be applied (Bradford 1975). In application, this means applying a shadow price to changes in private investment so that they are converted to the present values of their associated streams of consumption changes.

Shadow Prices

Much of the challenge of CBA lies in deriving appropriate shadow prices when policies have effects beyond those that can be taken into account as changes of prices or quantities in undistorted markets. In developing countries, for example, import and export controls and the presence of subsistence agriculture often distort virtually all prices, necessitating the determination of a complete set of shadow prices based on prices in international markets (Little and Mirlees 1974; Squire and van der Tak 1975; Dinwiddy and Teal 1996). Economic research provides a number of shadow price estimates that can be used in conducting CBA. Indeed, were these shadow prices not readily available, the plausible range of application of CBA would be much narrower.

One of the most commonly needed shadow prices is the value of a statistical life. That is, what is the willingness of a representative member of a population to pay for reductions in mortality risk? Economists have used a variety of methods to estimate the value of a statistical life, most commonly taking advantage of differences in risks and wages across occupations or the purchases of safety devices. The number of studies is sufficiently large that a number of meta-analyses have been conducted to develop estimates of the value of a statistical life for the United States in the range of roughly $4 million to $6 million in 2002 dollars (Miller 2000; Viscusi and Aldy 2003). Tied to any estimate of the value of a statistical life is the value of a life year. Health economists have developed a number of methods for estimating the quality of life in various health states, so that, in conjunction with the value of a life year, they can monetize a quality-adjusted life year (QALY) for use in CBAs of health care interventions (Dolan 2000). Estimates of shadow prices for injuries, noise, recreational activities, air pollutants, commuting time, and the marginal excess burden of taxation (for application to changes in government revenue) are also readily available (Boardman et al. 2006).

Cost–Benefit Analysis: Philosophical Issues

Sven Ove Hansson

Abstract

Cost–benefit analysis (CBA) gives rise to a whole range of philosophical issues. The most discussed among these is the status of economic values that are assigned to assets conceived as incommensurable with money, such as a human life or the continued existence of an animal species. CBA also involves other

contentious assumptions, for instance that a disadvantage affecting one person can be fully compensated for by an advantage affecting some other person. Another controversial issue is whether a CBA should cover all aspects in a decision or rather leave out certain issues (such as justice) so that they can instead be treated separately.

Cost–Benefit Analysis: Philosophical Issues

Cost–benefit analysis (CBA) is a collection of decision-aiding techniques that weigh advantages against disadvantages in numerical terms. In a typical CBA, multi-dimensional problems are reduced to one dimension, usually with monetary value as the common currency. Such a reduction raises several important philosophical issues (Hansson 2007; Sen 2000; Sunstein 2005).

Incommensurability

The most discussed among these issues concerns the status of the economic values that cost–benefit analysts assign to assets that do not have a market value. Many of these assets are conceived as invaluable, such as a human life or the continued existence of an animal species. Critics have claimed that CBA desecrates human life when it assigns a monetary value to the loss of human lives. Such criticism would probably have been less common if the nature of these values had been better explained. In particular, they are not prices. (No market – no price.) The assignment of a sum of money to the loss of a human life does not imply that someone can buy another person, or the right to kill her, at that price. What it implies is that society tends to pay (alternative: ought to pay) up to that sum to save a human life.

The incommensurability between life and money is only one of many incommensurabilities that are dealt with in CBA. There is no definite answer to the question how many cases of juvenile diabetes correspond to one death, or what amount of human suffering or death corresponds to the extinction of an antelope species. Since such comparisons are technically effected in a CBA by assigning monetary values, the problem of incommensurability appears to be a problem of monetisation. But even if money were removed from the analysis it would still be necessary to deal with comparisons between deaths, diseases and environmental damage. The fundamental problem is that for decision-making purposes we need to evaluate comparatively entities that we conceive as incomparable. Such 'impossible' comparisons are inherent in all major social decisions. CBA brings them to light.

Interpersonal Aggregation

In a CBA, all costs and all benefits are combined into one and the same balance. This means that a disadvantage affecting one person can be fully compensated for by an advantage affecting some other person. In other words, *interpersonal compensability* of advantages and disadvantages is assumed. (Interpersonal compensability should not be conflated with the related but distinct issue of interpersonal comparability. Even if a benefit to one person is greater than a harm to another person, it need not cancel out the harm.) The assumption of interpersonal compensability is one of several features that CBA analysis shares with utilitarian moral theory.

There is, at least theoretically, an alternative to this approach. Advantages and disadvantages can

be weighted against each other separately for each affected person, and a positive balance for each individual person can be required for a policy to be accepted. This is the approach that has dominated mainstream economics since the 1930s, when Lionel Robbins showed how economic analysis can dispense with interpersonal comparability. The approach that prevails in CBA is more akin to the collective, aggregating approach of the so-called old welfare economics. There is an obvious but surprisingly little discussed tension between standard CBA and Paretian welfare economics. The former, but not the latter, tends to sanction the sacrifice of individual interests for the sake of collective goals.

Many of the value assignments used in CBA are based on estimates or measurements of (hypothetical) willingness to pay. This applies for instance to values based on contingent valuation. All evaluation methods that are based on willingness to pay tend to give more influence to affluent people since they can pay more than others to have it their way. This can be corrected with income-based adjustments of the reported willingness to pay.

Exclusion of Aspects

All evaluations of the future effects of decisions tend, irrespective of methodology, to leave out or downplay effects that are difficult to predict. Furthermore, since CBA aims at numerical calculations, it tends to leave out aspects of future developments that can only be predicted in non-quantitative terms. This applies for instance to risks of cultural impoverishment, social isolation, and increased tensions between social strata. These limitations can lead to bias when alternatives with mostly quantifiable negative consequences are compared to alternatives whose major drawbacks are nonquantifiable. Furthermore, due to their aggregative structure, CBAs often leave out social justice and other distributional aspects from the analysis even when they are accessible to quantitative treatment.

Cost–benefit analysts have given two major answers to this criticism. One of these is that all such neglected factors could and should be included in the analysis. It is for instance not difficult to put a price on inequality and include it in the analysis, and the same applies to other aspects that are commonly left out. (However, such all-encompassing CBAs are much more seldom performed than they are referred to in defence of the CBA methodology.)

The other answer is that a CBA only covers some of the aspects of a decision. It should therefore not be treated as the last word in an issue, but has to be followed by reports and discussions that cover aspects not covered in the CBA. Some discussants consider it inappropriate to include distributive justice in the total calculations of a CBA, since such issues are better dealt with separately.

Transferability Across Contexts

In CBA, cost estimates are regularly transferred across contexts. This applies for instance to values of human life. A CBA that the U.S. Environmental Protection Agency performed for a new standard for arsenic in drinking water can be used as an example of this. The values of life used in this analysis were standard values derived from studies of how much male workers receive in compensation for risks of fatal accidents. However, as was noted by Heinzerling (2002), it was not necessary in this case to import life values from another context. It would have been possible to use life values derived from the very context of the CBA in question. There is a market for bottled, presumably non-toxic, water. Willingness to pay could have been derived from an analysis of prices on that market. Alternatively, consumers could have been asked how much they are prepared to pay for reduced levels of arsenic in drinking water, given realistic assumptions about the health effects of such a reduction.

The transfer across contexts that is illustrated in this example is an essential component in the methodology of CBA. If all values used in a CBAwere derived from the precise context of its

subject matter, then its usefulness for comparative purposes could be put in question. But even though transferability across contexts is an essential assumption in CBA, it is far from trivial to defend it from a philosophical point of view. Such a defence would have to show that our evaluations of a consequence should be the same irrespective of the context in which that consequence appears. For instance, a life lost in a workplace accident and a (statistical) life lost due to arsenic in drinking water should be assigned the same value.

In practice, we tend to pay much more to save a life in some contexts than in others. It is far from self-evident that all such differences lack sensible normative justification. It may for instance be justified to pay more to protect people from risks that they cannot avoid than to protect them against risks that they can avoid at small cost to themselves. For similar reasons, it may be justified to pay more to protect children than adults. Furthermore, some causes of death are considered particularly pernicious, and therefore worth more expensive countermeasures than other causes of death. We may for instance choose to pay more per life saved in a law enforcement programme that reduces the frequency of manslaughter than we would pay for most other life-saving activities.

Decisional Synopticism

The effects of a decision often depend heavily on other, parallel decisions. A CBA devoted to one of several interconnected decisions can be misleading due to the impact of the decisions that it does not cover. As one example of this, a CBA (or any other type of analysis) aimed at optimising the road traffic system may result in a suboptimal recommendation due to potentials of rail traffic that it does not take into account. Such effects of non-inclusion can in principle be remedied by framing decisions in large coordinated units that cover as many social areas as possible. The tendency to do so has been called 'super synopticism'. (Hornstein 1993, p. 387) However, such large-scale optimisation does not always work, largely for reasons similar to those that make centralised planning inefficient.

As one example of this, the willingness to pay for safety, as measured in the marginal cost for saving a life, differs widely between policy areas. Some cost–benefit analysts claim that all decisions on risk acceptance should be coordinated so that willingness to pay is equalised across policy areas. The implementation of such a unified price would require a high degree of coordination across policy areas. This is not easy to achieve since risk decisions are interwoven with other decisions in their respective policy areas. It may not always be feasible in practice to make risk decisions in a fully coordinated and centralised way while retaining a decentralised decision structure for other decisions.

This and several other issues connected with CBA will be much less problematic if a CBA is considered as one of several inputs into a decision than if it is presented as the last word which a rational decision-maker has to abide by.

Cost-Push Inflation

George L. Perry

Abstract

The concept of cost-push inflation emerged after the Second World War to describe the price increases arising from labour unions pushing up wages despite excessive unemployment. With the oil price shocks of the 1970s, it was used to describe any important shift up in supply schedules at given levels of aggregate demand. Most central banks differentiate between supply shock effects and demand effects by distinguishing between overall inflation and core inflation, the latter omitting the direct contribution of shocks to oil and food prices, the two most important sources of supply shock large enough to register on broad inflation measures.

The concept of cost-push inflation emerged in the period after the Second World War. The Keynesian model of that time emphasized that the economy could operate with inefficiently low utilization of its capital and labour resources, and that expanding demand would employ those resources. Once full employment was achieved, further expansion of demand would only pull up nominal wages and prices. In contrast to this demand-pull inflation, cost-push described the price increases that came from labour unions pushing up wages despite the existence of excessive unemployment. Since the 1970s, when oil prices rose by many times in two abrupt steps, the idea of cost push has been extended to describe price increases arising from any important shift up in supply schedules at given levels of aggregate demand.

The key distinction between price increases arising from monopoly power in wage settings or from any other supply shock and price increases arising from an increase in aggregate demand along an unchanged supply curve is important both for empirical modelling of inflation and for stabilization policy. By the 1960s, the short- run Phillips curve had emerged as a description of the relation between inflation and unemployment over the business cycle. It described an empirical regularity according to which wages rose gradually faster as unemployment declined, with the relation becoming steeper the lower the unemployment rate. Subsequent amendments to this model took explicit account of learning and expectations and of the interrelation between wages and prices. In the dominant model that emerged, inflation will accelerate (decelerate) indefinitely if the economy operates persistently below (above) a natural rate of unemployment. And in models that stress the importance of expectations, the anticipation of faster or slower price increases speeds up this process of acceleration or deceleration.

While inflation is responsive to aggregate demand in all these models, its responsiveness to supply shocks is more nuanced. In models that stress inflationary expectations, shocks that are widely perceived as one-time shifts up nominal supply curves will lead only to one-time shocks to the price level. In models with institutions that partially or fully index wages to prices, or models with adaptive expectations of inflation, such shocks will have larger and more protracted effects.

Empirically, the distinction between cost-push and excess-demand effects is not always easily drawn. The inflation identified with

unemployment below the natural rate or with the steep portion of the short-run Phillips curve is attributable to excess demand. The more modest variations in inflation that may occur as unemployment varies above the natural rate are not characterized so readily. A useful interpretation of these systematic cyclical tendencies is that they represent the normal operation of heterogeneous labour markets in response to cyclical variations in aggregate demand, with wages and prices in some sectors rising faster as their markets tighten while slack is still present in other sectors. On this interpretation, they neither signal that the economy is at a natural rate nor indicate the presence of exogenous cost-push effects on prices. However, these modest variations in inflation may also indicate cost-push effects in wage settings that interfere with achieving full employment, and at times past policymakers have interpreted them in this way and tried to suppress them.

The interdependence between prices and wages presents another difficulty in distinguishing endogenous from exogenous changes in wages. If labour supply depends on real wages – that is, wages relative to the average price level – then labour supply will not change if nominal wages change proportionally in response to disturbances to the cost of living. The narrowest concept of cost-push would, therefore, include only shifts up in labour supply schedules that raise wages relative both to their normal response to cyclical demand conditions and to their normal response to consumer prices.

Such complications obscure the possible presence of cost push from wages in typical circumstances. However, when the exercise of market power in wage setting is extreme, it becomes more apparent. In the United States, large wage increases in the early post-war years are examples of cost push. Coming after wartime controls, these did not raise the concerns that the abrupt acceleration of wages in many industrialized economies did in the late 1960s and early 1970s. For example, in Germany annual increases in hourly compensation jumped from 7.5 per cent in 1968 to 17.5 per cent in 1970, and in the United Kingdom the acceleration over the same period was from seven per cent to 15.5 per cent.

During the 1970s, supply shocks to important raw materials prices dominated world price developments in the decade, producing the second main type of cost- push inflation. These supply shocks included the historic increases in oil prices in 1973–4 and again in 1979, and the food price explosion of 1973. Although world aggregate demand was relatively strong in both 1973 and 1979, the magnitude of the price increases that resulted would not be expected, and is better seen as a consequence of major shifts in world supplies. A succession of poor crops provoked the food price rise, while the successful organization of the OPEC oil cartel, aided by a levelling off in United States oil production, caused the oil price explosion.

Coincident with the 1973–5 supply shocks, further large jumps in wage inflation occurred in several countries. In both the United Kingdom and Japan, annual increases in hourly compensation rose to more than 30 per cent from less than half that rate in 1972. Most other major industrial countries experienced similar, though less dramatic, accelerations in wages. Although these wage developments were doubtless fuelled by the effects of the supply shocks on consumer prices, the differences across countries indicate another round of wage push in many, even when one allows for a normal response to price changes. The rapid wage increases in turn further boosted consumer prices. The eventual changes in real wages, as well as the eventual increase in price levels, varied significantly among the industrial countries during the mid-1970s. In the United States, the speed-ups and slowdowns in wage increases and in prices were far less dramatic than in Europe and Japan. However, over the entire decade of the 1970s wages in the highly unionized sectors of the US economy outpaced economy-wide wages substantially, indicating a moderate but persistent wage push from important major industries.

While this post-war record shows that both wage push and supply shocks have at times been important in pushing up price levels, several difficulties remain with the idea of cost push as a distinct source of inflation, and some analysts reject the idea altogether. First of all, inflation

refers to an ongoing rate of increase in prices. A one-time rise in the average price level will translate into some rate of increase in prices over a period spanning the rise. Without quibbles over how long a time period is needed before a measurement qualifies as an 'inflation rate', the distinction between a one-time rise in the price level and an ongoing inflation rate is important. Second, inflation refers to the general price level, not to a subset of prices. A rise in oil prices is, first of all, a rise in the relative price of oil. If wages and prices were fully flexible and responded instantly to changes in the balance between demand and supply, then, in the presence of non-accommodating macroeconomic policies, cost-push shocks would indeed create only relative price changes; inflation, in the aggregate, would be impossible. Those who see monetary policy as able to control the overall price level, if not instantly at least over a relatively short period of time, see a cost push from some sectors as a relative price change that becomes a change in the overall price level only if accommodated by monetary policy. On this view, the accommodation rather than the cost-push causes the inflation.

However, such reasoning ignores the considerable downward rigidity in wages and stickiness in many prices as well as the interactions between prices and wages in modern economies, and thus loses the important role that cost-push shocks played in shaping economic performance in these inflationary periods. There are positive correlations among most prices and wages in the economy. In part these reflect common reactions to aggregate developments and in part they represent causal links among wages and prices throughout the economy.

When the links are strong, as they were in the inflationary periods of the late 1960s and 1970s, a cost-push supply shock will not only add directly to the average price level but will set in motion increases in other prices and wages strong enough to persist for some time, even in the face of slowing demand and increasing underutilization of resources. Consequently, an attempt by monetary policy to hold the overall price level unchanged in the face of such a cost-push shock will result mainly in reducing output and employment. Only gradually will the upward movement of prices originating from a supply shock yield to restrictive monetary policies. On the other hand, because the initial shock induces positively correlated responses in wages and other prices, an accommodative policy that aims to maintain output and employment in the face of the shock will result in a rise in the overall price level that is substantially greater than the direct effect of the shock itself. The question confronting stabilization policy is thus how much to accommodate. And the best answer will differ with different institutions and at different times.

The idea that cost-push inflation originating in excessive union wage demands would interfere with the attainment of full employment prompted attempts in several countries to design incomes policies as part of the stabilization policy arsenal. The idea was that demand management by government would aim at keeping the economy around full employment, while understandings among government, labour and business would aim at heading off wage-push inflation that might otherwise arise before full employment was achieved. There was some evidence of success from incomes policies, known as wage-price guideposts in the United States, in the mid-1960s (Perry 1967). But whatever chance such policies may have had in the longer run in a relatively benign environment, they were overwhelmed once economies were driven into the excess demand region during the Vietnam War, and the oil and food supply shocks of the early 1970s sharply raised average price levels everywhere. There has been little interest in incomes policies since that time.

By the 1990s, conventional stabilization policies had achieved low inflation rates throughout the industrial world, and the power of unions to originate more inflationary wage increases was very sharply reduced in almost all countries. Both these developments have lessened the problems of stabilization policy. There is evidence that the low-inflation environment has sharply reduced the links that formerly caused price shocks to spark a wage-price inflationary spiral, as they did in the 1970s (Brainard and Perry 2000). Wages did not accelerate in response to the world oil price shocks

of the mid-2000s, and monetary policymakers were able to focus largely on the core inflation rate – the aggregate inflation rate excluding food and energy prices – in setting policy. At least for now, inflation originating from cost push poses a much smaller risk for stabilization policies today than it has at times in the past.

Counterfactuals

Donald N. McCloskey

Counterfactuals are what ifs, thought experiments, *Gedankenexperimenten,* alternatives to actual history; they imagine what would have happened to an economy if, contrary to fact, some present condition were changed; in the philosophical literature therefore they are known also as 'contrary-to-fact conditionals'.

The notion has been used most self-consciously in historical economics. For example: 'If railroads had not been invented the national income of the United States in 1890 would have been at most 5% lower.' Counterfactuals are implied, however, in many other parts of economics, such as macroeconomics: 'If a monetary rule with a small growth rate of M_1 were adopted then the rate of inflation would fall.' Or industrial organization: 'If the instant camera industry had 100 suppliers it would be competitive.'

The philosophical problem that counterfactuals raise, and part of the reason they have attracted the attention of modern philosophers, can be seen in the last example. We wish to contrast the present monopoly of instant cameras with (nearly) perfect competition. Perhaps we wish to do so in order to measure the welfare cost of the monopoly and to advise a judge. Now of course if somehow the instant camera industry were to have 100 sellers then each seller would be small relative to the whole demand or supply. Speaking mechanically, the usual formulas for elasticities imply that the elasticity of individual demand facing any one of them would be large, roughly 100 times the elasticity of total supply plus 100 times the elasticity of total demand. Such calculations are the heart of applied economics: If the cigarette tax were lowered what would be the new relative price of cigarettes? If the money supply were increased what would happen to the price level? If foreign doctors could practise freely in the United States what would happen to the cost of American medical care?

Such questions involve looking into a world having, say, an instant camera industry with 100 sellers rather than one. It would not be our world, which saw the miraculous birth of Polaroid, the struggle with Kodak, and the final triumph of patent over antitrust law. So much is clear. But how then is the counterfactual world to be imagined? A world in which the conditions of technology, personality, and law resulted in 100 Edwin Lands and 100 miniature Polaroid companies would be a different one – there's the condition contrary to fact.

The problems which can afflict counterfactuals are two: vagueness and absurdity. The vagueness arises when the model has not been fully specified. The world could arrive at 100 companies in many different ways, each with different implications for the original question about welfare. One can imagine getting 100 Polaroid companies, for example, by fragmenting edict now, well after the invention, in the style of the American Telephone and Telegraph case. Whatever the advantages, there might be inefficiencies in this. It would certainly change the future patent law. The change in law would in turn change things for good or ill elsewhere in the economy. A world in which patents are granted and then prematurely abrogated differs from the present world. Alternatively one might imagine subsidies in the 1940s that would have resulted originally in 100 alternative technologies of instant cameras (though actually only two were invented). This counterfactual likewise would have its costs, though different ones, changing for example the expectations of inventors about subsidies. A counterfactual requires a model broad enough to do the job.

Vagueness is solved by explicitness. The conditions required for various counterfactuals are made explicit, and being explicit can be tested for plausibility. Historical economists have been making counterfactuals explicit since the 1960s, using them to explore the causes of the American revolution and the consequences of American slavery (the counterfactual work is well surveyed by McClelland 1975).

In the most famous use of counterfactuals Robert W. Fogel (1964) calculated what the transport system of the United States in 1890 would have looked like without railroads. He argued that evaluating the 'indispensability' of the railroads entailed calculating what American life would have been like without them. Some historians were reluctant to talk about such a counterfactual, saying that it was "as if" history, quasi-history, fictitious history – that is not really history at all . . ., a figment' (Redlich 1968, in Andreano (ed.), pp. 95f). But economists find the notion natural, and philosophers accept it as routine. Indeed, the philosophers point out that the following are nearly equivalent (Goodman 1965, p. 44):

Scientific Law: All inflations arise from money growth.

Causal Assertion: Money growth alone causes inflation.

Factual Conditional: Since inflation has changed, money growth has changed.

Dispositional Statement: Inflation is controllable with money growth.

Parallel Worlds: In a world identical (or sufficiently similar) to ours except that money growth differed, inflation would be different.

Counterfactual: If money growth were to be held at zero, inflation would be zero.

The philosophy of counterfactuals revolves around the translation of one of these into another. Historians, not realizing that one is translatable into the other, flee the counterfactual in terror and cling to the causal statement. Yet economists have on this score no cause for smugness, since they have parallel philosophical fears. Economists flee the causal statement as historians flee the counterfactual, and believe as historians do that the thing itself can be avoided by suppressing its name.

Fogel's calculations stirred great controversy, but were robust (Fogel 1979). Since he was interested in long-term economic growth he did not imagine a sudden closure of the railroads in 1890: that clearly would have resulted in a very large drop in national income. Mental experiments like this commonly lie behind claims that railroads (or airlines or postal services or garbage collection) are 'essential'. Fogel imagined instead what the American economy would have looked like without access to railroads from the beginning, forced from the 1830s onward to rely on substitutes.

Such an economy would have invested more in canals and roads (Fogel introduced some of these into his counterfactual world, using contemporary engineering studies proposing them). It would have been an economy closer to waterways, with a bigger St. Louis and a smaller Denver. It would doubtless have invented more improvements in road transport, arriving at internal combustion a little earlier than the world we know.

Fogel could not specify every feature of the 'true' counterfactual world. But he suspected anyway that the true counterfactual would give a national income only a little below the actual. To test the suspicion, therefore, he biased the case against himself, choosing a 'practical' counterfactual world in which income would be if anything lower than in the true counterfactual: he did not introduce the internal combustion engine before its time; and he did not shift the location of the population to accommodate the non-railroad transportation. He forced his practical counterfactual to carry supplies by river, canal and horse cart (not by the motor trucks that might have been) to a Denver no smaller than it actually became at the height of the railroad age. The result was a calculable upper bound on the true impact on national income: since the 'true' counterfactual would have economized relative to the clumsy 'practical' counterfactual, a use of the practical counterfactual biases the case against a large impact. Fogel reckoned that the impact was at most five per cent of 1890 income, a couple of years of economic growth.

He was merely applying in a bold way the usual methods of economics. The usual method is to imagine an explicit economic model, *M*, with parameters, *P*, and initial conditions (or exogeneous variables), *I*, and results by way of endogenous variables, *R*. The counterfactual varies some element of the setup, the simplest being a variation in *I* – where *I* might be a tax rate in a model of cigarette consumption or the number of firms in a naive model of instant camera pricing – and examines the results. Fogel removed from the initial conditions one of the technologies of transportation. In similar fashion a 500-equation model of the American economy permits experimentation in counterfactual worlds: What would happen if the price of oil fell? What would be the effect of a tax change? (The main empirical attack on Fogel's finding, indeed, was an highly explicit general equilibrium model of the Midwest and East (Williamson 1974).)

Counterfactuals are one of the two main ways that economists at present explore the world (the third, controlled experiment, is still not common). The first is regression, or the comparative method, asking how *in fact* results have varied with initial or exogenous conditions. The second is the counterfactual, or simulation, asking how the results *would* vary. The regression infers parameters *P* from data on initial conditions *I* and results *R* and from arguments about the model, *M*; the counterfactual simulation infers *R* from data on *P* and from arguments about *M* and *I*.

But in solving the vagueness of counterfactuals by positing explicit models the economist runs against the other philosophical problem of counterfactuals: absurdity. Consider again the counterfactual of a 100-firm industry selling instant cameras. The problem is that the initial conditions that would lead to such an industry may themselves be absurd. Indeed, they may violate the very model used. The counterfactual assertion 'If the instant camera industry were perfectly competitive then price would be lower than it is now' takes on the character of the proverbial line 'If my grandmother had wheels she'd be a tram.' The model may be true (wheeled grandmothers may indeed be trams) but the counterfactual may be impossible – that is, a contradiction of the model itself or of some other, wider model felt to be persuasive.

It is possible to argue on these grounds that *all* counterfactuals are absurd. One might argue, as did Leibniz, that a world that did not invent the railroad would strictly speaking have to be a world different from ours right back to the big bang. Such a world might be one in which the seas were boiling hot or pigs had wings, with different transportation problems. The theory being violated by the counterfactual is the theory that the world hangs tightly together. As J.S. Mill remarked in attacking counterfactual comparison of free trade and protection, 'Two nations which agreed in everything except their commercial policy would agree also in that' (1872, p. 575).

A less intense scepticism on the matter has figured widely in economics. The theory of games, for example, can be viewed as an inquiry into counterfactuals, which sometimes violate wider theories (Selten and Leopold 1982); the usual criticisms of the Cournot solution made by students of industrial organization involve the same point. Most notably, the Lucas Critique of

econometric policy evaluation (Lucas 1976) can be restated as a criticism of the usual counterfactual. The usual counterfactual imagines the effects of a change in the initial conditions *I* on a model *M* with given parameters *P*, fitted under the old regime. A new monetary policy would change the regime under which people believed they operated, changing *P* and *M* as much as *I*. Some broader model of how people adjust to regime changes is necessary to decide which would change: a new policy believed to be temporary would have very different effects from one believed to signal a revolution in government. The usual counterfactual violates the broader model, by supposing that people do not anticipate changes of regime or understand them when they occur. A broader model of rational expectations shows the counterfactual to be absurd.

John Elster, in a penetrating discussion of the role of counterfactuals in the economic sciences, posed the Basic Paradox of Counterfactuals: the less vague the theory, the more likely is a counterfactual using the theory to encounter absurdity. If Fogel had developed a theory of invention to draw a less vague picture of road transport without railroads he would have faced the problem that the very theory would predict the existence of railroads. After all, railroads were actually invented and therefore should be predicted by a sound theory of innovation. Elster wrote, 'If he attempted to strengthen his conclusion … he would be sawing off the branch he is sitting on. In this kind of exercise it is often the case that more is less and that ignorance is strength' (1978, p. 206). The counterfactual must be 'capable of insertion into the real past'.

The Basic Paradox illuminates the discussion in economics about simplicity of models. A simpler model is harder to believe in its simulation because it is not so rich; but because of its lack of richness it is more likely to be insertable into the real past. A 500-equation model of the economy will more tightly constrain the past from which it comes than will a 10-equation model. Model selection has its own type I and type II errors.

Many of the meta-criticisms of economics, then, reduce to remarks about a counterfactual. This is scarcely odd, since counterfactuals are equivalent to causal statements and the point of economics is to make causal statements. The philosophical literature on counterfactuals is illuminating, though large, technical, and mainly inconclusive (Lewis 1973; Goodman 1965). It comes to a position more sophisticated than mere scepticism. Counterfactuals are a way economists speak, and philosophers wish usually to assist the speaking, not end it. Self-aware or not, economists will go on speaking counterfactually about non-cooperative games, macroeconomic policy, and the retrospective welfare calculations of historical economics. The task of a philosophy of the economic counterfactual would be to understand the practice, not to change it.

Countertrade

Dalia Marin and Monika Schnitzer

Abstract

International countertrade – tying an import to an export – emerged in the 1980s in response to the international debt crisis. Barter – the exchange of goods without using money – re-emerged in transition economies in the 1990s, in response to a domestic debt crisis. Both phenomena can be explained as institutional responses to contractual problems arising in imperfect capital and goods markets. Countertrade introduces a deal-specific collateral that improves the creditworthiness of countries and firms, and facilitates technology transfer to developing countries. Barter helps to overcome the lack of trust problem in the former Soviet Union.

Countertrade is a commercial transaction in which a seller, typically from an industrialized country, supplies goods, services or technology to a buyer in a developing country or a formerly planned economy, and in which, in return, the seller purchases from the buyer an agreed amount of goods, services or technology. A distinctive feature of countertrade is the existence of a link between the two transactions, the original import in the developing country and the subsequent export.

Countertrade takes a variety of forms. The three most commonly distinguished are 'barter', 'counterpurchase' and 'buyback'. Barter in the strict sense of the word refers to an import that is paid entirely or partly with an export from the importing country without using foreign exchange. Counterpurchase refers to a transaction in which the import is paid with foreign exchange, but the industrialized country commits to buy export goods from the developing country in return. Buyback is a transaction in which the seller supplies a production facility and the parties agree that the supplier of the facility will buy goods produced with that production facility. All three forms of countertrade are frequently observed in international trade.

Under central planning, countertrade was especially observed in international trade among countries belonging to the Council for Mutual Economic Assistance (Comecon, an economic organization of communist states) as well as in East–West trade. In particular in the 1980s, in the aftermath of the international debt crisis, countertrade became prevalent in international trade with developing countries and Eastern Europe. Before 1989 countertrade accounted for up to 40 per cent of total trade between East and West. After 1989, with the domestic debt crisis in transition countries, barter became dominant in domestic trade in these countries. While countertrade continues to be significant in North–South trade, reliable estimates are not available.

Explanations for Countertrade

One of the most frequently cited explanations of countertrade is that it allows countries to

overcome a shortage of hard currency. The observation that countertrading countries are highly indebted is taken as evidence that these countries face a shortage of foreign exchange and that their low creditworthiness makes it impossible to finance imports with a simple loan from an international bank (for example, OECD 1981, 1985). This interpretation is not fully plausible because countertrade uses export goods which otherwise could have been used to generate foreign exchange to pay for future imports. Furthermore, if the foreign-exchange shortage were the main explanation of countertrade we would expect barter to be the prevalent form of countertrade since only barter does in fact avoid the use of hard currency. However, barter accounts for only a small portion of total international countertrade (Marin and Schnitzer 2002a). Mirus and Yeung (1987) find that countertrade in the form of simple barter or counterpurchase does not improve a country's foreign exchange position unless it improves economic efficiency in the sense that it leads to an increase in national income.

Empirical evidence points to another explanation, starting from the observation that in international trade contract enforcement is problematic and hence conventional contracts cannot be relied on as the main mechanism to sustain economic exchange. International countertrade (as well as domestic barter, as pointed out below) can be explained as an institutional response to such contractual problems arising in imperfect capital and goods markets. Difficulties in contract enforcement are an important impediment to international transactions in the world economy. In international trade, national sovereignty interferes with contract enforcement because national borders demarcate national jurisdictions. Such demarcations segment markets and impose severe transaction costs on exchanges across national jurisdictions. The hazards involved in international transactions are often disregarded, but they make headlines each time a sovereign debtor threatens to stop servicing its debt, as it happened in the international debt crisis in the 1980s or in the Russian financial crisis in 1998.

If contract enforcement is weak, problems may arise on both ends of a business transaction: the seller may fail to deliver the goods, and the buyer may fail to pay for them. If buyers have no cash to pay, and thus face liquidity constraints at the time of delivery, the business transaction can take place only if the seller can trust the buyer to pay in due course. On the other hand, the buyer is willing to engage in a business transaction only if she can trust the seller to deliver the right goods. Both problems are prevalent in international trade. Enforcing the payment of goods can pose serious problems. In the aftermath of the debt crisis, highly indebted countries were liquidity constrained and could not finance necessary imports. Given their level of indebtedness, debt repayment could not be relied on. The debtor country could create more liquidity by not repaying its debt rather than by receiving a new loan. There are also important problems arising on the seller's side. In international trade, the most conspicuous example is the technology transfer problem. It is often reported that explicit contracts cannot be relied on to make sure that developing countries receive the advanced technology promised (Parsons 1987; Kogut 1986). These countries often complain that firms from industrialized countries sell inferior technology to them, technology that is outdated and cannot be sold on Western markets.

Solving the Creditworthiness Problem

Countertrade can be interpreted as the institutional response to the lack of creditworthiness of countries and firms. Countertrade introduces a deal-specific collateral for the credit granted for the original import. This collateral protects the interests of the creditor for one particular business transaction and thus mitigates the contractual hazards associated with indebtedness that would otherwise prevent the transaction from taking place.

The argument that payments in kind may have advantages over payments in cash contradicts the conventional wisdom in the theory of money. The common view is that barter is inefficient because it does not overcome the 'double coincidence of wants problem' (where each trading partner wants to buy exactly what the other partner wants to sell

and vice versa) as money does. A seller may need to accept goods for which she has no use herself. The point, however, is that goods have superior credit enforcement properties to those of money. Money is an anonymous medium of exchange. This anonymity can prove disadvantageous in trade with countries which lack creditworthiness, since the debtor in the developing country or eastern Europe can use it for purposes other than repaying debt. Goods, by contrast, can more easily be earmarked as the property of the creditor and can thus serve as collateral. However, payment in goods is problematic if it is difficult to judge the quality of the goods offered as means of payment. Thus, it is important to choose goods that are very liquid and hardly anonymous, making it both easy to determine their value and easy to earmark. Goods can be ranked with respect to their liquidity and anonymity properties, providing an explanation for the export pattern of countertrade and barter (Marin and Schnitzer 2002b).

Solving the Technology Transfer Problem

Buyback contracts have been interpreted as incentive contracts that ensure the transfer of desirable quality technology and post-installation service performance if standard forms of internalization, like joint ventures or foreign direct investment, are not possible due to political and ownership constraints (Hennart 1989; Chan and Hoy 1991; Mirus and Yeung 1993). But for the argument to work, it is essential that there be a technological relation between the two goods to be traded. However, buyback accounts for a surprisingly small fraction of all countertrade transactions. Thus, even though this explanation is theoretically appealing, it cannot explain the great majority of technology imports, which take the form of counterpurchase.

Interestingly, the technology transfer problem can be solved with a simple counterpurchase transaction as well, despite the lack of a technological link (Marin and Schnitzer 1995). Although the lack of liquidity makes it difficult to finance imports, it is this very lack of liquidity that can actually help when it comes to dealing with problems on the supplier's side. The idea is that the export from the developing country serves as a hostage that deters cheating on technology quality and defaulting on the payment of the original import from the industrialized country. For this mechanism to work, the export has to be profitable to both the industrialized country firm and developing country, and the contract is so designed that the export becomes sufficiently less profitable for either party that does not fulfil its obligations in the original import, be it technology transfer or payment of the import. The technology seller offers high-quality technology because otherwise she loses her collateral for the credit as the developing country firm would lack the revenues that are generated with the technology and that are necessary to produce the export goods. This contractual arrangement makes the technology supplier internalize the externality her technology imposes on the developing country. The developing country party will deliver the export goods because the terms of the contract are designed such that this is more profitable than selling them otherwise. So although the import and the export are not technologically related, the countertrade contract establishes a financial link that improves the incentives of the parties involved. Thus, countertrade is a first-best substitute for foreign direct investment when these countries are reluctant to give access to foreign ownership in their markets. This goes to prove that, in an imperfect world in which contract enforcement is weak, as in developing countries or imperfect capital markets, something that seems to be worse – that contractual problems arise on both sides of the business transaction rather than on only one side – can improve contract enforcement. In international trade, the liquidity constraint helps to solve the technology transfer problem.

Other Explanations

Some other possible explanations of countertrade are that developing countries use

countertrade transactions to promote the export of 'new' goods – goods they have not previously exported to industrialized countries – in order to gain access to new markets and to diversify their exports (OECD 1981, 1985). The empirical evidence gives some support for the view that countertrade has helped to stimulate and diversify exports. Other studies confirm that the goods exported by developing countries through countertrade arrangements are often goods for which export markets have yet to be established. Readily marketable products, like raw materials, are usually not available for countertrade. It can also be observed that a country removes goods from the countertrade shopping list once it has gained some experience with exporting these particular goods (Banks 1983). Furthermore, it has been argued that countertrade corrects distortions in non-competitive markets (Caves 1974). Using barter may allow competing more aggressively without openly violating collusive agreements. It may also allow more effective price discrimination. There is indeed some evidence that barter is used as a vehicle to change the terms of trade to allow price discrimination by Western monopolists (Caves and Marin 1992). Mandated countertrade has also been discussed as a policy response to contracting failures arising from asymmetric information about goods valuations (Ellingson and Stole 1996).

Barter Trade in Transition Economies

Barter trade has received renewed attention in the 1990s, when it became a dominant phenomenon in domestic trade in a number of transition countries, most notably in the successor states of the former Soviet Union. After 1989, domestic barter in Russia increased manifold after macroeconomic stabilization in 1994, from five per cent of GDP to 60 per cent in 1998. In Ukraine, the share of barter in industrial sales is estimated to have been more than 50 per cent in 1997. Only since the financial crisis in August 1998 have barter and the use of other money surrogates started to decline again.

A number of different explanations have been put forward for this phenomenon. Some experts have viewed it as a tax-avoidance mechanism because it allows a distortion of the true value of profits, and thus reduces tax liabilities. Furthermore, since the banking sector acts as a tax collection agency that transfers firms' cash income in bank accounts to the state to pay for outstanding tax arrears, barter allows tax avoidance because it avoids payments in cash. While there may be some truth in this kind of argument, few firms report tax advantages as a major reason for using barter (Marin and Schnitzer 2002a).

A more popular explanation refers to soft budget constraints and the lack of market discipline. The absence of hard budget constraints, so the argument goes, leads managers and workers to avoid the costs arising from restructuring by maintaining production in inefficient activities. Barter would allow concealing the true market value of output. But the empirical evidence suggests that barter is not a phenomenon of state-owned enterprises. Newly established private firms display an exposure to barter that is similar to or greater than that of state-owned firms or cooperatives (Marin and Schnitzer 2002a).

The 'virtual economy' argument of Gaddy and Ickes (1998) has been one of the most influential explanations of barter in Russia. The virtual economy argument claims that barter helps to create the image that the manufacturing sector in Russia is producing value while in fact it is not. This argument rests on the assumption that the manufacturing sector is value-subtracting, and most participants in the economy have an interest to pretend that it is not. Barter allows the parties to keep up this illusion by allowing the manufacturing sector to sell its output at a higher price than its market value and the value-adding natural resource sector (Gazprom) to accept this high price because of a lack of other sources. This way the manufacturing sector survives by drawing resources from the natural resource sector. According to the argument, keeping up the illusion of a value-adding manufacturing sector is highly costly for the Russian economy at large because this cross-subsidizing from the value-adding natural resource sector to the value-

subtracting manufacturing sector prevents the manufacturing sector from moving into valuable activity.

This argument appeals to experts of central planning and policy observers in transition economies, because the practice of cross-subsidizing across different activities in the economy was a widespread feature of central planning. But it raises a number of questions. If the natural resource sector is producing valuable output, why does the sector not have other opportunities than to subsidize the manufacturing sector? In fact, the natural resource sector is supposed to have significant bargaining power in the interaction with other sectors when it is producing goods which the market values highly. Why then does the sector end up subsidizing the rest of the economy? And in fact, evidence from barter transactions in the Ukraine suggests that, in contrast to the assertions of the virtual economy proponents, the electricity and gas industries in the natural resource sector gained from barter transactions, instead of losing (Marin 2002).

A more plausible explanation refers to the similarities between barter in international trade and barter in transition economies, and links the surge of domestic barter to a 'lack of trust' problem (Marin and Schnitzer 2005). In transition countries, poorly developed legal and financial institutions made contract enforcement unreliable and imposed severe transaction costs on any economic activity. These costs became prohibitively large in times of historic change and revolution. Unstable business partner relationships and rapidly changing social norms limited the extent to which economic exchanges could be sustained by reputation, by repeated interactions or by embedding them in social networks. This led to a lack of trust, meaning that reliable input supplies on the one hand and credit enforcement on the other hand were difficult to sustain, resulting in economic disorganization and a tremendous output fall. In such an environment, barter can be used as a commitment device to overcome the problems of unreliable input supplies and credit enforcement, by linking transactions and specifying terms of trade that give the right incentives to adhere to the terms of the barter contract.

'Countervailing power' is a term coined by J.K. Galbraith (1952) to describe the ability of large buyers in concentrated downstream markets to extract price concessions from suppliers. Galbraith saw countervailing power as an important force offsetting suppliers' increased market power arising from the general trend of increased concentration in US industries. He provided examples such as a nationwide grocery chain extracting wholesale price discounts from food producers, and large auto manufacturers extracting price discounts from steel producers.

The concept of countervailing power was controversial in Galbraith's day (see Stigler's 1954, criticism), and continues to be so today. Formalizing the concept is difficult because it is difficult to model bilateral monopoly or oligopoly, and there exists no single canonical model. Whether and how wholesale discounts to large downstream firms are passed through to final-good consumers is unclear. The concept has the controversial antitrust implication that horizontal mergers between downstream firms may be pro-competitive.

There are a number of theories explaining why large buyers obtain price discounts from sellers. A simple theory is that the cost of serving large buyers is lower per unit than that of serving small buyers. Serving large buyers may involve lower distribution costs. For example, the supplier may be able to ship its product to a large buyer's central warehouse rather than having to ship it to the individual retail outlets owned by small buyers. Serving large buyers may also involve lower production costs. For example, if the supplier's production function exhibits increasing returns to scale and the supplier serves one buyer at a time each production period, per-unit production costs will be lower when serving a large buyer.

Other theories involve more subtle strategic effects. A literature including Horn and Wolinsky (1986), Stole and Zwiebel (1996), Chipty and Snyder (1999), Inderst and Wey (2003) and Raskovich (2003) considers a model in which a monopoly supplier bargains under symmetric information separately and simultaneously with each of a number of buyers. Each buyer regards itself as marginal, conjecturing that all other buyers consummate their negotiations with the supplier efficiently. If aggregate surplus across all negotiations is concave in quantity, the marginal surplus from a transaction involving a large quantity is higher per unit than that from one involving a small quantity. This higher per-unit marginal surplus for large buyers translates into a lower per-unit price. The aggregate surplus function would be concave, for example, if the supplier has increasing marginal production costs. Even if the supplier's cost function were linear, the total surplus function effectively becomes concave if the supplier is assumed to be risk averse, as in Chae and Heidhues (2004) and DeGraba (2005).

Size discounts also emerge if large buyers' outside options are better. In Katz (1987) and Sheffman and Spiller (1992), for example, the larger the buyer, the more credible are its threat of integrating backward and producing the good itself. Size discounts also emerge if the supplier's

outside option is worse when facing a large buyer. In Inderst and Wey (2007), for example, if bargaining with a large buyer breaks down, it is difficult for the supplier to unload this large quantity on the other buyers since this involves marching down these other buyers' declining marginal surplus functions.

Size discounts also emerge if one departs from the bargaining model with a monopoly supplier and instead considers competing suppliers. In Snyder (1998), collusion is difficult to sustain in the presence of a larger buyer because the benefit from undercutting and supplying the buyer is greater. To prevent undercutting in equilibrium, suppliers collude on a lower price for large buyers. In Dana (2004) and Inderst and Shaffer (2007), by pooling their demands and buying as a group from one supplier, buyers can increase the intensity of competition among suppliers of differentiated products.

Several papers have begun to examine the question of whether a downstream firm's countervailing power translates into lower final-good prices, using a model with competing downstream firms (Dobson and Waterson 1997; von Ungern-Sternberg 1996; Chen 2003). This work suggests that an increase in countervailing power can have the opposite effect, raising consumer prices and/or lowering social welfare.

Early empirical studies of countervailing power (see Scherer and Ross 1990, for a survey) took the standard structure–conduct–performance regressions (regressions of supplier profits or markups on supplier concentration using cross-sectional observations at the industry level) and added a buyer-concentration variable, often finding a significantly negative coefficient. Later intra-industry studies found more nuanced circumstances under which buyer-size discounts emerge. Ellison and Snyder (2002) and Sorensen (2003) observed size discounts in pharmaceutical and hospital-services markets only if there were competing, not monopoly, suppliers. In an experimental study, Normann et al. (2007) observed buyer-size discounts only when the total surplus function exhibited a certain curvature, consistent with theory.

French economist and economic adviser. Born in the Dordogne, he studied law in Paris, then returned to his native region to manage an industrial firm. At the same time, during the July monarchy, he wrote for Republican newspapers and economic periodicals. After the 1848 revolution, he held briefly a high position in the Ministry of Finance. In the following years he became a frequent contributor to the *Journal des économistes,* and published a successful textbook on banking in 1852. In 1853, the Chilean government contracted him to teach economics at the University of Chile in Santiago, and to be available as official economic adviser; he stayed for ten years, until 1863, when he returned to France. While in Chile he published his most ambitious work in economics, the *Traité théorique et pratique d'économie politique* (1858), which the Chilean government arranged to bring out in a Spanish translation. After his return to France, he resumed his activity as prolific writer of books and articles on economic affairs. He also published several works on political and historical topics and translated into French John Stuart Mill's *Principles of Political Economy,* Summer Maine's *Ancient Law* and William Graham Sumner's *What Social Classes Owe to Each Other.* He was appointed councillor of state in 1879, and three years later was elected member of the Académie des Sciences Morales et Politiques.

Throughout his life, Courcelle-Seneuil was a stalwart defender of free trade and laissez-faire. Charles Gide, the co-author (with Charles Rist) of a well-known history of economic doctrines, wrote about him in rather sarcastic terms:

> He was virtually the *pontifex maximus* of the classical school; the holy doctrines were entrusted to him and it was his vocation to denounce and exterminate the heretics. During many years he fulfilled this mission through book reviews in the *Journal des économistes* with priestly dignity. Argus-eyed, he knew how to detect the slightest deviations from the liberal school. (Gide 1895, p. 710)

Courcelle-Seneuil's special interest, starting with the publication of a small book on bank reform in 1840, was the introduction of more freedom into banking or, to use a modern term, the 'deregulation' of this industry. Above all, he advocated the abolition of the Bank of France's exclusive right of issue. According to Gide, Courcelle-Seneuil was more esteemed in England and the United States than in France. In any event, adoption of his monetary and banking proposals was never seriously considered in his own country.

Once in Chile, Courceile-Seneuil became a powerful policymaker and influential teacher. He arrived at a time when the international prestige of the laissez-faire doctrine was at its height and when gold booms and subsequent busts in California and Australia caused considerable fluctuations in Chile's agricultural exports to these areas, creating a need for flexible short- and long-term

credit facilities. This combination of events, joined with the prestige emanating from the foreign savant, permitted him to obtain in Chile what he had failed to achieve in his own country: under his guidance, the administration of Manuel Montt (1851–1861) promulgated a banking law that established total freedom for any solvent person to found a bank and permitted all banks to issue currency subject only to one limitation: the banknotes in circulation were not to exceed 150 per cent of the issuing bank's capital.

Courcelle-Seneuil's advice was also sought in connection with a new customs tariff and here again he achieved substantial change: the level of protection was severely cut back, although some tariffs were retained for revenue purposes.

But the principal influence exercised by Courcelle-Seneuil resided in his forceful teaching: as the University of Chile's first professor of economics, he was apparently successful in instilling doctrinaire zeal in his students, some of whom later became influential policymakers. Thus, Chilean historians have not only traced the abandonment of convertibility in 1878 to the permissiveness of the 1860 Banking Law and the lack of industrial development to the 1864 tariff; they also see Courcelle-Seneuil's indirect influence in the acquisition of the nitrate mines of Tarapacá by private foreign interests after Chile's victory over Peru in the War of the Pacific (1882) had given it title to the mines. Alienation of the mines was indeed recommended by a government committee dominated by Courcelle-Seneuil's disciples, who felt, like their teacher, that state ownership and management of business enterprises was to be strictly shunned. Secular inflation, industrial backwardness, domination of the country's principal natural resources by foreigners – all of these protracted ills of the Chilean economy have been attributed to the French expert.

Since the economically advanced countries were also those where economic science first flourished, they soon produced a peculiar export product: the foreign economic expert or adviser. Courcelle-Seneuil is probably the earliest prototype of the genre and his ironic career in Chile exhibits characteristics that were to remain typical of numerous later representatives. First, the adviser is deeply convinced that, thanks to the advances of economic science, he knows the correct solutions to economic problems no matter they may arise. Secondly, the country which invites the expert looks forward to his advice as to some magic medicine which will work even when (perhaps especially when) it hurts. Some countries seem particularly prone to this attitude. In Chile foreign or foreign-trained experts have played key roles at crisis junctures, from Courcelle-Seneuil in the mid-19th century to Edwin Kemmerer in the 1920s, the Klein-Saks Mission in the 1950s, and finally to the 'Chicago boys' in the 1970s. Thirdly, the influence of the adviser derives not only from the intrinsic value and persuasiveness of his message, but from the fact that he usually has good connections in his home country and can therefore facilitate access to its capital market. Courcelle-Seneuil, for example, suspended his university courses in 1858–1859 to accompany a Chilean financial mission that travelled to France in search of a railroad construction loan. Fourthly, the foreign adviser is often criticized for wishing to transplant the institutions of his own country to the country he advises, but his real ambition is more extravagant: it is to endow the country with those ideal institutions which exist in his mind only, for he has been unable to persuade his own countrymen to adopt them. Fifthly, history in general, and nationalist historiography in particular, is likely to be unkind to the foreign adviser. In retrospect he can easily become a universal scapegoat: whatever went wrong is attributed to his nefarious influence. This demonization is more damaging than the adviser himself could possible have been: it forestalls authentic learning from past experience.

Cournot Competition

Andrew F. Daughety

Abstract

Cournot's 1838 model of strategic interaction between competing firms has become the primary workhorse for the analysis of imperfect competition, and shows up in a variety of fields, notably industrial organization and international trade. This article begins with a tour of the basic Cournot model and its properties, touching on existence, uniqueness, stability, and efficiency; this discussion especially emphasizes considerations involved in using the Cournot model in multi-stage applications. A discussion of recent applications is provided as well as a reference to an extended bibliography of approximately 125 selected publications from 2001 through 2005.

The classic Cournot model is static in nature, with each (single-product) firm's strategy being the quantity of output it will produce in the market for a specific homogeneous good; as Kreps (1987) observed, Cournot's model was an early progenitor of Nash's famous paper. Many recent applications have involved multi-stage games; for example, each of n firms might first simultaneously choose investment levels (say, in cost-reducing R&D) and then simultaneously choose output levels in the second stage. Often now used in such a manner, we will see that the Cournot model is doing well, contributing to a range of new research, as it moves towards the two-century mark.

The Basic One-Stage Model and Associated Concepts

Consider an industry comprised of n firms, each firm choosing an amount of output to produce. Firm i's *output level* is denoted as q_i, $i = 1, \ldots, n$; let the vector of firm outputs be denoted $\boldsymbol{q} \equiv (q_1, q_2, \ldots, q_n)$. The firms' products are assumed to be perfect substitutes (the *homogeneous-goods* case); let Q denote the aggregate industry output level (that is, $Q \equiv \sum_{i=1}^{n} q_i$). We will refer to the $(n-1)$ vector of output levels chosen by firm i's

rivals as $\boldsymbol{q}_{-i}$; so, let ($\boldsymbol{q}_{-i}$, q_i) also be the n-vector $\boldsymbol{q}$. Market demand for the perfect-substitutes case is a function of aggregate output and its inverse is denoted as $p(Q)$; furthermore, let firm i's cost of producing q_i be denoted as $c_i(q_i)$. Thus, firm i's *profit* function is written as $\pi^i(\boldsymbol{q}) \equiv p(Q)q_i - c_i(q_i)$. All elements of the model are assumed to be commonly known by the firms, though extensions allowing incomplete information are not uncommon.

A *Cournot equilibrium* consists of a vector of output levels, $\boldsymbol{q}^{CE}$, such that no firm wishes to unilaterally change its output level when the other firms produce the output levels assigned to them in the (purported) equilibrium. Alternatively put (and reversing history), it is a Nash equilibrium of the normal-form game with quantities as strategies chosen from a compact space (for example, q_i in [0, Q^*], for some appropriate Q^*, such as $p(Q^*)= 0$) and with the $\pi^i(q)$ as the payoff functions. Thus, q^{CE} is a Cournot equilibrium if the following n equations are satisfied:

$$\pi^i\left(\boldsymbol{q}^{CE}\right) \geq \pi^i\left(\boldsymbol{q}^{CE}_{-i}, q_i\right) \text{ for all values of } q_i,$$
$$\text{for i} = 1, \ldots, n.$$

In analysing his model applied to a duopoly (he also considered the n-firm version), Cournot provided the notion of *best-response functions*. In the duopoly case, this is a pair of functions, $\psi^1(q_2)$ and $\psi^2(q_1)$, which provide the profit-maximizing choice of output for firm 1 and 2 (respectively), given conjectures about the output level chosen by the rival firm (that is, each firm's choice of its output level reflects a *best-response property*). Hence, $\psi^i(q_j)$= arg $\max_q \pi^i(q, q_j)$; $i, j = 1, 2$; $i \neq j$. That is, we want $\psi^i(q_j)$ to be the solution to firm i's first-order condition: $p(\psi^i(q_j) + q_j) + p'(\psi^i(q_j) + q_j)\psi^i(q_j) - c'(\psi^i(q_j)) = 0$, $i, j = 1, 2$, $i \neq j$. We ll assume for now that the problem has a nice solution and that some sort of sufficiency condition holds (for example, strict quasi-concavity of profits), but the discussion below on existence and uniqueness of equilibrium shows that such classical assumptions are overly strong and are overly restrictive for some modern applications, such as those involving multi-stage games or discontinuous cost functions. More generally, $\psi^i(\mathrm{q_j})$ could be a correspondence (a point-to-set map); we generally restrict the discussion below to functions, and assume as much differentiability as needed.

If output-level choices are best responses to conjectures about each firm's rival's choice of output, *and* if these conjectures are correct in equilibrium, then the resulting vector of output levels provides a Cournot equilibrium: $q_i^{CE} = \psi^i\left(q_j^{CE}\right)$ for $i,j = 1, 2$, and $j \neq i$. In other words, the equilibrium occurs where the best-response functions cross when graphed in the space of output levels. Generalizing to n firms, this condition can be written as $q_i^{CE} = \psi^i\left(q_j^{CE}\right)$ for $i = 1, \ldots, n$: $\boldsymbol{q}^{CE}$ is a Cournot equilibrium if it consists of mutual best-responses for all the firms.

Some variations on the basic model are worth mentioning. If the cost function for a firm has both fixed and variable components, and if the fixed component is avoidable (that is, is zero at zero output), then the best-response function for the firm will be discontinuous at the positive output level where variable profits just cover the avoidable cost. This is important for two reasons. First, avoidable fixed costs are not unusual in many entry scenarios: think of an airline entering a market where there are already some competitors, with the avoidable cost being advertising. Second, this discontinuity could mean that the only equilibrium might involve some or all firms choosing to not enter (or to exit) the market, even if absent these avoidable costs $\boldsymbol{q}^{CE}$ would be strictly positive.

Another avenue for interaction would consider imperfect factor markets, so that instead of $c_i(q_i)$ the cost function for firm i would be written as $c_i(\boldsymbol{q}_{-i}, q_i)$; then strategic interaction occurs not only through revenue but also via factor markets. Finally, if the model is one of short-run competition, then the output level of the firm may be restricted to be less than some predetermined capacity level; a simple version is that there are parameters k_i, $i = 1, \ldots, n$, such that a constraint on firm i's quantity choice is $q_i \leq k_i$; $i = 1, \ldots, n$; this induces a vertical segment (at the capacity level) in a firm's best-response function. Such capacity levels might be choices made in an earlier stage.

Finally, a number of papers develop 'non-Cournot' models which generate Cournot-model results. Kreps and Scheinkman (1983) provide a two-stage model of capacity choice followed by price setting in a homogeneous-goods duopoly; the result is a unique subgame-perfect equilibrium with Cournot capacities and a market-clearing price consistent with the standard Cournot model (however, Davidson and Deneckere 1986, show that this result is especially sensitive to the basis for rationing consumers over firms when out-of-equilibrium firm-level demand exceeds capacity). Klemperer and Meyer (1986) analyse a one-stage game wherein duopolists producing heterogeneous goods non-cooperatively choose either a price or a quantity as the firm's strategy; under either multiplicative or additive error in the demand function, if marginal costs are upward sloping, the outcome is that predicted by the Cournot model (applied to the heterogenous-goods case; see the discussion of this case in Section "Properties of the Cournot equilibrium" below). The classic embedding of the Cournot model is that of Bowley (1924), the best-known developer of models with 'conjectural variations' (CV). This is a static story wherein the first-order conditions in the analysis include firm i's conjecture of each rival's reaction to a small change in firm i's quantity (for example, $\partial_{qj}/\partial_{qj}$ need not be zero for each $j \neq i$); different values of the CV generate competitive, collusive, or Cournot outcomes (among others). Such a handy static embedding of alternative degrees of competition has been employed in a number of theoretical applications, and in a variety of empirical analyses trying to estimate market power. However, Daughety (1985) shows that a basic rationality requirement (that each firm's CV be the same as the actual slope of the best-response function) leads to the Cournot outcome, so that alternative CV values violate this form of rational expectations. Furthermore, Korts (1999) shows that empirical analyses using the CV approach to assess market power will generally mis-measure the degree of competitiveness of the industry.

Properties of the Cournot Equilibrium

For most of this section we emphasize results for an n-firm, homogeneous-goods, complete-information model, where a firm's cost function depends only on that firm's output level. As suggested earlier, possibly one of the most important reasons for the continuing interest in the properties of the Cournot equilibrium is that Cournot competition is frequently used as a final stage in a variety of models; analysis employing such refinements as subgame perfection rely on a well-behaved subgame.

Existence, Uniqueness and Stability

Novshek (1985) provides an existence theorem that has quite practical uses (for expository purposes we consider a slightly less general version). Besides continuity and twice differentiability of the inverse demand function, $p(Q)$, Novshek's existence theorem requires that: (1) $p(Q)$ crosses the quantity axis at a finite value and is strictly decreasing for quantities below that cut point; (2) the marginal revenue for each firm is decreasing in the aggregate output of its rivals; and (3) each firm's cost function is non-decreasing and lower semi-continuous. Requirement (2) is written formally as $p'(Q_{-i} + q_i)\ p''(Q_{-i} + q_i)\ q_i < 0$, where $Q_{-i} \equiv Q - q_i$, for all i. This is equivalent to the assumption that $\partial^2\pi^i(\boldsymbol{q})/\partial Q_{-i}\partial_{qi} < 0$ for all i, that is, that Q_{-i} and q_i are *strategic substitutes*, which means that an expansion in Q_{-i} implies that the optimal q_i falls. The third requirement means that costs cannot fall as the output level is increased and that cost functions can have jumps (discontinuities), as long as the functions are continuous from the left. This was a substantial improvement over previous existence theorems and it allows for an important case: avoidable fixed costs, such as those in the airline-entry example mentioned earlier. Amir (1996) applies an ordinal version of the theory of *supermodular games* to the existence issue (see Vives 2005, for a recent survey of supermodular games; see also Amir 2005, for a comparison of *ordinal* and *cardinal complementarity* in this

context); this change of techniques allows for weaker demand conditions (primarily that log $p(Q)$ is concave) but requires a slightly stronger condition on each firm's cost function (marginal costs are positive, so models wherein marginal costs might be zero – as might occur with capacity competition – are left out) in order to guarantee that a Cournot equilibrium exists. As an example of the advantages concerning demand analysis, let $p(Q) = \left(Q - \overline{Q}\right)^2$ for $Q \leq \overline{Q}$, and zero otherwise. Such a function satisfies (1) above, is log-concave (actually, convex), but is excluded from consideration by Novshek's second condition.

Gaudet and Salant (1991) provide conditions for a Cournot equilibrium to be *unique* which address an important consideration when Cournot models are used in a subgame of a larger game: their theorem allows for degeneracy (one or more firms produce zero output but have marginal cost equal to the equilibrium price); thus, such firms are just at the shutdown point in the equilibrium. In a one-stage application this could be eliminated via a small perturbation in the parameters, but in a multi-stage application such an outcome need not be pathological, as some of the second-stage 'parameters' are strategic variables in the first-stage model (the authors provide a simple, full-information entry game to illustrate this). The sufficient conditions for uniqueness are (not surprisingly) more restrictive than those for existence (on the assumption that Novshek's conditions hold as well): (1) each firm's cost function must be twice continuously differentiable and strictly increasing; and (2) the slope of the marginal cost function is strictly bounded above the slope of the demand function. Thus, concave costs are allowed, to some degree, but the cost function cannot be 'too concave', even on subsets of its domain.

Cournot provided an explicit dynamic stability argument for his model by imagining sequential play by each agent (myopically best-responding in the current period to the existing output levels of all rivals); this is referred to as *best-reply dynamics* and when this process converges the solution is termed *stable*. Using best-reply dynamics to rationalize a static solution has, historically, been a source of substantial criticism, but nonetheless some papers use the requirement of Cournot stability to select an equilibrium when there are multiple equilibria (dynamic stability should not be confused with equilibrium refinement criteria in game theory such as strategic stability). A sufficient condition in the duopoly case is that $|\partial\psi^1(q_2)/\partial q_2||\partial\psi^2(q_1)/\partial q_1| < 1$ (see Fudenberg and Tirole 1991); see Seade (1980) for more general conditions (and problems) for best-reply dynamics in the n-firm case. For an approach employing an explicit evolutionary process via replicator dynamics with noise, with firms able to choose 'behavioural' strategies (including, but not limited to, best-reply), see Droste et al. (2002).

Welfare

Two types of inefficiency can occur in a Cournot equilibrium: the equilibrium price exceeds the marginal cost of production, and aggregate output is inefficiently distributed over the firms. Compare the first-order conditions for firms in a duopoly, each producing under conditions of non-decreasing marginal costs (that is, $p(Q) + p'(Q)q_i = c_i'(q_i), \quad i = 1, 2$) with those for a central planner choosing q_1 and q_2 so as to maximize total surplus: $p(Q) = c_i'(q_i), \quad i = 1, 2$. Clearly, if demand is downward-sloping at the equilibrium, aggregate output in the Cournot equilibrium will be less than what the social planner would choose. However, a second distortion can be seen in this comparison: under the social planner, each firm's marginal costs are equalized with the others'. This will hold only in a symmetric Cournot equilibrium (where $q_1 = q_2$): production is, in general, inefficiently allocated across the firms.

The maldistribution of production implies that strategic interaction readily may yield counter-intuitive welfare results. As a simple example, consider a duopoly wherein (inverse) industry demand is $p = a - Q$ and firm i's cost function is $c_i(q) = C_i q$, $i = 1, 2$, with $a > C_1 > C_2 > 0$; that is, the linear demand, constant- but-unequal-marginal-cost case. It is straightforward to find the equilibrium and show that it is interior and

unique. Let W be the sum of producers' and consumers' surplus. Then a little work shows that $dW/dC_1 > 0$ if $11C_1 - 7C_2 - 4a > 0$; to see that these conditions are non-empty, consider the parameter specification ($a = 20$, $C_1 = 13$, $C_2 = 8$), which satisfies all the foregoing requirements. The point of the example is that a *reduction* of firm 1's marginal cost leads to a *decrease* in equilibrium welfare. Thus, strategic interaction by the firms in the marketplace can lead to reversals of the usual welfare intuition that cost-improving technological change is beneficial. The reason this occurs is that the cost reduction results in an increase in the high-cost firm's equilibrium output level and a (smaller) decrease in the low-cost firm's output level; this increased inefficiency in aggregate production can be sufficient to overwhelm other efficiency improvements (such as the increase in industry output). This is similarly true if in the above model firm 2 is an incumbent monopolist (using simple monopoly pricing) and firm 1 an entrant: welfare will fall due to entry.

In the n-firm version of the constant-marginal-cost model, changes in the distribution of production costs (holding the mean fixed) do not affect industry output; this is seen by summing over the first-order conditions, whence $np(Q) + p'(Q)Q = \sum_{i=1}^{n} C_i$. Bergstrom and Varian (1985) showed that (on the assumption that the pre-and post-change equilibria are interior) such mean-preserving changes in the marginal costs strictly improve welfare if and only if the variance of the marginal costs strictly increases; the reason is that the aggregate cost of production has decreased if the variance increases. Salant and Shaffer (1999) extend this idea to consider the effects of changes in first-stage parameters (for example, cost-reducing R&D investments) on second-stage costs in models wherein Cournot competition is employed in the second stage. They argue that, since aggregate production costs are *maximized* when all firms have the same costs, it is the asymmetric equilibria in such games (which are often assumed away) which may yield the most important outcomes to examine, from both a social and a private perspective.

Does entry necessarily reduce the equilibrium price? A recent contribution provides a clean result if we restrict attention to the symmetric case wherein all firms have the same twice continuously differentiable and non-decreasing cost function, and demand is continuously differentiable and downward-sloping. Amir and Lambson (2000) show that the equilibrium price falls with an increase in the number of competitors if, for all Q, $p'(Q) < c''(q)$ for all q in [0, Q]. Thus, even with some degree of returns to scale (for example, as might occur with U-shaped average costs), entry will reduce price, at least with identical firms. However, Hoernig (2003) shows that, even if the equilibria are stable and there are no returns to scale, price can rise with entry if products are differentiated.

If the products of the firms are imperfect substitutes (that is, products are differentiated), then (in general) there is no aggregate demand function $p(Q)$; rather firm i's inverse demand function would be written as $p_i(\boldsymbol{q})$ and profits would be written as $\pi^i(\boldsymbol{q}) = p_i(\boldsymbol{q})q_i - c_i(q_i)$, $i = 1, \ldots, n$. Welfare in this model can be contrasted with a reformulation of the model so that each firm chooses a price for its product; standard parlance is to call the price-strategy model the *(differentiated products) Bertrand model* (even though Bertrand's famous review of Cournot did not envision heterogeneity in products; see Friedman's 1988 translation of Bertrand's review). Without going into detail on the (differentiated products) Bertrand model, Singh and Vives (1984) have shown (for linear, symmetric demand and constant marginal costs in a duopoly setting) that, while profits under Cournot competition exceed those under Bertrand competition, total surplus is higher under Bertrand competition than under Cournot competition. Note that this result holds in the one-stage game. However, these results may be reversed in a two-stage application. For example, Symeonidis (2003) considers R&D investment with spillovers in a two-stage game, and shows that (at least for a portion of the parameter space) Cournot competition leads to higher welfare than Bertrand competition. The basic intuition is that, if profits are higher for second-stage Cournot competition

than for second-stage Bertrand competition, and first-stage investment is inefficiently low in either case, then the increased second-stage profits may partly correct the inefficiently low first-stage investment, leading to an overall welfare gain for competition in quantities rather than prices.

Finally, convergence of a Cournot equilibrium to a competitive equilibrium, as the number of firms grows, was considered by Cournot in Chapter ▶ "Hearn, William Edward (1826–1888)" of his book, and has been the subject of a number of papers; see Novshek and Sonnenschein (1978, 1987) for a general equilibrium treatment where appropriate replication of Cournot economies yields equilibria arbitrarily close to the Walrasian equilibrium; see Alos-Ferrer (2004) for an evolutionary model (which allows for memory) at the level of an industry.

Applications

The literature exploring and applying the Cournot model is vast; an earlier extended bibliography can be found in Daughety (1988/2005). The more recent literature employing the Cournot model is already becoming significant in size: a survey of articles in 16 top mainline and field journals, for the period 2001–5, netted approximately 125 articles exploring or applying the Cournot model in one of its various common forms. An online Excel file of (abbreviated) citations and some characteristics of each article (number of firms, number of stages, welfare considerations, informational regime, and topic classification), as accessed on 21 November 2006, is available at http://www.vanderbilt.edu/Econ/faculty/Daughety/ExtendedCournotBib2001-2005.xls

However, some excellent papers have undoubtedly been missed (not to mention papers from the 1990s), and space limitations preclude anything beyond the briefest of tours and just a taste of the literature, so only a very few can be discussed below. This section addresses five topics which account for a significant portion of the literature, three areas that overlap other fields, and two (comparatively) new areas of research.

Delegation

Vickers (1985) uses an *n*-firm, two-stage model to examine performance measures for managers. Restricting the manager's performance measure to be a weighted average of profits and output, with the weights determined by the owner of each firm in the first stage, he shows that the weight on output is non-zero. This makes each manager more aggressive (each chooses to produce a higher output level), thereby leading to lower profits per firm. Sklivas (1987) considers the differentiated-products Bertrand version and shows that owners choose weights on revenue and profits so as to make managers more passive (they post higher prices), leading to increased profits. Miller and Pazgal (2001) have unified this literature, showing that incentive schemes based on own and rival's profits result in an equilibrium which is insensitive to whether the firm chooses price or quantity as its strategic variable.

Information Transfer

Vives (1984), Gal-Or (1985), and Li (1985) all consider variants of 'information transfer' models to examine the possibility of information sharing, whereby firms may choose to pool information on either demand or cost parameters. These models are analysed as *Bayesian–Nash games*, so that, before seeing a private signal about the parameter of interest (for example, the demand intercept), each firm chooses whether or not to share the information with the other firms; then information is received and production (or pricing) occurs in the second stage. The nature of the good (substitutes or complements), the type of information (common or individual), and the strategy space (quantities or prices) all affect whether firms will share information. Ziv (1993) relaxes the verifiability of information and finds that firms will send misleading information if they can; he then considers mechanisms for eliciting truthful messages.

Intellectual Property

Katz and Shapiro (1985) and Kamien and Tauman (1986) consider the licensing of innovations in an oligopoly. Katz and Shapiro employ a three-stage duopoly game in which the innovation is

developed, then a single license is auctioned, and then the firms compete. Kamien and Tauman use a two-stage, *n*-firm game with a posted price for the innovation (a fee or a royalty), followed by competition. More recently, Fauli-Oller and Sandonis (2003) consider optimal competition policy when considering licences as an alternative to merger. Anton and Yao (2004) allow for weak patent protection and consider how disclosure of information about an innovation (for example, through the patent application) can be a signalling device to influence competitors, but those same competitors may be able to employ the information to successfully use (infringe on) the patent; here small innovations are patented and substantial innovations are protected through secrecy.

Mergers

Salant et al. (1983) show that exogenously determined mergers of a subset of firms in the constant-marginal-cost set-up yields a problematical result: a sufficient condition for a merger to be unprofitable is that it involve less than 80 per cent of the industry, hardly a resounding endorsement of using such a model to analyse mergers. This result, however, is partly driven by the assumptions of homogeneous products, constant unit costs, and industry structure. Perry and Porter (1985) show that various mergers can be profitable if firms have sufficiently increasing marginal costs. Daughety (1990), using a two-tiered-industry, *n*-firm model, with m firms choosing output in the first stage (tier) and $n - m$ firms choosing output in the second stage, shows that if $1 < m < n$, then, when m is comparatively small ($m < n/3$), mergers of two second-tier firms to make a first-tier firm can be both profitable and social-welfare-enhancing, even though such mergers increase concentration and have no cost synergies (all firms have identical constant unit costs). Recently, Pesendorfer (2005), using a repeated game model with entry, has found that merger to monopoly may not be profitable, but merger in a non-concentrated industry can be; these differences from the previous literature partly reflect long-run versus short-run profitability computations.

R&D

D'Aspremont and Jacquemin (1988) considered cost-reducing R&D in the presence of spillovers, and considered both non-cooperative and cooperative R&D decision-making; there have been a number of recent papers on cost-reducing spillovers (see, for example, Zhao 2001, for more on the negative welfare effects of cost-reducing innovation, and Symeonidis 2003, cited in Section "Properties of the Cournot equilibrium" above, as well as the work discussed below under the subject of auctions with competition). Toshimitsu (2003) considers the incentive and welfare properties of quality-based R&D subsidies for firms in a model of endogenously determined product quality (and thus product differentiation); subsidizing high quality is welfare-enhancing (independent of whether the Cournot or Bertrand model is employed).

Other Fields

Areas of ongoing effort which extend into other fields include *experimental economics*, *the financial structure of the firm* (see, for example, Brander and Lewis 1986, on determinate debt-equity due to imperfect competition, and see Povel and Raith 2004, extending Brander and Lewis via endogenously determined debt contracts); and *international trade* (see, for example, Brander and Spencer 1985, analysing the strategic use of subsidies in international competition; Mezzetti and Dinopoulos 1991, discussing domestic firm–union bargaining and import competition; and Spencer and Qiu 2001, concerning relationship-specific investments and trade).

New Topics

Finally, a few examples of comparatively new topics. While auctions with private information has long been an area of interest, the developing literature on *auctions with competition* has started to take seriously the combination of incomplete information and post-auction competition. For example, see Das Varma (2003) or Goeree (2003), who find that signalling by winners of an auction causes bids to be biased when post-auction interaction between the auction's winner and losers can be influenced by the size of the bid.

A nice example is when firms have private information about how acquiring a cost-reducing innovation might affect the firm's production costs, and bidding for a licence for the innovation precedes Cournot oligopoly interaction; here signalling with a high bid suggests that the winner will have low costs and will produce a high level of output.

A second new area is *networks*; one recent example is Goyal and Moraga-Gonzalez (2001), who model bilateral agreements to share knowledge, and allow for the possibility of partial collaboration, via considering possible networks of relationships. They examine how the nature of the firms' interaction in markets can contribute to the instability of certain types of strategic alliances and the stability of other ones.

A Broader Perspective on Cournot Competition

If alive to critique this essay, Cournot might view the interpretation of the term 'Cournot competition' being limited merely to the legacy of his oligopoly analysis to be an overly restrictive interpretation of the assignment. And well he should. Hicks (1935, 1939) argues that Cournot was the first to present a modern model of monopoly as well as the precise conditions for perfect competition; furthermore, as noted earlier, Cournot's eighth chapter concerned 'unlimited competition'. In the 1937 Cournot Memorial session of the Econometric Society, A. J. Nichol (1938) observed that, if ever there was an apt illustration of Carnegie's dictum that 'It does not pay to pioneer', then Cournot's life and work would be it. Cournot's oligopoly model was essentially ignored for many years, or was relegated to dusty corners of microeconomics texts, but over recent decades it has come to be an essential tool in many an economist's toolbox, and is likely to continue as such.

Cournot was born at Gray (Haute-Saône) on 28 August 1801 and died in Paris on 30 March 1877. Until the age of 15 his education was at Gray. After studying at Besançon he was admitted to the Ecole Normale Supérieure in Paris in 1821. In 1823 he obtained his licentiate in sciences and in October of that year was employed by Marshal Gouvion-Saint-Cyr as literary adviser to the Marshal and tutor to his son. In 1829 he obtained his doctorate in science with a main thesis in mechanics and a secondary one in astronomy. Through the sponsorship of Poisson in 1834 he obtained the professorship in analysis and mechanics at Lyon.

After a year of teaching he became primarily involved in university administration. In 1835 he became rector of the Académie de Grenoble and subsequently became inspector general of education and from 1854 to 1862 was rector of the Académie de Dijon. He became a Knight of the Legion of Honour in 1838 and an Officer in 1845. He was afflicted with failing eyesight and in the last part of his life was nearly blind. In 1862 he retired from public life but continued his own researches in Paris until his death.

Cournot was a prolific writer. His writings can be broadly divided into three categories: (1) mathematics; (2) economics and (3) the philosophy of science and philosophy of history.

In considering Cournot as an economist it is necessary to place his major economic work, *Recherches sur les principes mathématiques de la théorie des richesses* (1838) in the context not only of *Principes de la théorie des richesses* (1863), which can be regarded as a literary version of his work of a quarter of a century earlier, and his *Revue sommaire des doctrines économiques* (1877) which appeared in the last year of his life, but also of his writings on probability and the philosophy of science, in particular *Exposition de la théorie des chances et des probabilités* (1843) and *Matérialisme, vitalisme, rationalisme*: *Etudes des données de la science en philosophie* (1875).

It is possible to weave a broad cloth of interpretation taking into account not merely Cournot's other works but what appears to be known of his personality and the considerable social and political flux in France during the times in which he lived. Guitton (1968) has suggested that Cournot had a rather melancholic and solitary temperament and 'did nothing to make his books attractive'. He notes that: 'Cournot was a pioneer. He did nothing to court his contemporaries, and they, in turn, not only failed to appreciate him but ignored him.' Palomba ([1981], 1984) provides a sketch of the historical background of his time, noting the growth of socialist ideas in Europe, the political actions and reactions to the French Revolution and the challenges to the concept of ownership. Rather than challenge or repeat the broad contextual interpretation of Cournot provided by Palomba, this article is confined primarily to the direct interpretation of his works in economics and supporting texts in the light of many of the developments in economics which are consistent with and may be indebted to his original ideas.

The texts followed here include the French given in the complete works of Cournot (1973) and the Nathaniel T. Bacon translation (1899) entitled *Researches into the Mathematical Principles of the Theory of Wealth,* which also contains an essay by Irving Fisher on Cournot and Mathematical Economics as well as a bibliography on Mathematical Economics from 1711 to 1897. The 1929 reprint of the 1897 edition was used.

The preface sets forth with great clarity Cournot's fundamental approach to political economy. He states:

> But the title of this work sets forth not only theoretical researches; it shows also that I intend to apply to them the forms and symbols of mathematical analysis. Most authors who have devoted themselves to political economy seem also to have had a wrong idea of the nature of the applications of mathematical analysis to the theory of wealth.
>
> But those skilled in mathematical analysis know that its object is not simply to calculate numbers, but that it is also employed to find the relations between magnitudes which cannot be expressed in numbers and between functions whose law is not capable of algebraic expression. Thus the theory of probabilities furnishes a demonstration of very important propositions, although without the help of experience it is impossible to give numerical values for contingent events, except in questions of mere curiosity, such as arise from certain games of chance. (p. 3)

Cournot continues in the preface to note that only the first principles of differential and integral calculus are required for his treatise. Professional mathematicians could be interested in it for the questions raised rather than the level of mathematics presented. He ends the preface with the caveat:

> I am far from having thought of writing in support of any system, and from joining the banners of any party; I believe that there is an immense step in passing from theory to governmental applications; I believe that theory loses none of its value in thus remaining preserved from contact with impassioned polemics; and I believe, if this essay is of any practical value, it will be chiefly in making clear how far we are from being able to solve, with full knowledge of the case, a multitude of questions which are boldly decided every day. (p. 5)

The first chapter, 'Of Value in Exchange or of Wealth in General', provides insight into the breadth of Cournot's concern for the social and historical context of wealth.

> Property, power, the distinctions between masters, servants and slaves, abundance, and poverty, rights and privileges, all these are found among the most savage tribes, and seem to flow necessarily from the natural laws which preside over aggregations of individuals and of families; but such an idea of wealth as we draw from our advanced state of civilization, and such as is necessary to give rise to a theory, can only be slowly developed as a consequence of the progress of commercial relations, and of the gradual reaction of those relations on civil institutions. (pp. 7–8)

He notes that: 'it is a long step to the abstract idea of *value in exchange* which supposes that the objects to which such value is attributed *are in commercial circulation*.'

In order to illustrate the distinction between the word *wealth* in ordinary speech and value in exchange, he presents an example of a publisher who destroys two-thirds of his stock expecting to derive more profit from the remainder than the entire edition. The economics of elasticity is developed more formally in Chapter 4 on demand, but the concept is clear.

Chapter 2, 'On Changes in Value, Absolute and Relative', begins by noting that 'we can only assign value to a commodity by reference to other commodities'. This leads to a discussion of the use of a corrected money which would serve as 'the equivalent of the mean sun of the astronomers'.

Chapter 3, 'Of the Exchanges', is the first in which formal mathematical manipulation is employed. He considers a silver standard in which all currencies are fixed in ratio to a gram of fine silver. He observes that the ratios of exchange for the same weight of fine silver cannot differ by more than transportation and smuggling costs. Given the volume of trade measured in silver he considers the arbitrage conditions for the $m(m-1)/2$ ratios among m centres. Fisher (1892) notes, however, that Cournot did not appear to be acquainted with determinants as he did not attempt a general solution of the exchange equations he proposed, but limited his calculations to three centres of exchange.

It is in Chapter 4, 'On the Law of Demand', that the modernity of his approach stands out. He is interested in demand as it is revealed in sales at a given price. He represents the relationship between sales and price by the continuous function $D = F(p)$ and observes that this function generally increases in size with a fall in price and that the empirical problem is to determine the form of $F(p)$. He indicates an appreciation of the concept of elasticity of demand although he did not develop the formal measure.

Chapters 5 and 6 deal with monopoly without and with taxation; Chapter 7 is on the competition of producers and Chapter 8 on unlimited competition. The ninth chapter is on the mutual relations of producers and the tenth on the communication

of markets. The final two chapters are somewhat macroeconomic in scope. Chapter 11 is entitled 'Of the Social Income' and 12 'Of Variations in the Social Income, Resulting from the Communication of Markets'.

As our commentary is primarily on Chapters 5–8, the order is reversed and 11 and 12 are dealt with first. Cournot explicitly avoids setting up the whole closed microeconomic system.

> It seems, therefore, as if, for a complete and rigorous solution of the problems relative to some parts of the economic system, it were indispensable to take the entire system into consideration. But this would surpass the powers of mathematical analysis and of our practical methods of calculation, even if the values of all the constants could be assigned to them numerically. The object of this chapter and of the following one is to show how far it is possible to avoid this difficulty, while maintaining a certain kind of approximation, and to carry on, by the aid of mathematical symbols, a useful analysis of the most general questions which this subject brings up.
>
> We will denote by *social income* the sum, not only of incomes properly so called, which belong to members of society in their quality of real estate owners or capitalists, but also the wages and annual profits which come to them in their capacity of workers and industrial agents. We will also include in it the annual amount of the stipends by means of which individuals or the state sustain those classes of men which economic writers have characterized as unproductive, because the product of their labour is not anything material or saleable. (pp. 127–8)

But, using a first order approximation, he studies the effect of a change in price and consumption of a good on social income as a whole under competition, under monopoly and when a new product is introduced.

> Finally, although we make continuous and almost exclusive use of the word *commodity,* it must not be lost sight of (Article 8) that in this work we assimilate to commodities the rendering of services which have for their object the satisfaction of wants or the procuring of enjoyment. Thus when we say that funds are diverted from the demand for commodity A to be applied to the demand for commodity B, it may be meant by this expression that the funds diverted from the demand for a commodity properly so called, are employed to pay for services or vice versa. When the population of a great city loses its taste for taverns and takes up that for theatrical representations, the funds which were used in the demand for alcoholic beverages go to pay actors, authors, and musicians, whose annual income, according to our definition, appears on the balance sheet of the social income, as well as the rent of the vineyard owner, the vine-dresser's wages, and the tavern-keeper's profits. (p. 149)

The last chapter considers international trade and national income and uses a first order approximation rather than a closed equilibrium system to study the benefits of opening up trade.

> Moreover (and this is the favourite argument of writers of the school of Adam Smith), it should be inferred from the asserted advantage assigned to the exporting market, and the asserted disadvantage suffered by the importing market, that a nation should so arrange as always to export and never to import, which is evidently absurd, as it can only export on condition of importing, and even the sum of the values exported, calculated at the moment of leaving the national market, must necessarily be equal to the sum of the values imported, calculated at the moment of arrival on the national market. (p. 161)

Cournot also notes the problem of analysing a tariff war:

> The question would no longer be the same if establishment of a barrier for the benefit of A producers might provoke, by way of retaliation, the establishment of another barrier for the benefit of B producers, against whom the first barrier was raised. The government of A would then have to weigh the advantage resulting from the first measure to the citizens of A against the drawbacks caused by the retaliation. The two markets A and B would thus again be placed in symmetrical conditions, and each should be considered as acting the double part of an exporting and importing market. (p. 164)

He closes his comments with:

> We have just laid a finger on the question which is at the bottom of all discussions on measures which prohibit or restrict freedom of trade. It is not enough to accurately analyse the influence of such measures on the national income; their tendency as to the distribution of the wealth of society should also be looked into. We have no intention of taking up here this delicate question, which would carry us too far away from the purely abstract discussions with which this essay has to do. If we have tried to overthrow the doctrine of Smith's school as to barriers, it was only from theoretical considerations, and not in the least to make ourselves the advocates of prohibitory and restrictive laws. Moreover, it must be recognized that such questions as that of commercial liberty are not settled either by the arguments of scientific men or even by the wisdom of statesmen. (p. 171)

He closes his work with the observation about theory that:

> By giving more light on a debated point, it soothes the passions which are aroused. Systems have their fanatics, but the science which succeeds to systems never has them. Finally, even if theories relating to social organization do not guide the doings of the day, they at least throw light on the history of accomplished facts. (p. 171)

Although the contribution of these last chapters is not as great as those to which we now turn, the spirit and style is that of a major theorist concerned deeply and objectively with application to practical affairs.

In Chapters 5–9 Cournot develops his theory of monopoly, oligopoly and unlimited competition. This can be contrasted with Ricardo (1817) before and Walras (1874) after, who concentrated on unlimited competition with no aim at producing a unified theory involving numbers.

In Chapter 5 Cournot deals with monopoly, considering increasing, decreasing and constant returns and in Chapter 6 the influence of taxation on a monopoly is considered. He notes direct taxes and indirect taxes as well as bounties and their influences on both producers and consumers; and closes with an examination of two variations of taxation in kind.

Chapter 7 provides a smooth transformation from single person maximization to non-cooperative optimization where agents who mutually influence each other act without explicit cooperation.

> We say *each independently,* and this restriction is very important, as will soon appear; for if they should come to an agreement so as to obtain for each the greatest possible income, the results would be entirely different, and would not differ, so far as consumers are concerned, from those obtained in treating of a monopoly.
>
> Instead of adopting $D = F(p)$ as before, in this case it will be convenient to adopt the inverse notation $p = f(D)$; and then the profits of proprietors (1) and (2) will be respectively expressed by
>
> $$D_1 f(D_1 + D_2), \text{and } D_2 f(D_1 + D_2),$$
>
> i.e. by functions into each of which enter two variables, D_1 and D_2. (p. 80)

It is at this point that Cournot switches from price to quantity of a homogeneous product as the strategic variable used by the competitors. His words and the mathematics do not quite match. He says, 'This he will be able to accomplish by properly adjusting his price.' The first order condition for the existence of a non-cooperative equilibrium with quantity as the strategic variable is given. A diagram showing a stable equilibrium and another with a non-stable equilibrium are presented. The analysis is generalized to n producers including the possibility of an extra group of producers beyond n, all of whom produce at capacity. He obtains n symmetric equations for the firms with interior production levels and sets the others at capacity.

When he introduces n different general cost functions for the n firms he handles the situation with all having an equilibrium defined by the simultaneous satisfaction of the equations arising from the first order conditions. But he does not deal with the possibility that costs could be such that different subsets of firms could be active in different equilibria.

The criticism levelled by Bertrand (1883) in his review written well after Cournot's death concerns the modelling rather than the mathematics. As Cournot considered competition without entry among firms selling an identical product it was fairly natural to avoid the discontinuity in the payoff function caused by selecting price as an independent variable. But the observation of Bertrand matters for markets with a finite number of firms. The choice of strategic variable causes not only mathematical difficulties but raises questions concerning economic realism and relevance. Quantity, price, quality, product differentiation and scope can all be considered as playing dominant roles in different markets. But the general explanation of price and quantity as strategic variables was and is critical to the development of economic theory. Cournot provided the foundations for the understanding of quantity. Bertrand, whose review of the books of Cournot and Walras was somewhat tangential to his professional interests offered only an example rather than a developed theory of price competition. It remained for Edgeworth (1925, pp. 111–42) to explore the underlying difficulties with the payoff functions for duopoly with increasing marginal costs; and it

has only been since the 1950s with the advent of the theory of games that there has been an adequate study of the properties of non-cooperative equilibria in games with price and quantity as strategic variables, without or with product differentiation.

The thesis of Nash (1951) on the existence of non-cooperative equilibria for a class of games in strategic form provided a broad general underpinning for the concept of non-cooperative equilibrium. It was then immediately observable that, although Cournot's work with equilibria of games with a continuum of strategies was not strictly covered by Nash's work, conceptually Cournot's solution could be viewed as an application of non-cooperative equilibrium theory to oligopoly (see Mayberry et al. 1953). The broader investigation of the price model and the interpretation of the instability of the Edgeworth cycle in terms of mixed strategy equilibria has only taken place recently. This also includes a growing literature on how to embed both the Cournot and Bertrand–Edgeworth models into a closed economic system or Walrasian framework. A summary of much of this work is presented by Shubik (1984).

It is important to appreciate that the developments in the theory of monopolistic competition such as those of Hotelling (1929) and Chamberlin (1933) and J. Robinson (1933) were based upon the Cournot non-cooperative game model. Although it may be argued that Chamberlin's and Mrs. Robinson's works possibly contained broader and richer models of competition among the few than that of Cournot, they represented a step backwards in their lack of mathematical sophistication and analysis. The Chamberlin discussion of large group equilibrium does have price as the strategic variable along with product differentiation and entry, but the solution concept is the non-cooperative equilibrium à la Cournot with the caveat that an attempt to produce a strict formal mathematical model of Chamberlin's large group equilibrium leads one to conclude that the game having price as a strategic variable is closer to Edgeworth's analysis than that of Cournot and a price strategy non-cooperative equilibrium may not exist.

In Chapter 8 Cournot shows his basic grasp of the important strategic difference between pure competition and oligopolistic competition. Using his own words, he states:

> The effects of competition have reached their limit, when each of the partial productions D_2 is *inappreciable,* not only with reference to the total production $D = F(p)$, but also with reference to the derivative $F'(p)$, so that the partial production D_k could be subtracted from D without any appreciable variation resulting in the price of the commodity. This hypothesis is the one which is realized, in social economy, for a multitude of products, and, among them, for the most important products. It introduces a great simplification into the calculations, and this chapter is meant to develop the consequences of it. (p. 90)

In modern mathematical economics, in the linking of competition among the few and the Walrasian system into a logically consistent whole, two approaches to the study of large numbers have been adopted. The first is replication and has its roots in Cournot and, more formally, Edgeworth (1881). Following Edgeworth this method was used in cooperative core theory by Shubik (1959). The second involves considering a continuum of economic agents where each agent can be regarded as a set of measure zero. Cournot clearly saw the need to consider a market in which each individual firm is too small to influence price. But it remained for Aumann (1964) to fully formalize the concept of an economic game with a continuum of agents.

After 25 years during which his seminal work in mathematical economics was essentially ignored, Cournot demonstrated his concern for his ideas by publishing *Principes de la théorie des richesses* (1863), where he offered a non-mathematical rendition of his early work. This book is of considerably greater length than its predecessor and is divided into four books: Book 1, Les Richesses (eight chapters); Book 2, Les Monnaies (seven chapters); Book 3, Le Système économique (ten chapters) and Book 4, L'Optimisme économique (seven chapters).

This book met with no more immediate success than his original work and is not as deep. For example the chapters on money, although they contain discursive and historical material of interest, have little material of analytic depth.

In spite of the indifference of the environment to his writings in economics, Cournot regarded his contribution as sufficiently important that some 14 years later, in the year of his death, he published his *Revue sommaire des doctrines économiques* (1877). This book was also longer, non-mathematical and of less significance than the work of almost 40 years earlier. But Cournot's own sense of having been at least partially vindicated after 40-odd years is indicated in his *avant-propos*:

> I was at that point in 1863, when I had the desire to find out whether I had sinned in the substance of ideas or only in their form. To that end, I went back to my work of 1838, expanding it where needed, and, most of all, removing entirely the algebraic apparatus which intimidates so much in these subjects. Whence the book entitled: 'Principes de la théorie des richesses'. 'Since it took me,' I said in the preface, 'twenty-five years to lodge an appeal of the first sentence, it goes without saying that I do not intend, whatever happens, to resort to any other means. If I lose my case a second time, I will be left only with the consolation which never abandons disgraced authors: that of thinking that the sentence that condemns them will one day be quashed in the interest of the law, that is of the truth.'
>
> When I took this engagement in 1863, I did not think that I would live long enough to see my 1838 case reviewed as a matter of course. Nevertheless, more than thirty years later, another generation of economists, to put it like Mr. the commander Boccardo, discovered that I opened up back then, though too timidly and too partially, a good path to be followed, on which I was even somewhat preceded by a man of merit, the doctor Whewell. While another Englishman, Mr. Jevons, was undertaking to enlarge this path, a young Frenchman, Mr. Leon Walras, professor of Political Economy at Lausanne, dared to maintain right in the Institute that it was wrong to pay so little attention to my method and my algorithm, which he used rightfully to expose a new theory, more amply developed.
>
> Now, look at my bad luck. If I won a little late, without any involvement, my 1838 case, I lost my 1863 case. If one wanted in retrospective to make a case for my algebra, my prose (I am ashamed of saying it) did not get better success from the publisher. The *Journal des Economistes* (August 1864) criticized me mainly 'for not having moved on from Ricardo,' for not having taken into account the discoveries that so many men of merit have made in twenty-five years in the field of political economy; thus the poor author that no one of the official world of French economists wanted to quote incurred the reproach of not having quoted others enough.

Cournot was central to the founding of modern mathematical economics. The average reader tends not to be aware that the textbook presentations of the 'marginal cost equals marginal revenue' optimizing condition for monopoly and 'marginal cost equals price' for the firm in pure competition come directly from the work of Cournot (including an investigation of the second order conditions).

He had to wait many years for recognition, but when it came in the works of Jevons, Marshall, Edgeworth, Walras and others, it moved the course of economic theory. Marshall notes (*Memorials of Alfred Marshall,* pp. 412–13, letter 2, July 1900) 'I fancy I read Cournot in 1868', this was when Marshall was 26, some 30 years after the book appeared. He acknowledges him both as a great master and as his source 'as regards the form of thought' for Marshall's theory of distribution. Jevons, in his preface to the second edition of *The Theory of Political Economy* records 'I procured a copy of the work as far back as 1872' and that it 'contains a wonderful analysis of the laws of supply and demand, and of the relations of prices, production, consumption, expenses and profits'. He excuses himself for his lateness in coming to Cournot observing: 'English economists can hardly be blamed for their ignorance of Cournot's economic works when we find French writers equally bad.' Walras in the preface to the fourth edition of *Elements of Pure Economic* (Jaffé translation, p. 37) acknowledges his 'father Auguste Walras, for the fundamental principles of my economic doctrine'; and 'Augustin Cournot for the idea of using the calculus of functions in the elaboration of this doctrine'. His liberal references to Cournot include his discussion of monopoly and the description of supply and demand.

The art of formal modelling is different from but related to the use of mathematical analysis in

economics. The clarity and parsimony of Cournot's modelling stand out and have served as beacons guiding the development of mathematical economics.

An important feature missing from Cournot's seminal work is the discussion of the role of chance and uncertainty in the economy. He stressed the importance of chance in both his book *Exposition de la théorie des chances et des probabilités* (1843) and in *Matérialisme, vitalisme, rationalisme* (1875).

Although economics was the only social science he attempted to mathematize, he was well aware of the simplifications being made in cutting economic analysis from the context of history and society.

> The economist considers the body social in a state of division and so to say of extreme pulverization, where all the particularities of organization and of individual life offset each other and vanish. The laws that he discovers or believes to discover are those of a mechanism, not those of a living organism. For him, it is no longer a question of social physiology, but of what is rightfully called social physics (p. 56). We mention that these cases of regression which imply abstractions of the same kind, if not of the same type and of the same value, reappear in various stages of scientific construction.

Cournot's work on chance and probability does not appear to have provided any new mathematical analysis, but he made three distinctions concerning the nature of probability. His book of 1843 was a text with the dual purpose of teaching the non-mathematician the rules of the calculus of probability and of dissipating the obscurities on the delicate subject of probability. He stressed the distinction between objective and subjective probability. His opening chapters provide a discussion of the appropriate combinatorics and frequency of occurrence interpretation of probability.

Cournot stressed the distinction between objective probability where frequencies are known and subjective probability. He noted:

> We could, since then, relying on the theorems of Jacques Bernoulli, who was already aware of their meaning and scope, pass immediately to the applications those theorems had in the sciences of facts and observations. However, a principle, first stated by the Englishman Bayes, and on which Condorcet, Laplace and their successors wanted to build the doctrine of 'a posteriori' probabilities, became the source of much ambiguity which must first be clarified, of serious mistakes which must be corrected and which are corrected as soon as one has in mind the fundamental distinction between probabilities which have an objective existence, which give a measure of the possibility of things, and subjective probabilities, relating partly to one's knowledge, partly to one's ignorance, depending on one's intelligence level and on the available data. (p. 155)

Subjective probability rests on the consideration of events which our ignorance calls for us to treat as equiprobable due to insufficient cause.

He added a third category which he entitled 'philosophical probability' (Chapter 17) 'where probabilities are not reducible to an enumeration of chances' but 'which depend mainly on the idea that we have of the simplicity of the laws of nature' (p. 440).

Cournot's views on probability appear to be intimately related to his concern for social statistics and economic modelling. Although he did not establish formal links between his mathematical economics models and chance he regarded history and the development of institutions as dependent on chance and economics as set in the context of institutions.

Cournot was at best an indifferent mathematician. Bertrand clearly dominated him in that profession. But from his own writings it is clear that Cournot was well aware of both his purpose in applying mathematics to economics and his limitations as a mathematician. At the age of 58 he wrote his *Souvenirs* which he finished in Dijon in October 1859. They were published many years later with an introduction by Botinelli (1913). In these writings Cournot provides his self-assessment as a mathematician.

> I was starting to be a little known in the academic world through a fairly large number of scientific articles. This was the basis of my fortune. Some of these articles ended up with Mr. Poisson, who was then the leader in Mathematics at the Institute, and mainly at the University, and he liked them

particularly. He found in them philosophical insight, which I think was not all that wrong. Furthermore, he foresaw that I would go a long way in the field of pure mathematical speculation, which was (I always thought it and never hesitated to say it) one of his mistakes.

The general tenor of his *Souvenirs* is of a moderately conservative, quietly humourous, self-effacing man with considerable understanding of his environment and a broad belief in science and its value to society.

Regarding his work as a whole, his dedication and power as the founder of mathematical economics and the promoter of empirical numerical investigations emerges. He strove for around 40 years to have his ideas accepted. He did so with persistence and humour (referring to his major work as 'mon opuscule'). He understood the need to wait for a generation to die. And before his death with the work and words of Jevons and Walras he saw the vindication of his approach.

Court, Louis Mehel (Born 1910)

M. Ali Khan

Court obtained his PhD degree in economics from Columbia University in 1942. He was at Columbia from the Summer Term of 1936 through the Spring Term of 1938 and held the Granville W. Garth Fellow-ship. He was a 'student at large' at the University of Chicago during the Winter and Spring Quarters of 1941. It is also known that he was an Instructor of Mathematics at Rutgers University during the years 1946–8. This sparse and sketchy information allows some gleaning into the intellectual influences on Louis Court.

Court's first published paper appeared in the *Journal of Mathematics and Physics* and concerned what would now fall under the heading of duality in mathematical programming. In particular he showed that:

> if $\phi\ (q_{1,\ldots,}\ q_n)$ is maximized subject to the single constraint $\sum_{i=1}^{n} p_i q_i = m$ and $q_i(\ p_1\ ,\ldots,\ p_n\ )(i = 1,\ldots,\ n)$ [satisfy] the first order conditions for this maximization, then the function $\psi(p_1,\ldots,p_n)\equiv\phi[q_1(p_1,\ldots,p_n),\ \ldots,\ q_n(p_1,\ldots,p_n)]$ is minimized subject to the same constraint except that the p's are now regarded as the active variables.

Court returned to this result in his 1951 paper which he presented at the International Congress of Mathematicians and in which he not only generalized his result but also noted its relevance to isoperimetric problems in the calculus of variations and to possible applications concerning integrability problems in the theory of differential equations. He had by then already applied his result to statistical decision, theory. One can only wonder why he did not pursue applications in economic theory.

Louis Court's place among the pioneers of mathematical economics thus rests on his 1941 *Econometrica* articles in which he extended the theories of consumer and producer behaviour to a setting with infinitely many commodities. He introduced his paper with the following rather modern statement:

> Apart from its utility in treating commodity groups embracing large, though not necessarily infinite numbers of items, the extension is stamped with true intellectual concinnity. The finite theories are contained, as very special cases, in the infinite analyses. . . . Housing provides an instance in which it is profitable to use the commodity-spectrum concept.

Court worked in the space of square Lebesgue integrable functions over a compact interval; saw the relevance of the theory of Hilbert spaces, still in its infancy; formulated the price system as an element of the topological dual of his commodity space and emphasized the distinction between functions and their equivalence classes (see ibid., footnote 5, p. 248). However, he did not see the relevance of Ramsey's (1928) work or the importance of the weak, weak star and Mackey topologies, the latter omission being justified by the fact that the basic papers dealing with these concepts had yet to be written. Court's results were extended to reflexive Banach spaces by Berger (1971).

In summary, Court's *Econometrica* papers may be seen as a first serious application of functional analysis (see, for example, Dieudonné 1981) to economic theory and as a precursor of Debreu (1954), Hurwicz (1958), Bewley (1972) and of the burgeoning literature inspired by these contributions; and in another context, of Dornbush–Fischer–Samuelson (1977). The evaluation of the (then) editor of *Econometrica*, Ragnar Frisch, still stands:

> Even though considerable portions of [the] mathematical technique are in essence the same as that developed by Volterra and others, a presentation of this technique shaped especially with the econometric problems in view, is highly useful. Economic theory is now growing into a stage where much of the work will consist of a combination of mathematical and economic analyses so intimate that it is difficult to say where one begins and the other ends. Mr. Court's paper is a valuable contribution towards this type of work.

Covered Interest Parity

C. Emre Alper and Oya Pinar Ardic

Abstract

Covered Interest Parity describes an idealised situation in foreign exchange markets in which the interest rates on assets differing only in the currency of denomination will be equal. This article describes the theoretical assumptions under which CIP holds and the evidence for CIP in practice.

Keywords

CIP; Counterparty risk; Emerging markets; Foreign exchange

JEL Classifications

F31

The Covered Interest Parity (CIP) condition states that the actions of foreign exchange market participants, when hedged against exchange rate risk using the forward exchange market, should equalise interest rates on any two assets that differ only in currency of denomination. The assumptions under which the CIP condition holds are (i) negligible transaction costs, (ii) perfect capital mobility, (iii) many participants in the spot and the forward exchange markets with ample funds and no counterparty risks, and (iv) identical default and political riskiness, liquidity, maturity and seniority of the underlying assets. These assumptions in essence rule out transactions involving smaller currencies, the existence of capital controls or taxes on financial flows, as well as thin markets and periods of crisis.

Algebraically, suppose that $i_{t,k}$ and $i^*_{t,k}$ denote the interest rates on domestic currency and foreign-currency-denominated assets at time t, respectively, for an investment horizon of k. Suppose also that S_t denotes the spot exchange rate at time t, i.e. the current price of one unit of foreign currency in domestic currency units, while $F_{t,k}$ is the k-period forward exchange rate at time t, i.e. the exchange rate currently agreed upon for a transaction k periods ahead. The CIP condition states that

$$\left(1 + i_{t,k}\right) = \left(1 + i^*_{t,k}\right)\frac{F_{t,k}}{S_t} \qquad (1)$$

In most settings, the log approximation of (1) is used

$$f_t^k - s_t = i_t - i_t^* \tag{2}$$

where f and s denote the natural logarithms of F and S, respectively.

There is a vast literature that studies whether the CIP condition holds for a variety of currency pairs, asset types etc. Officer and Willett (1970) and Taylor (1992) provide essential surveys of this literature. There are two broad reasons to be interested in the validity of the CIP condition. First, it is taken as an indicator of market efficiency and international market integration. Second, many models in international finance and open economy macroeconomics assume the CIP condition and use it as a key building block. Lack of empirical support for such models might in fact be due to the failure of the CIP condition (among other possible factors).

Empirical tests of the CIP condition mainly consider larger currencies and in general involve US dollars on one side of the transaction. These tests can be broadly grouped into two based on their methodologies. The first set of studies calculate deviations from the CIP condition and analyse the time series properties of these deviations. The second conducts regression analyses of an estimable CIP relation of the form

$$f_t^k - s_t = \mathrm{A} + \beta\left(i_t - i_t^*\right) + \varepsilon_t \tag{3}$$

to test if $\alpha = 0$ and $\beta = 1$ while simultaneously testing if ε_t is independently and identically distributed.

Overall, empirical evidence from developed economies supports the validity of the CIP condition. See, for example, Frenkel and Levich (1975, 1977), and Taylor (1987, 1989) among others. Progressive financial liberalisation and the integration of international financial markets since the 1990s are likely to result in even more favourable evidence for the CIP condition. One may summarise the key observations of this literature as follows. First, deviations from the CIP condition, only to the extent that they exceed transaction costs, can be deemed significant. Second, during times of financial turbulence, when counterparty risk is especially prevalent, deviations from the CIP condition tend to be significant and persistent. Third, as opposed to monthly averages or daily closing values, real-time data should be used, as this is what the market participants face at the time of transactions. Fourth, it is not possible to test the validity of the CIP condition over long horizons since the longest maturity forward contract publicly traded is in general for 12 months.

As for the emerging market economies, it is not yet possible to state whether the CIP condition holds or not because the four underlying assumptions of the CIP condition do not hold in general. Nevertheless, Kumhof (2001) reports, for a number of emerging markets, that although there are substantial deviations from the CIP condition in the short run, a stable relationship exists between the forward premium and the interest differential in the long run.

Crawling Peg

David Vines

A 'crawling peg' denotes an exchange rate system in which the value of a country's currency is fixed but moveable. The country would undertake to keep its currency at a fixed, or 'par' value. But that par value itself would be *gradually* changed, if this were necessary to correct a 'fundamental disequilibrium' in the country's balance of payments. As elaborated by Williamson (1965) the rate of gradual adjustment would be limited to a maximum rate of one twenty-sixth of one per cent per week. Such a proposal had earlier been put forward by Meade (1964), and the idea originally came from Harrod (see Harrod 1969, p. 92).

The reason for giving this proposal the label of 'crawling peg' should be apparent. The 'adjustable peg' of the Bretton Woods system was one in which changes in par values of exchange rates were carried out infrequently, suddenly, and in a sizeable, discrete step.

The 'crawling peg' was proposed as a system under which such par changes as occur are implemented slowly, in such a large number of small steps to make the process of exchange rate adjustment continuous for all practical purposes; a system therefore under which the peg crawls from one level to another (Williamson 1965, p. 2).

If a 'crawling peg' system were not to give rise to large, and possibly disorderly, international capital flows, it would need to be accompanied by an appropriate interest rate policy. For example, if a country's exchange rate were crawling downwards by two per cent per year, then its interest rate would need to be two per cent higher than in other countries whose exchange rates were not moving, in order to avoid stimulating capital outflow.

The 'crawling peg' offered, in the late 1960s, considerable attractions. The 'adjustable peg' regime of the Bretton Woods system was then beginning to disintegrate under the influence of speculative capital flows. The trouble with the adjustable-peg system was that it delayed exchange rate adjustment until the point at which it had become a near certainty, encouraging a speculative attack which then precipitated the inevitable crisis (and which handed speculators a one way bet on a substantial capital gain). Such speculative attacks in the end broke the Bretton Woods system, and ushered in the era of floating exchange rates, with all its difficulties. The 'crawling peg' would have allowed countries to defend par values for their currencies and yet change these par values themselves without disrupting the whole system. A number of countries have, in fact, used the 'crawling peg' at some time (including Argentina, Brazil, Chile, Columbia, Israel, Uruguay and Vietnam). And there is 'rather general agreement' that it has succeeded in allowing them to neutralize efficiently the effects on their balance of payments of high inflation rates (see Williamson 1977). Although these countries are underdeveloped, their favourable experience with the crawling peg may be relevant to the major industrialized nations.

The great difficulty about a 'crawling peg' system is, however, that it makes it very difficult, or even impossible, to use interest rate policy in the pursuit of domestic economic management. Consider a country in balance of payments deficit which was also experiencing the threat of unemployment. The exchange rate would crawl downwards (because of the deficit) and this would require a relatively high level of domestic interest rates (in order to prevent capital outflow) which would be inconsistent with combatting unemployment. If, instead, interest rates were lowered to combat the unemployment, then capital would flow out. In that case either the rate of downward crawl would increase (and become a cumulative downward spiral) or the capital outflow would become a torrent (as speculators anticipated the defeat of the crawling peg system by means of a large instant currency collapse). An implied great disadvantage of the 'crawling peg' is the fact that where large changes in the exchange rate prove

necessary it is impossible to effect them immediately: this in effect means that the interest rate in the country may have to be tied down to offsetting the anticipated exchange rate change during a *very* lengthy adjustment period.

Nevertheless, the 'crawling peg' idea is still of contemporary relevance. There have been a number of recent proposals to reform the international monetary system in the direction of greater management of exchange rates, so as to limit the misalignments which are intrinsic to the present non-system of floating exchange rates. Such a new system would require 'target zones', or 'central rates', for its implementation (see Williamson 1983; Meade 1984). These target zones, or central rates, should crawl, rather than being rigidly pegged and discretely adjusted, for exactly the reasons discussed above. But the implications that this would have for domestic interest rate policy, so as to avoid destabilizing capital flows, should be clearly noted.

Creative Destruction

Ricardo J. Caballero

C

Abstract

Creative destruction refers to the incessant product and process innovation mechanism by which new production units replace outdated ones. This restructuring process permeates major aspects of macroeconomic performance, not only long-run growth but also economic fluctuations, structural adjustment and the functioning of factor markets. Over the long run, the process of creative destruction accounts for over 50 per cent of productivity growth. At business cycle frequency, restructuring typically declines during recessions, and this add a significant cost to downturns. Obstacles to the process of creative destruction can have severe short- and long-run macroeconomic consequences.

Creative destruction refers to the incessant product and process innovation mechanism by which new production units replace outdated ones. It was coined by Joseph Schumpeter (1942), who considered it 'the essential fact about capitalism'.

The process of Schumpeterian creative destruction (restructuring) permeates major aspects of

macroeconomic performance, not only long-run growth but also economic fluctuations, structural adjustment and the functioning of factor markets.

At the microeconomic level, restructuring is characterized by countless decisions to create and destroy production arrangements. These decisions are often complex, involving multiple parties as well as strategic and technological considerations. The efficiency of those decisions not only depends on managerial talent but also hinges on the existence of sound institutions that provide a proper transactional framework. Failure along this dimension can have severe macroeconomic consequences once it interacts with the process of creative destruction (see Caballero and Hammour 1994, 1996a, b, c, 1998a, b, 2005). Some of these limitations are natural, as they derive from the sheer complexity of these transactions. Others are man-made, with their origins ranging from ill-conceived economic ideas to the achievement of higher human goals, such as the inalienability of human capital. In moderate amounts, these institutional limitations give rise to business cycle patterns such as those observed in the most developed and flexible economies. They can help explain perennial macroeconomic issues such as the cyclical behaviour of unemployment, investment and wages. In higher doses, by limiting the economy's ability to tap new technological opportunities and adapt to a changing environment, institutional failure can result in dysfunctional factor markets, resource misallocation, economic stagnation, and exposure to deep crises.

Given the nature of this short piece, I will skip any discussion of models, and refer the reader to Caballero (2006) for a review of the models behind the previous paragraph, and to Aghion and Howitt (1998) for an exhaustive survey of Schumpeterian growth models. Instead, *I* focus on reviewing recent empirical evidence on different aspects of the process of creative destruction.

Recent Evidence on the Pace of Creative Destruction

There is abundant recent empirical evidence supporting the Schumpeterian view that the process of creative destruction is a major phenomenon at the core of economic growth in market economies.

The most commonly used empirical proxies for the intensity of the process of creative destruction are those of factor reallocation and, in particular, job flows. Davis et al. (1996) (henceforth DHS) offered the clearest peek into this process by documenting and characterizing the large magnitude of job flows within US manufacturing. They defined job creation (destruction) as the positive (negative) net employment change at the establishment level from one period to the next. Using these definitions, they concluded that over ten per cent of the jobs that exist at any point in time did not exist a year before or will not exist a year later. That is, over ten per cent of existing jobs are destroyed each year and about the same amount is created within the same year. Following the work by DHS for the United States, many authors have constructed more or less comparable measures of job flows for a variety of countries and episodes. Although there are important differences across them, there are some common findings. In particular, job creation and destruction flows are large, ongoing and persistent. Moreover, most job flows take place within rather than between narrowly defined sectors of the economy.

Given the magnitude of these flows and that they take place mostly within narrowly defined sectors, the presumption is strong that they are an integral part of the process by which an economy upgrades its technology. Foster et al. (2001) provide empirical support for this presumption. They decompose changes in industry-level productivity into within-plant and reallocation (between-plant) components, and conclude that the latter – the most closely related to the creative destruction component – accounts for over 50 per cent of the ten-year productivity growth in the US manufacturing sector between 1977 and 1987. Moreover, in further decompositions they document that entry and exit account for half of this contribution: exiting plants have lower productivity than continuing plants. New plants, on the other hand, experience a learning and selection period through which they gradually catch up with incumbents. Other studies of US manufacturing based on somewhat different methodologies

(see Baily et al. 1992; Bartelsman and Dhrymes 1994) concur with the conclusion that reallocation accounts for a major component of within-industry productivity growth. Bartelsman et al. (2004) provide further evidence along these lines for a sample of 24 countries and two-digit industries over the 1990s.

Recent Evidence on the Cyclical Features of Creative Destruction

At the business cycle frequency, sharp liquidations (rises in job destruction) constitute the most noted impact of contractions on creative destruction. In contrast, job creation is substantially less volatile and mildly pro-cyclical. There is an extensive literature that, extrapolating from the spikes in liquidations (recently measured in job flows but long noticed in other contexts), finds that recessions are times of increased reallocation. In fact, this has been a source of controversy among economists at least since the pre-Keynesian 'liquidationist' theses of such economists as Hayek, Schumpeter, and Robbins. These economists saw in the process of liquidation and reallocation of factors of production the main function of recessions. In the words of Schumpeter (1934, p. 16): 'depressions are not simply evils, which we might attempt to suppress, but… forms of something which has to be done, namely, adjustment to … change.'

In Caballero and Hammour (2005) we turned the liquidationist view upside down. While we sided with Schumpeter and others on the view that increasing the pace of restructuring of the economy is likely to be beneficial, we provided evidence that, contrary to conventional wisdom, restructuring *falls* rather than rises during contractions.

Since the rise in liquidations during recessions is not accompanied by a contemporaneous increase in creation, implicit in the increased-reallocation view is the idea that increased destruction is followed by a surge in creation during the recovery phase of the cyclical downturn. This presumption is the only possible outcome in a representative firm economy, as the representative firm must replace each job it destroys during a recession by creating a new job during the ensuing recovery. However, once one considers a heterogeneous productive structure that experiences ongoing creative destruction, other scenarios are possible. The cumulative effect of a recession on overall restructuring may be positive, zero, or even negative, depending not only on how the economy contracts but also on how it recovers. Thus, the relation between recessions and economic restructuring requires one to examine the effect of a recession on aggregate separations not only at impact, but cumulatively throughout the recession-recovery episode. We explored this issue using quarterly US manufacturing gross job flows and employment data for the 1972–93 period, and found that, along the recovery path, job destruction declines and falls below average for a significant amount of time, more than offsetting its initial peak. On the other hand, job creation recovers, but it does not exceed its average level by any significant extent to offset its initial decline. As a result, our evidence indicates that, on average, recessions *depress* restructuring.

Similarly, in Caballero and Hammour (2001) we approached the question of the pace of restructuring over the cycle from the perspective of corporate assets. Studying the aggregate patterns of merger and acquisition (M&A) activity and its institutional underpinnings, we reached a conclusion that also amounts to a rejection of the liquidationist perspective. Essentially, a liquidationist perspective in this context would consider fire sales during sharp liquidity contractions as the occasion for intense restructuring of corporate assets. The evidence points, on the contrary, to briskly expansionary periods characterized by high stock market valuations and abundant liquidity as the occasion for intense M&A activity.

Recent Evidence on Institutional Impediments to Creative Destruction and Their Cost

For all practical purposes, some product or process innovation is taking place at every instant in

time. Absent obstacles to adjustment, continuous innovation would entail infinite rates of restructuring. What are these obstacles to adjustment? The bulk of it is technological – adjustment consumes resources – but (over-?) regulation and other man-made institutional impediments are also a source of depressed restructuring.

While few economists would object to the hypothesis that labour market regulation hinders the process of creative destruction, its empirical support is limited. In Caballero et al. (2004) we revisited this hypothesis using a sectoral panel for 60 countries. We found that job security provisions – measured by variables such as grounds for dismissal protection, protection regarding dismissal procedures, notice and severance payments, and protection of employment in the constitution – hamper the creative destruction process, especially in countries where regulations are likely to be enforced. Moving from the 20th to the 80th percentile in job security cuts the annual speed of adjustment to shocks by a third. By impairing worker movements from less to more productive units, effective labour protection reduces aggregate output and slows down economic growth. We estimated that moving from the 20th to the 80th percentile of job security lowers annual productivity growth by as much as 1.7 per cent.

Similarly, the idea that well-functioning financial institutions and markets are important factors behind economic growth is an old one. The process of creative destruction is likely to be a chief factor behind this link. In Caballero et al. (2006) we analysed the decade-long Japanese slowdown of the 1990s and early 2000s. The starting point of our analysis is the well-known observation that many large Japanese banks would have been out of business had regulators forced them to recognize all their loan losses. Because of this, the banks kept many zombie firms alive by rolling over loans that they knew would not be collected (evergreening). Thus, the normal competitive outcome whereby the zombies would shed workers and lose market share was thwarted. Using an extensive data-set, we documented that roughly 30 per cent of firms were on life support from the banks in 2002 and about 15 per cent of assets resided in these firms. The main idea in our article is that the counterpart to the congestion created by the zombies is a reduction in profits for potential and more productive entrants, which discourages their entry. We found clear evidence of such a pattern in firm-level data and of the corresponding reduced restructuring in sectoral data.

Bertrand et al. (2004) further drive home the point that problems in the banking sector can have grave consequences for the health of the restructuring process. They use a differences-in-differences approach on firm-level data for the period 1977–99 to analyse the impact of the banking reforms of the mid-1980s on firm and bank behaviour. These reforms eliminated government interference in bank lending decisions, eliminated subsidized bank loans, and allowed French banks to compete more freely in the credit market. They find that, after the reforms, firms' exit rates and asset reallocation rise, and are more correlated with performances.

International competition is an important source of creative destruction. Trefler (2004) concludes that there are significant productivity and reallocation effects from trade openness, even in industrialized economies. To reach this conclusion, Trefler takes advantage of the Canada–US Free Trade Agreement (FTA) to study the effects of a reciprocal trade agreement on Canada. He finds that, for industries that experienced the deepest Canadian tariff reductions, the contraction of low-productivity plants reduced employment by 12 per cent while raising industry-level labour productivity by 15 per cent. Moreover, he finds that at least half of this increase is related to exit and/or contraction of low-productivity plants. Finally, for industries that experienced the largest US tariff reductions, plant-level labour productivity soared by 14 per cent. Consistent with this evidence, Bernard et al. (2006) find that in the United States productivity growth is fastest in industries where trade costs (barriers) have declined the most.

Domestic deregulation of goods markets can have similar effects. For example, Olley and Pakes (1996) find that deregulation in the US telecommunications industry increased productivity predominantly through factor reallocation towards more productive plants rather than

through intra-plant productivity gains. More broadly, Klapper et al. (2004) study the effect of entry regulation on firm behaviour in a sample including firm-level data from countries of western and eastern Europe. Their findings support the notion that regulation affects entry: 'naturally high-entry' industries have relatively lower entry in countries that have higher entry regulations. Moreover, both the growth rate and share of high-entry industries are depressed in countries with more stringent barriers to entry. Finally, Fishman and Sarria-Allende (2004) extend the Klapper, Laeven and Rajan study to countries outside Europe and include both industry- and firm-level data from the UNIDO and WorldScope databases, and reach similar conclusions.

Final Remarks

Evidence and models coincide in their conclusion that the process of creative destruction is an integral part of economic growth and fluctuations. Obstacles to this process can have severe short- and long-run macroeconomic consequences.

Schumpeter invented the phrase 'creative destruction' in his famous book on the development of capitalism into socialism (Schumpeter 1942). In his view the process of creative destruction is the essential fact about capitalism and refers to the incessant mutation of the economic structure from within, destroying the old and creating a new.

In the footsteps of Karl Marx, Schumpeter argues that in dealing with capitalism we are dealing with an evolutionary process. It is by nature a form or method of economic change and not only never is but never can be stationary. The fundamental impulse that sets and keeps the capitalist engine in motion comes from new goods and new methods of production and transportation, created by the Schumpeterian entrepreneur, who is always on the outlook for new combinations of the factors of production (Heertje 2006).

The process of creative destruction takes time. For that reason there is no point in appraising its performance within a static framework. A system may produce an optimal allocation of resources at every point of time and may yet in the long run be inferior to a system without such optimal allocation, because the non-optimality may be a condition for the level and speed of long-run performances, in other words for dynamic efficiency. Furthermore, the process of creative destruction in Schumpeter's vision must be seen as the background for individual decisions and strategies. Economic theory has a tendency to concentrate on decisions about prices by firms, which are assumed to maximize profits, within a given structure. Schumpeter argues that the relevant problem is how capitalism creates and destroys these structures (Metcalfe 1998).

Schumpeter's conception of creative destruction overturns the idea that price competition is the only component of the market behaviour of entrepreneurs. In fact, it is not that kind of competition which counts, but the competition from the new commodity, the new technology, the new source of supply, and the new type of organization. Instead of marginal changes, fundamental upheavals are brought about by process and product innovations of existing firms and potential competitors.

Restrictive practices of monopolists and large firms are to be judged against the background of the perennial gale of creative destruction, rather than in the context of stationary development. The potential threat of process and product innovation reduces the scope and importance of restrictive practices that aim to guarantee the monopolist or big firm a quiet life. If however the profits are used to counterattack, restrictive practices may help to deepen the process of creative destruction and, therefore, the dynamic effects of capitalism (Reisman 2004).

The process of creative destruction as described by Schumpeter has been experienced again since the 1980s in the United States,

Japan, and Western Europe and since the 1990s in China and India as well. On the basis of new technologies many old firms, structures, and professions have been swept away, and new industrial organizations and labour relations have emerged. In particular, the application of information technology and the Internet with the dramatic decrease in transaction costs of communication is leading to major changes of a quantitative and qualitative nature in both the private and public sector of the economy. On the one hand, 'external' growth of already large firms which take over others is a feature of modern capitalism; on the other hand, every day new small firms are established, often created by former executives of existing (and long-lived) companies.

This extensive discussion of the process of creative destruction illustrates Schumpeter's strong emphasis on the supply side of the economy. It would be an interesting question to study the impact of the process of creative destruction on employment. My guess would be that, on balance, the process of creative destruction is more creative than destructive, not only with regard to employment but also concerning broader perspectives of growth and welfare. This may be one of the reasons why Schumpeter's work has had a lasting and ever-increasing influence on economic theory.

Credit

Ernst Baltensperger

While the volume and complexity of credit transactions has grown immensely over the centuries, the act of credit extension and debt creation, or lending and borrowing, as such, is probably as old as human society. To extend credit means to transfer the property rights on a given object (e.g. a sum of money) in exchange for a claim on specified objects (e.g. certain sums of money) at specified points of time in the future. To take credit, or go into debt, is the other side of the coin. Credit and debt have always posed some special problems of understanding for economists, beyond those associated with the production, trade and consumption of 'ordinary' goods like wheat or cloth, or factors of production like labour services. There exists, of course, a wide array of different forms of credit contracts in today's economies. Classifications are customary; for example, according to types of debtors or creditors (domestic or foreign, public or private, etc.), length of contract duration, type of security put forward by the debtor, or the use of the loan by the borrower. However, this essay will attempt to concentrate on the essential features common to all or most groups of credit transactions, rather than enumerate and describe the differences between specific types and forms of credit.

The Economic Function of Credit

The credit market is essentially a market for intertemporal exchange. Something is given up in the present in exchange for something else in the future – or vice versa, if seen from the point of view of the borrower. The future 'repayment' typically includes a compensation in excess of the original 'payment'; that is, interest. The rate of interest represents the relative price in the market for intertemporal exchange.

The possibility of intertemporal exchanges allows market participants the realization of utility gains, just as voluntary exchange in general is mutually advantageous. The basic reason for this is that individuals are not normally indifferent about the distribution of their consumption over time but care about it. This notion of 'time preference' – used here in its most general and neutral sense, which does not necessarily imply a preference for present over future consumption – was first clearly formulated by Fisher (1930), who viewed *dated* consumption possibilities as the consumer's objects of choice; that is, as separate arguments of his utility function. This allowed the application of the standard tools of microeconomic analysis to problems of inter-temporal choice and proved to be the clue to a clear understanding and analytical treatment of credit and debt. Fisher's treatment still captures the essence of credit and the function it performs in the economy. The given time profile of income (endowments) faced by individuals will often not represent their most desired distribution of the given total consumption over time. The existence of a credit market (the possibility of intertemporal exchange) allows them to transfer a given stream into a preferred stream – either by anticipating future consumption via borrowing ('deficit units') or by transferring consumption into the future via saving and lending ('surplus units'). Transactions of this kind can be mutually advantageous, due to differences in endowments and/or differences in preferences between individuals.

Given real investment opportunities (capital accumulation), the existence of a credit market in general also allows the choice of superior investment decisions, ultimately leading to a higher level of utility. Thus the presence of a credit market, like any other market, permits a more efficient allocation of inputs and outputs, especially with respect to time.

This Fisherian view of the credit market makes clear that it constitutes part of the 'real' economy. That is, it performs a 'real' function by helping to determine the 'real' equilibrium of the economy and the levels of satisfaction reached by its members. It also makes clear that credit can play an important role even in a pure exchange economy with no production and capital formation, given sufficient divergence in individual tastes and/or endowments. On the other hand, production and capital formation can, in principle, take place without credit. Resources can be set aside and invested directly by their owners (the savers). If the owners have no taste or ability for administering these investments, they can, in principle, hire labour (managers) to perform this job (wage, or equity, contracts instead of credit, or debt, contracts). That is, alternative contractual arrangements allowing capital formation and production are available. Of course, credit (debt) contracts, on the one hand, and work (equity) contracts, on the other hand, differ with respect to the way in which risks are shared between the parties involved and with respect to their incentive effects, and a credit market will in general, as already pointed out, be helpful in achieving an efficient allocation of resources and, ultimately, consumption.

Credit and Budget Constraints

A basic question arising with any credit transaction concerns the mechanisms which ensure that the debtor will meet his future payment obligations. As soon as he has obtained his credit, the borrower has, in principle, a strong incentive to 'run off'. This is linked to the question of the appropriate formulation of budget constraints in the presence of credit. What limits credit demand and present consumption (and the incentive to cheat)? Obviously, a credit market can come into existence and survive only if there exist disciplining mechanisms which serve to prevent, or at least severely restrict, dishonest behaviour. Penalties of one sort or another must be in force, be it through legal provisions (bankruptcy laws), social stigmatization or simply the exclusion from, or discrimination in, future credit market participation.

The appropriate formulation of intertemporal budget constraints, in view of a credit market, is comparatively unproblematic (1) as long as the future payment capacity of a potential debtor (his future income stream) is known with perfect certainty, and (2) if, due to social institutions guaranteeing complete enforceability, there is

complete confidence in his willingness to fulfil his future payment obligations, as long as he objectively can. Under these conditions, the relevant magnitude serving to constrain an individual's lifetime consumption obviously is the present value of his lifetime income stream.

Matters are more complicated if the future is not perfectly foreseeable and/or contract enforceability is less than perfect. Unless credit extension is limited to the most pessimistic estimate of the debtor's future income or willingness to repay, there is then a possibility of default. Normally, creditors are willing to accept a certain positive probability of default in exchange for compensation in the form of a higher contractual rate of interest (a risk premium). However, the willingness to extend credit is affected, of course, by the possibility of default and its dependence on the amount of credit extended. Given a finite repayment capacity (finite future income), an increasing level of indebtedness increases the probability of default in two ways. First, for 'external' reasons: the possibility that the future payment obligations exceed the (uncertain) future repayment ability increases with increasing debt. Second, for 'internal' reasons (moral hazard): the incentive to 'run off' after credit has been obtained increases with an increasing repayment obligation; similarly, the incentive to produce future income may be lowered, since in case of partial default the debtor does not benefit from his own efforts. Given a finite repayment capacity, in fact, a point will be reached, sooner or later, where no increase in the contractual interest rate (no risk premium) can compensate the lender for the extra risk of non-payment resulting from a further increase in the level of debt, thus creating an absolute limit to the supply of credit to individuals. This was pointed out by Hodgman (1960), and has led him to speak of credit rationing.

An adequate level of trust in the implicit and explicit promises associated with outstanding debt contracts is an important prerequisite of a smoothly and efficiently operating financial system. Due to the intangible nature of 'trust', the danger of financial crises occurring whenever it is somehow weakened has always been inherent in a credit system. Institutional arrangements, such as a lender of last resort (usually the central bank) or an insurance system of one sort or another (e.g. deposit insurance) are important elements affecting the probability of such occurrences. They are traditionally seen as devices serving to eliminate, or at least contain, the risk of adverse chain reactions. Of course, one danger of institutions of this sort is that they may easily create a moral hazard problem themselves, by lowering the private costs of illiquidity and payment difficulties and thus reducing the private incentives to avoid excessive risks.

Imperfect Information and the Credit Market

In recent years the fact has been stressed that asymmetric information between market participants, and the resultant problems of adverse incentives and adverse selection, can lead to the breakdown of certain markets (incomplete markets) and to unusual types of market equilibria. These include equilibria with non-price rationing; that is, situations where the interest rate on a loan category is set by the lender at a given level and maintained there, even if there exists an excess demand for loans at this rate (Stiglitz and Weiss 1981). Starting from the notion that the lender, due to asymmetric information, must, to a certain degree, lump heterogeneous loan customers together, the basic idea is that an increase in the loan rate (applying equally to all customers) will induce 'good' (high quality) customers to leave and 'bad' (low quality) customers to stay (adverse selection), or that individual customers will be induced by the higher loan rate to choose riskier investment projects (moral hazard). In either case, the average quality of loan customers is reduced. Thus an increase in the loan rate here has, in addition to its usual positive effect on lender return, a negative effect which may possibly dominate the former. If this is the case, it is not in the interest of the lender to raise the loan rate, even in the face of an excess demand for loans. The loan rate has then lost its traditional allocative role of bringing in line supply and demand, and instead serves as a device to limit the damages resulting

from adverse selection and adverse incentives. Funds then must be allocated to customers in some other way.

This problem disappears again if creditors are able to overcome the underlying information asymmetries and identify different quality customers. Then they can offer different types of contracts (combinations of credit volumes and interest rates, possibly also of collateral levels and equity requirements) to different types of customers. One possibility which has been discussed, in analogy to similar problems in insurance and labour markets, concerns the feasibility of self-selection mechanisms. Under certain conditions it may be possible, by exploring the differences in preferences between high and low quality customers, to offer different types of contracts, so that each potential debtor has an incentive to choose of his own will the appropriate offer designed for his quality class. Another possibility concerns the ability of lenders to overcome the information deficiencies underlying the problems of adverse selection and incentives directly through information acquisition technologies of various sorts (direct screening and policing). Since this kind of information is customer-specific, this can encourage the development of long-term customer relationships. The empirical importance of the information-asymmetry models of credit-market behaviour referred to above thus will ultimately have to be judged in view of the empirical weight of these alternative response possibilities.

Credit and Credit Institutions

The role of credit as such must be clearly separated from the economic role of credit institutions, such as banks, playing the role of specialized intermediaries in the credit market by buying and simultaneously selling credit instruments (of a different type and quality). Since the ultimate borrowers and lenders can, in principle, do business with each other directly, without the help of such an intermediary, the function of these middlemen must be viewed as separate from that of credit as such.

Two main functions of institutions of this kind can be distinguished. The first is the function of risk consolidation or transformation. By dealing with a large number of creditors and debtors acting, to a considerable extent, independently of each other, the bank can, by exploiting the law of large numbers, achieve a consolidation of risks. In a world of subjective risk aversion, or if risk implies 'objective' costs of one sort or another (costs of adjusting to certain unfavourable states of the world), such a risk consolidation represents a utility gain for the individuals concerned, and this is a marketable service offered by these institutions to the public. Thus existence of risk and uncertainty (imperfect information) is fundamental for this first function of credit institutions.

The second major function of these institutions is that of a broker in the credit markets. As such, they specialize in producing intertemporal exchange transactions and owe their existence to their ability to bring together creditors and debtors at lower costs than the latter can achieve in direct transactions themselves. Transactions and information costs ('market imperfections') in the credit market, including the cost of evaluating credit risks as an especially important example, are fundamental for the financial intermediary in this second function. To summarize: the existence and function of credit institutions is linked in an essential way to the presence of uncertainty, imperfect information, and transactions costs in the credit market. In the absence of these elements, financial intermediaries would have no raison d'être (while credit as such can still perform an important function). Government, when issuing government bonds, can be viewed as an intermediary in a similar sense.

Another, basically similar, 'institutional' question concerns the marketability, or negotiability, of credit contracts and the existence of 'secondary' markets where they can be traded on a regular basis. This requires certain characteristics. In particular, the market cannot be too small, it must be comparatively homogeneous, and it must be possible to assess the quality of the traded contracts at reasonably low costs. The advantage to the

creditor of such a resale market is, of course, its contribution to the liquidity of these assets.

Credit in Macroeconomic Theory

In macroeconomic theory, the credit market has frequently played the role of the 'hidden' market eliminated from explicit consideration via application of Walras' Law. Although not explicitly appearing, a credit market (in the form of a bond market) is, however, present in most traditional macromodels. This was clearly brought out, in particular, by Patinkin (1956). Credit has traditionally played a prominent role in some specific issues of macroanalysis, nevertheless. In particular, this is the case with respect to the question of wealth effects. To what extent does credit creation represent creation of net wealth (and in turn affect aggregate demand)? This became one of the dominant issues in monetary theory and macroeconomics during the 1950s and 1960s. See, in particular, Patinkin (1956). Aggregate demand for goods (as well as for money and other assets) was seen as depending on aggregate net wealth of the private sector, in addition to income and relative prices, and all assets were examined with regard to the existence of an equivalent and offsetting liability within the private sector. For most financial assets, such an offsetting liability obviously exists. The exceptions, in the traditional view, were money and – with less confidence, because of the question of the capitalization of future tax liabilities required to finance interest payments – government bonds. As Niehans (1978, p. 91) has argued, this emphasis on net wealth was misplaced in the sense that it failed to appreciate that demand effects arising from individual components of wealth can be powerful even if net wealth effects are negligible or nonexistent. That is, it is not just net wealth which affects the demand for goods and assets; rather, the stocks of the various wealth components given at any point in time, and their difference from the corresponding long-run desired levels, determine the economy's attempts to build up or reduce these components over time.

Another macroeconomic area where the credit market has traditionally played an important role is money supply theory or, more generally, aggregate models of the financial sector of the economy (e.g. Brunner and Meltzer 1968; Tobin 1969). Credit markets and credit creation are seen in these models in the light of their relation to money markets and money creation and nominal (price level) control of the system. Financial markets here are typically disaggregated into markets for assets serving as media of exchange (government money and bank demand deposits) and other (non-money) assets, such as bonds and other similar credit instruments. Models of this type have helped considerably to clarify the role of central bank policies in controlling monetary aggregates and, ultimately, the price level. In particular, they have shown that, as long as the degree of substitutability between money and other assets is less than perfect, central bank control over a comparatively narrow monetary aggregate, such as base money, is sufficient for nominal control of the system (price level control), a large menu and volume of private credit notwithstanding.

The concept of a general purpose credit card originated in 1949, when Frank McNamara dined in a New York restaurant and discovered that he could not pay for his meal (Evans and Schmalensee 1999). By the 1980s credit cards had become ubiquitous, and they remain a popular form of payment in most economies. Banks offer cards, setting terms such as interest rates and annual fees. Transactions are handled by networks such as Visa and MasterCard, which emerged in the 1970s as joint member associations. Early research examining the market typically focused on the retail level, while more recent work has tended to focus on the network level, mirroring a shift in policy concerns in the 1980s.

In its early years the US retail credit card market was characterized by extreme interest rate 'stickiness' – credit card rates remained virtually constant over time, regardless of economy-wide changes in interest rates. Credit card issuers also appear to have earned super-normal profits during the same period. This presents a puzzle in an industry displaying many classic characteristics of a perfectly competitive market (Ausubel 1991). Ausubel suggests a variety of explanations for this puzzle, including the possibility that credit card borrowers do not fully anticipate the degree to which they will use the cards.

Ausubel's research spurred a wave of subsequent work proposing explanations for interest rate stickiness. Mester (1994) and Brito and Hartley (1995) provide theoretical explanations for interest rate stickiness based on asymmetric information or consumer transaction costs. Calem and Mester (1995) provide empirical evidence that consumer search and switching costs might explain interest rate stickiness. A complementary explanation for interest rate stickiness is that state-level interest rate ceilings during the 1980s facilitated tacit collusion among card issuers, leading to greater-than-normal interest rate stability (Knittel and Stango 2003).

By the early 1990s interest rates had become much more flexible as credit card issuers switched to variable interest rates. By most accounts, the market also became more competitive during this time. One explanation for the change is technological progress that allowed more efficient credit scoring by large nationally marketed card issuers, creating a truly national market that fostered aggressive competition. Other explanations include the threat of interest rate regulation and the entry of new issuers.

At the network level, the key economic issue is that payment card systems like MasterCard and Visa are two-sided markets: they have to attract cardholders to get merchants and merchants to get cardholders. Diners Club did this in 1950 by initially giving away cards to consumers and charging merchants seven per cent of their bill. These days, consumers obtain rewards for using their cards. This structure of pricing has raised the concern of some policymakers. In their view, retailers pay too much to accept credit cards, costs that end up being covered by consumers who do not use credit cards (by way of higher retail prices). Card associations sustain such a price structure through the setting of an interchange fee, which determines how much the merchant's bank must pay the cardholder's bank for each card transaction. A high interchange fee results in a high merchant fee and a low (or negative) fee for cardholders.

The issue of how much to charge each type of user is a common one in other two-sided markets. Magazines and newspapers decide how much to charge readers versus advertisers, and shopping malls decide how much to charge shoppers versus shops. The interest of policymakers in credit cards has spurred research in two-sided markets more generally.

Baxter (1983) provides an early analysis of interchange fees (see Rochet 2003, for a survey). His key insight is that efficiency calls for card transactions whenever the *joint* benefits to the consumer and merchant of using the card exceed the joint costs of doing so. In the absence of an interchange fee, each type of user will face only the private costs and benefits of cards. A payment from the merchant's bank (acquirer) to the cardholder's bank (issuer) via the interchange fee can align the private incentive to use cards with the social incentive. This provides a justification for setting an interchange fee, but does not imply that card associations will set it at the right level.

One reason a card association might set the interchange fee too high is that acquirers may pass through a larger proportion of interchange fees into merchant fees than issuers pass back to cardholders (in the form of lower fees or higher rewards). Then associations will want to pass revenues to the issuing side, via high interchange fees, where they are competed away less aggressively. A second possible reason is that, if merchants accept cards to attract customers from each other, their private willingness to accept cards includes the surplus their customers get from using cards. As a result, cardholder surplus is over-represented, and card associations tend to charge merchants too much and cardholders too little. Although these theoretical possibilities highlight possible divergences between privately and socially optimal interchange fees, they provide no basis for the cost-based regulation of interchange fees.

Credit Crunch Chronology: April 2007–September 2009

Barry Turner

Abstract

The global financial crisis that began in mid-2007 and exploded in the fall of 2008 shocked most economists. Some had raised concerns about the rapid growth in the housing market in developed countries, especially to "sub-prime," high-risk borrowers. Others had been concerned about large banks being "Too Big to Fail," worrying that such banks might take inordinate risk since they had an implicit government backstop. But the typical economist–even the typical macroeconomic forecaster–was not predicting a massive global recession over the 2007–2008 period. Thus, the crisis was a genuine surprise.

While economists have theories to help explain and understand recessions, bubbles, manias and crashes, only by taking these theories to the data will we learn which models are relevant and which are mere theoretical curiosities. The chronology below should help refresh reader's memories about the world-shaking events surrounding the crisis while also reminding them of some of less-famous but possibly still crucial moments from the 2007 to 2009 period. Many of the events,

institutions, and concepts below are discussed in full-length articles elsewhere in the Dictionary.

JEL Classifications

N12; N14; N22; N24; E44

April 2007

2nd – New Century Financial, based in California and second only to HSBC in the US sub-prime mortgage market, filed for Chapter 11 bankruptcy protection, making over 3,200 employees redundant.

May 2007

3rd – Dillon Read Capital Management, a hedge fund, was forced to shut down following a SFr150m. (US$123 m.) first-quarter loss on US sub-prime mortgage investments.

June 2007

25th – Queen's Walk Investment announced a loss of €67.7 m. (US$91 m.) in the year ending 31 March, reflecting a decline in the value of its UK and US mortgage-linked securities holdings.

28th – Caliber Global Investment, a London-listed fund, announced it would wind down over twelve months following a £4.4 m. (US$8.8 m.) loss from sub-prime investments.

29th – US investment bank Bear Stearns replaced the chairman and chief executive of its asset management business in an effort to restore investor confidence following the collapse of two of its hedge funds invested in the sub-prime mortgage market.

July 2007

3rd – United Capital Asset Management, a Florida-based hedge fund, suspended investor redemptions following heavy losses in sub-prime bonds and derivatives.

11th – Braddock Financial, based in Denver, Colorado closed its US$300 m. Galena fund owing to sub-prime losses.

19th – Ben Bernanke, chairman of the Federal Reserve, warned that the sub-prime crisis in the USA could cost up to US$100bn.

27th – Absolute Capital, an Australian hedge fund, temporarily suspended redemptions for two of its funds.

31st – After losing over 50% of its capital, Boston-based hedge fund, Sowood Capital Management, was bought by larger rival, Citadel.

August 2007

1st – Shares in Australia's Macquarie Bank fell by more than 10% after a warning to investors that its two Fortress funds could lose more than $A300m. (US$256 m.).

1st – Bear Stearns halted redemptions in a third hedge fund, Asset-Backed Securities, following a rush of withdrawals.

1st – German bank IKB was bailed out by rival banks for h8bn. after it was exposed to losses in the US sub-prime sector.

6th – American Home Mortgage Investment (AHM), the tenth biggest home loan lender in the USA, filed for Chapter 11 bankruptcy protection.

9th – France's largest bank, BNP Paribas, suspended three of its funds exposed to the US sub-prime mortgage market.

9th – The European Central Bank (ECB) injected €94.8bn. into the eurozone banking market to stabilize overnight interest rates. The Fed quickly followed the ECB by announcing that it would provide US$12bn. of temporary reserves to the American banking system.

10th – Continuing turmoil in the markets forced action from the world's central banks. In total US$120bn. of extra liquidity was pumped into financial markets.

10th – The FTSE 100 Index fell by 3.7%, its largest drop in four years.

13th – Investment bank Goldman Sachs injected US$3bn. into its Global Equity Opportunities hedge fund.

16th – The USA's largest mortgage lender, Countrywide Financial, received an US$11.5bn. lifeline from 40 of the world's largest banks.

17th – The US Federal Reserve cut its primary discount rate, the rate at which it lends money to banks, by half a point from 6.25% to 5.75%.

22nd – Countrywide Financial received a US$2bn. capital injection from the Bank of America.

23rd – US and European banks, including the Bank of America, Citigroup, JP Morgan Chase and Germany's Deutsche Bank, borrowed US$2bn. from the US Federal Reserve to improve credit access.

23rd – Lehman Brothers closed its sub-prime mortgage unit, BNC Mortgage, releasing 1,200 workers.

31st – President George W. Bush announced plans to help struggling sub-prime mortgage borrowers. Federal Reserve chairman Ben Bernanke pledged to take action to protect the wider economy from market turmoil.

September 2007

6th – The US Federal Reserve added US$31.25bn. to the US money markets and the ECB lent an extra €42.2bn. to banks.

10th – Victoria Mortgages, owned by US private equity group Venturion Capital, was forced into administration, becoming the first UK casualty of the sub-prime crisis.

13th – The Bank of England provided emergency financial support to Northern Rock, the UK's fifth largest mortgage lender.

17th – UK Chancellor Alistair Darling guaranteed Northern Rock's savings accounts, following several days of a run on the bank's deposits.

18th – The US Federal Reserve cut interest rates by half a point from 5.25% to 4.75%.

20th – Goldman Sachs announced record profits after hedging that the value of mortgage bonds would fall, despite losing US$1.5bn. from the sub-prime crisis.

26th – UK banks shunned the Bank of England's auction of £10bn. worth of three-month loans, an emergency funding facility introduced by Governor Mervyn King.

October 2007

1st – Swiss bank UBS revealed a writedown of SFr4bn. (US$3.4bn.) on hedge fund losses and exposure to the sub-prime mortgage market. The group announced plans to shed 1,500 jobs.

5th – Investment bank Merrill Lynch revealed a third-quarter writedown of US$5.5bn.

15th – Citigroup announced a total of US$6.5bn. in writedowns.

24th – Merrill Lynch announced US$8.4bn. of losses and writedowns. A quarterly loss of US$2.24bn. was the largest in its history. Stan O'Neal, chief executive, resigned six days later.

31st – The US Federal Reserve reduced interest rates from 4.75% to 4.5%.

November 2007

1st – Swiss bank Credit Suisse revealed a US$1bn. writedown.

4th – Citigroup announced further writedowns of US$8–11bn. Charles Prince resigned as chairman and chief executive.

7th – US investment bank Morgan Stanley forecast a loss of US$3.7bn. against fourth-quarter revenues.

9th – Wachovia, the USA's fourth largest lender, unveiled losses of US$1.1bn. for Oct. owing to the continued decline in value of its mortgage debt.

13th – The Bank of America revealed it would write off US$3bn. of bad debts linked to the US sub-prime crisis during the last quarter of 2007 and would inject a further US$600 m. into a structured investment vehicle with high exposure to sub-prime mortgages.

14th – HSBC, the world's second largest bank, claimed it was writing off US$38 m. of loans a day to struggling Americans and raising its sub-prime bad debt provision to US$3.4bn.

14th – The Bank of England forecast a sharp slowdown in UK domestic growth in 2008 together with higher inflation.

15th – Barclays, the UK's third largest bank, announced a writedown of US$2.6bn. on securities related to the US sub-prime mortgage market, having lost US$1.64bn. in Oct. alone.

16th – Northern Rock's Adam Applegarth resigned as chief executive.

20th – Shares in Paragon, the UK's third largest buy-to-let mortgage lender, were suspended after falling in value by 50%. It warned shareholders it could face collapse if it could not raise an extra £250m.

20th – Freddie Mac, the USA's second largest provider of mortgage financing, announced its largest quarterly loss so far after unveiling US$4.8bn. of bad debts and writedowns.

27th – Citigroup agreed to sell shares in its company worth US$7.5bn. to the Abu Dhabi Investment Authority, making it the largest shareholder with a stake of 4.9%.

December 2007

4th – The Bank of Canada cut interest rates by a quarter of a percentage point from 4.5% to 4.25%.

6th – The Bank of England lowered interest rates, from 5.75% to 5.5%.

6th – RBS warned investors it expected to write off £1.25bn. as a result of exposure to the US sub-prime mortgage market.

6th – President Bush unveiled plans to freeze rates on sub-prime mortgages for the next five years.

10th – UBS revealed it had written off a further SFr11.2bn. (US$10bn.) against its US sub-prime mortgage exposure.

10th – France's second largest bank, Société Générale, moved to bailout its structured investment vehicle with a credit line of up to US$4.3bn.

11th – The US Federal Reserve cut interest rates for the third time in four months, reducing them from 4.5% to 4.25%.

12th – Five central banks from the UK, Europe and USA launched a US$110bn. joint cash injection targeting international interbank borrowing markets.

14th – Citigroup brought US$49bn. worth of sub-prime debts to keep afloat seven high-risk structured investment vehicles.

17th – The US Federal Reserve made US$20bn. available to major banks to ease interbank lending rates as the first part of a plan agreed by five central banks.

18th – The Bank of England released d10bn. of funds to UK banks and financial institutions.

18th – The ECB injected €348.7bn. (US$502bn.) into banks to help ease credit fears over the Christmas period.

19th – US investment bank Morgan Stanley wrote down US$9.4bn. in sub-prime losses. A cash injection of US$5bn. (equating to 9.9% of the bank) was provided by China Investment Corporation (CIC).

January 2008

9th – The World Bank forecast a 0.3% slowdown in global economic growth to 3.3% in 2008 but claimed growth in China and India would soften the impact.

9th – James Cayne, chief executive of US investment bank Bear Stearns, stepped down.

11th – Countrywide Financial, the USA's largest mortgage lender, was bought by the Bank of America for US$4bn.

15th – Citigroup reported a US$9.8bn. loss for the fourth quarter, the largest in its history. The bank also announced a capital injection of US$6.9bn. from the Government of Singapore Investment Corporation (GIC). In total Citigroup and Merrill Lynch had received over US$21bn. from foreign investors including Saudi Arabia and Kuwait.

21st – Stock markets across the world suffered their biggest losses since 11 Sept. 2001, triggered by fears of a looming recession in the USA.

22nd – The US Federal Reserve slashed interest rates by 0.75% to 3.5%, its largest cut in over 25 years.

28th – European bank Fortis warned that its losses connected to US sub-prime mortgage debt could be as much as €1bn. (US$1.5bn.).

30th – The US Federal Reserve cut interest rates by a further 50 basis points from 3.5% to 3.0%.

31st – MBIA, the world's largest bond insurer, revealed a US$2.3bn. loss in the fourth quarter.

February 2008

6th – Wall Street had its worst share losses in over a year, while the UK's FTSE 100 fell by 2.6%.

7th – The Bank of England reduced interest rates from 5.5% to 5.25%.

10th – Finance ministers from the G7 group of industrialized nations warned of worldwide losses from the US mortgage crisis of up to US$400bn.

13th – The Financial Services Agency, Japan's financial watchdog, said Japanese banks had lost a total of 600bn. yen (US$5.6bn.) from the US sub-prime mortgage crisis in the previous 12 months.

14th – UBS confirmed it had made a loss of SFr4.4bn. (US$4bn.) in 2007, following US$18.4bn. of writedowns.

14th – Commerzbank, Germany's second largest bank, announced writedowns of €774m. (US$1.1bn.), despite record-year profits.

17th – UK Chancellor Alistair Darling confirmed mortgage lender Northern Rock would be brought into temporary public ownership.

March 2008

3rd – HSBC, the UK's largest bank, unveiled total writedowns of US$17.2bn., despite an annual profit increase of 10%.

5th – Credit Agricole, France's largest retail bank, announced a loss of €857m. (US$1.3bn.) in the fourth quarter, following a €3.3bn. charge at its Calyon investment banking arm on losses related to the credit crisis.

6th – Peloton Partners, a London-based hedge fund, was forced to liquidate its £1bn. ABS Master Fund after failing to meet interest payments on loans taken out to buy assets.

7th – Carlyle Capital Corporation, a US$22bn. credit fund owned by US private equity firm Carlyle Group, collapsed.

7th – The former chief executives of Merrill Lynch, Citigroup and Countrywide Financial were questioned before a Congressional committee over their large salary and pay-off packages while their firms experienced heavy losses.

7th – The US Federal Reserve made available up to US$200bn. of emergency financing in response to 'rapid deterioration' in the credit markets.

14th – US investment bank Bear Stearns received emergency funding from JP Morgan Chase with the US Federal Reserve's backing, following a collapse in confidence from its hedge fund clients.

16th – Bear Stearns was bought out by JP Morgan Chase for US$236 m or US$2 per share, a fraction of its previous value, backed by US$30bn. in loans from the US Federal Reserve.

16th – The US Federal Reserve lowered its lending rate to financial institutions by a quarter of a point to 3.25% and created a new lending facility for large investment banks to secure short-term loans.

18th – Wall Street investment banks Goldman Sachs and Lehman Brothers reported a halving of profits in the first quarter of 2008. The results were better than expected, boosting shares in both firms.

31st – Henry Paulson, the US Treasury Secretary, announced a package of reforms designed to help the Federal Reserve tackle financial market turmoil and improve regulation of the financial system.

April 2008

1st – UBS revealed a further US$19bn. of asset writedowns on top of the US$18.4bn. already lost in 2007. Chief executive Marcel Ospel resigned.

7th – UK mortgage lender Abbey withdrew 100% mortgage deals available to UK borrowers.

8th – The IMF warned potential losses from the global credit crunch could reach US$945bn.

10th – The Bank of England cut interest rates by a quarter point to 5%.

14th – Wachovia, the fourth largest US bank, revealed a US$4.4bn. writedown for the first quarter following a jump in foreclosures in California and Florida.

16th – JP Morgan Chase reported a US$5.1bn. writedown for the first quarter against investments in mortgage-backed securities and its portfolio of homeloans.

17th – Merrill Lynch unveiled a loss of US$1.96bn. in the first quarter.

18th – Citigroup posted its second consecutive quarterly loss, of US$5.1bn., and announced it would cut 9,000 jobs after writing off US$15.1bn. in toxic assets.

21st – The Bank of England unveiled a £50bn. plan to aid the UK banks by allowing lenders to exchange potentially risky mortgage debts for government-backed bonds.

22nd – RBS, the UK's second largest bank, revealed pre-tax writedowns of £5.9bn. and requested £12bn. from shareholders to rebuild its capital base.

24th – Credit Suisse reported a quarterly loss of SFr2.5bn. (US$2.1bn.), its first loss in nearly five years, following asset writedowns of US$5.2bn.

30th – Nationwide Building Society recorded the first annual fall in UK house prices for ten years, with prices 1% lower in April than the previous year.

May 2008

2nd – The US Federal Reserve, European Central Bank and Swiss National Bank expanded liquidity by injecting an extra US$82bn. into the banking system.

12th – HSBC announced it had written off US$3.2bn. in the first quarter as a result of the sub-prime crisis.

13th – UK bank Alliance & Leicester disclosed a £391m. writedown in the first quarter.

14th – UK mortgage lender Bradford & Bingley launched an emergency £300m. rights issue.

15th – Barclays revealed a further £1.7bn. in writedowns.

22nd – Swiss bank UBS launched a SFr16bn. (US$15.5bn.) rights issue to cover its US$37bn. writedowns.

June 2008

19th – Chicago-based firm Hedge Fund Research showed 170 funds had been forced into liquidation during the first quarter, while fewer funds were launched than at any time since 2000.

19th – Two former managers of US investment bank Bear Stearns were charged with fraud. It was alleged they had misled investors about the health of their hedge funds.

25th – Major new investors in Barclays, including the Qatar Investment Authority, invested £1.7bn. (US$3.3bn.) for a 7.7% share in the business.

July 2008

8th – A quarterly survey of businesses by the British Chambers of Commerce (BCC) found that the UK faced a serious risk of recession.

10th – Share prices in the USA's two largest mortgage finance companies, Fannie Mae and Freddie Mac, plummeted by nearly 50% as investor anxiety grew over government intervention that would leave their stock worthless.

11th – The FTSE 100 fell deep into a bear market (a 20% fall from its market peak in June 2007) as blue-chip stocks reached their lowest level since 31 Oct. 2005.

13th – US mortgage lender IndyMac Bank, based in California, collapsed, becoming the second largest financial institution to fall in US history.

14th – The US government announced emergency measures to expand credit access to mortgage finance companies Fannie Mae and Freddie Mac, and allow the Treasury to buy shares in the companies.

30th – UK bank Lloyds TSB revealed £585m. of writedowns as pre-tax profits fell by 70% in the first half of the year.

31st – Nationwide recorded an 8.1% fall in the value of houses, the biggest annual fall in UK house prices since their surveys began in 1991.

31st – Halifax Bank of Scotland (HBOS) announced that its first-half profits fell by 72% to £848m. while bad debts rose by 36% to £1.31bn.

August 2008

1st – UK mortgage lender Alliance & Leicester revealed a £209m. hit on risky assets and higher funding costs as pre-tax profits for the first half of the year fell by 99% on the previous year.

1st – US mortgage lender IndyMac Bank filed for Chapter 7 bankruptcy protection.

4th – HSBC announced a 28% decline in half-year profits to £5.1bn.

5th – French bank Société Générale reported a 63% fall in second-quarter profits, after its investment banking division lost €1.2bn. (US$1.9bn.) from sub-prime related investments.

7th – RBS announced it would shed a further 9,000 jobs from its global operations over the next two years.

14th – Goldman Sachs reported a higher than expected pre-tax quarterly profit of US$1.8bn. The bank would also place US$5bn. worth of shares on the stock market in order to repay an emergency US$10bn. loan provided by the US government in 2008.

14th – Poland's government approached the IMF to secure a US$20.5bn. credit line to increase bank reserves and make Poland 'immune to the virus of the crisis and speculative attacks.'

14th – Fortis bank posted a loss of €20.6bn. (US$27.5bn.) for 2008 following writedowns on debt and a separation of the business.

15th – UBS unveiled a first quarter loss of SFr2bn. (US$1.75bn.) and announced it would cut 8,700 jobs by 2010 in an effort to reduce costs.

16th – China's growth rate slowed to 6.1% in the first quarter of 2009, its slowest pace since quarterly GDP data was first published in 1992. Growth was down from 6.8% in the previous quarter and 9% for the whole of 2008.

16th – Consumer prices in the USA fell by 0.4% over the year to March owing to weak energy and food prices, the first year-on-year drop since Aug. 1955.

16th – JP Morgan Chase reported a higher than expected first quarter profit of US$2.1bn. compared with net income of US$2.4bn. in the first quarter of 2008.

18th – The IMF formally agreed a US$47bn. credit line for Mexico under its new fast track scheme to help developing nations cope with the global financial crisis.

21st – UK annual inflation as measured by the Retail Prices Index (RPI) was −0.4% in March (down from zero in Feb.), the first negative figure since 1960.

21st – Sweden's central bank reduced its key interest rate by a half point to a record low of 0.5%.

22nd – UK chancellor Alistair Darling admitted the economy faced its worst year since the Second World War as he unveiled his latest Budget report. The annual budget deficit would rise sharply to £175bn. over the next two years with total government debt to reach 79% of GDP by 2013.

22nd – The IMF said global output would contract by 1.3% in 2009, a 'substantial downward revision' of its Jan. forecasts when it predicted growth of 0.5%. The UK economy was now projected to shrink by 4.1% in 2009, while Germany was set to decline by 5.6% and Japan by 6.2%.

22nd – India's central bank slashed interest rates for the sixth time in six months, reducing its key repo lending rate by a quarter point to 4.75%.

27th – National Australia Bank, Australia's largest lender, announced a 9.4% fall in cash earnings to A$2bn. (US$1.4bn.) for the Sept.–March period.

28th – Fears over a swine flu outbreak continued to have an impact on global shares – the FTSE100 closed down by 1.7%, markets in Paris and Frankfurt ended nearly 2% down, Japan's Nikkei index fell by 1.7% and Hong Kong's Hang Seng shed 1.4%.

28th – Lithuania's economy contracted by 12.6% in the first quarter of 2009 compared to the same period in 2008, the largest year-on-year fall in the EU since the start of the recession.

29th – US output contracted at an annualized rate of 6.1% in the first quarter of the year, a higher-than-expected result. The contraction was led

by a 30% decline in exports, its largest fall in 40 years.

May 2009

1st – US carmaker Chrysler filed for Chapter 11 bankruptcy protection after a group of hedge and investment funds refused to restructure the company's US$6.9bn. debt.

1st – The Reserve Bank of New Zealand reduced interest rates by 50 basis points to a record low of 2.5%. The bank governor, Alan Bollard, said he expected rates to remain at the current (or lower) level until the latter part of 2010.

4th – The European Commission forecast that the EU economy would contract by 4% in 2009, more than twice the level predicted at the beginning of the year. It claimed unemployment would now reach 10.9% in 2010.

5th – Japan offered US$100bn. of financial assistance to Asian economies affected by the global economic slowdown in a meeting of the finance ministers of the ten-member Association of South East Asian Nations.

5th – UBS confirmed it had made a SFr2bn. (US$1.75bn.) loss in the first quarter of 2009.

6th –Volkswagen and Porsche agreed to merge, relieving the sports carmaker of its debt burden.

7th – Barclays announced a pre-tax profit of £1.37bn. (US$2.07bn.) for the first three months of the year, up 15% from the previous year.

7th – Commerzbank agreed to relinquish the core of its commercial property lending business together with Eurohypo's role in public sector finance, in a deal with European competition authorities to compensate for €18.2bn. (US$24.2bn.) of state aid it received.

7th – The European Central Bank cut its main interest rate by a quarter point to a record low of 1% and also announced plans to purchase €60bn. (US$80.4bn.) of covered bonds, which are backed by mortgage or public sector loans.

7th – The Bank of England announced it would pump a further £50bn. (US$75bn.) into the UK economy in a substantial expansion of its program of government bond purchases.

8th – RBS reported a pre-tax loss of £44m. for the first quarter of 2009, compared with a profit of £479m. for the same period the previous year.

8th – Several US banks unveiled plans to raise cash a day after the US Treasury said that ten of America's 19 largest banks failed their stress tests and needed to raise a combined total of $74.6bn. Wells Fargo and Morgan Stanley planned to raise US$7.5bn. and US$3.5bn. respectively through share sales, while Bank of America planned to sell assets and raise capital to secure US$33.9bn. it needed.

13th – Franco-Belgian bank Dexia, which had been bailed out by three economies the previous year, posted a first quarter profit of €251m. (US$341 m.) compared to a loss of €3.3bn. (US$4.5bn.) in 2008.

13th – The German cabinet agreed a 'bad bank' scheme, in which banks would be able to swap their toxic debt for government-backed bonds in return for paying an annual fee.

14th – Spain suffered a fall in GDP of 1.8% in the first quarter of 2009, its largest contraction in 50 years, according to the National Statistics Institute.

14th – Crédit Agricole unveiled a net profit of €202m. (US$275 m.) in the first quarter, a 77% fall from the same period the previous year, after more than doubling its loan-loss provisions to €1.1bn.

15th – According to Eurostat economies that make up the eurozone contracted by 2.5% in the first quarter of 2009, a higher-than-forecast decline.

15th – The EBRD revealed plans to invest a record €7bn. (US$9.4bn.) in 2009 to tackle the slowdown through investments in infrastructure, energy, corporate and finance projects.

17th – Carmaker General Motors announced plans to close up to 1,100 dealerships in the USA as it battled to reduce costs and stave off bankruptcy.

19th – Inflation in the UK as measured by the Consumer Prices Index (CPI) slowed to 2.3% in April from 2.9% the previous month.

20th – Japan's GDP slid by 4% in the first quarter, its largest decline since records began in 1955.

20th – Venezuela experienced its slowest rate of growth in five years, with GDP growing by 0.3% in the first quarter of 2009 as the fall in oil prices took effect.

21st – The Office for National Statistics said public sector net borrowing in the UK rose to £8.46bn. in April compared to £1.84bn. in the same month the previous year. Concerned about its significant debt burden, Standard & Poor's downgraded the UK's credit rating from 'stable' to 'negative' for the first time since it began analyzing its public finances in 1978.

22nd – Private equity firms paid US$900 m. to rescue BankUnited, a Florida-based bank worth around US$13bn. It had been closed by federal regulators in what was the biggest US bank failure of 2009 so far.

22nd – The US Treasury provided automotive financing group GMAC with a further US$7.5bn. in state aid to help it stay in business and offer loans to potential Chrysler and GM car buyers.

22nd – UK output declined by an unrevised 1.9% in the first quarter of 2009, according to figures published by the Office for National Statistics.

26th – South Africa fell into recession for the first time since 1992 following an annualized contraction of 1.8% and 6.4% in the previous two quarters.

27th – Riksbank announced it was raising foreign currency to boost its US$22bn. currency reserves, causing a sharp fall in the Swedish krona as the central bank warned the worst of the financial crisis may not be over.

29th – India's economy grew by 5.8% in the first quarter of 2009, higher than forecast but down from 8.6% in the same quarter the previous year.

June 2009

1st – US car manufacturer General Motors filed for Chapter 11 bankruptcy protection, the biggest failure of an industrial company in US history.

2nd – Switzerland officially entered recession after the economy contracted by 0.8% in the first three months of 2009, following a decline of 0.3% in the final quarter of 2008.

3rd – Australia recorded a 0.4% rise in GDP for the first quarter compared to the same period last year, bucking international trends.

3rd – Lloyds Banking Group announced plans to cut 530 jobs and close one site in the UK by the end of 2009.

4th – Industrial and Commercial Bank of China (ICBC), the world's second largest bank by market value, unveiled plans to buy 70% of Bank of East Asia's Canadian unit as part of a move to expand overseas.

4th – The Bank of England kept interest rates unchanged at 0.5% for the third month in a row.

8th –The OECD claimed the pace of decline among its 30 member countries was slowing – the composite leading indicators index (CLI) rose 0.5 point in April.

9th – Lloyds Banking Group announced it was to shut all 164 Cheltenham & Gloucester branches, putting 1,660 jobs at risk.

9th – UK unemployment rose by 244,000 to 2.22 m. in the first three months of the year according to the Office for National Statistics (ONS), the largest quarterly rise in the jobless rate since 1981.

9th – Official figures showed that exports in Germany were 4.8% lower in April than in March and 28.7% down on the previous year, the biggest annual fall since records began in 1950.

10th – The European Central Bank provided an emergency €3bn. to the central bank in Sweden, whose banks dominate the Baltic region's financial sector.

10th – BP's annual statistical review indicated that global oil consumption fell by 0.6% in 2008, the first fall since 1993 and the largest drop since 1982.

10th – Ten of the largest US banks gained permission from the US Treasury to repay US$68bn. in government bail-out money received through the Troubled Asset Relief Programme (TARP).

11th – Figures revealed that Chinese exports fell by a record 26.4% in May from the same month the previous year.

11th – Revised GDP growth figures showed Japan contracted by 3.8% in the first quarter of 2009, less than the original estimate of 4%.

15th – The Confederation of British Industry (CBI) predicted the UK economy would contract by 3.9% in 2009 before seeing a return to growth of 0.7% in 2010.

15th – The IMF revised its growth forecast for 2010 for the USA, claiming that the economy would now grow by 0.75% compared to its forecast of 0% earlier in the year.

16th – The Bank of Japan said that the economy was no longer deteriorating, a more positive assessment than the previous month when it had stated that the economy was continuing to worsen. Nonetheless, it maintained interest rates at 0.1%.

16th – China introduced an explicit 'Buy Chinese' policy as part of its economic stimulus program, leading to fears of an increase in protectionism across the world.

17th – The US government announced a major reform of banking regulation to curb excessive risk-taking among big banks and to prevent future financial crises. President Obama described the reforms as 'the biggest shake-up of the US system of financial regulation since the 1930s.'

17th – The OECD revised its growth forecast for Italy, predicted the economy would grow by 0.4% in 2010 compared to a previously estimated contraction of 0.4%. However, it downgraded its forecast for 2009 from a 4.3% decline to 5.3%.

17th – The World Bank raised its GDP growth forecast for China to 7.2% in 2009 from a previously estimated 6.5%, citing the impact of a fiscal stimulus package.

18th – Official figures showed inflation in India had turned negative for the first time since 1977. Wholesale prices fell 1.61% in the year to 6 June.

22nd – The Japanese government looked set to provide up to 100bn. yen (US$1bn.) in state aid to Japan Airlines, the country's biggest airline, on condition that the organization's management improves.

24th – The OECD said the world economy was near the bottom of the worst recession in post-war history and predicted that the 30 most industrialized countries would shrink by 4.1% in 2009. UK output was predicted to contract by 4.3% in 2009 and experience zero-growth in 2010.

24th – The European Central Bank pumped €442.2bn. (US$628bn.) in one-year loans into the eurozone's weakened banking system in an effort to unlock credit markets and revive the region's economies.

24th – Orders for new durable goods in the USA rose unexpectedly by 1.8% in May from the previous month, going against expectations of a drop of 0.9%.

25th – The IMF said that Ireland's economy would contract by 8.5% in 2009 and warned it would experience the worst recession in the developed world and struggle to bail out its banks.

26th – New Zealand suffered a fifth straight quarterly contraction after official figures showed the economy shrank by 2.7% in the first quarter of 2009.

26th – Consumer prices in Japan fell by 1.1% in May compared to the same month the previous year, its biggest fall since records began in 1970, fuelling fears of a new bout of deflation.

26th – Spain unveiled a €9bn. (US$12.7bn.) fund aimed at saving banks suffering during the downturn.

30th – Eurozone inflation turned negative for the first time since records began in 1991, with consumer prices 0.1% lower in June than twelve months earlier.

30th – Malaysia launched economic liberalization measures aimed at attracting foreign investments, including changes to its long-standing policy of giving preferential treatment to the country's ethnic Malay majority.

July 2009

1st – Japan's Shinsei Bank and Aozora Bank merged to create the country's sixth largest bank with assets of 18trn. yen (US$186bn.).

1st – Unemployment in Ireland reached 11.9% in June, its highest level since 1996.

1st – India's exports were down 29.2% in May from the same month the previous year, the economy's eighth consecutive fall in exports.

7th – Inflation in the Philippines fell to 1.5% in June, its lowest level in 22 years.

10th – US carmaker General Motors (GM), 61% owned by the US government, emerged from its bankruptcy protection after creating a 'new GM' made up of four key brands, including Cadillac.

13th – The US deficit moved above US$1trn. for the first time in history.

14th – Inflation in the UK fell below the Bank of England's target rate of 2% for the first time since 2007. Lower food prices caused the Consumer Prices Index to drop to an annual rate of 1.8% in June, down from 2.2% in May.

14th – Singapore grew at an annualized rate of 20.4% in the second quarter, its first quarterly expansion in a year following a revised contraction of 12.7% from January to March.

14th – Goldman Sachs reported a net profit of US$3.44bn. for the second quarter of the year, higher than analysts had forecast.

15th – UK unemployment increased by a record 281,000 to 2.38 m. in the three months to May, its highest level in over ten years.

15th – Japan's central bank downgraded its economic forecast to a contraction of 3.4% from 3.1% for the 12 months to end-March 2010, but reiterated that the worst of the recession was over.

15th – Russia's economy contracted by 10.1% in the first half of 2009, its sharpest decline since the early 1990s.

16th – China's economy grew at an annualized rate of 7.9% in the second quarter, up from 6.1% between January and March, as the government upgraded the growth forecast to 8% for 2009 as a whole.

16th – JP Morgan Chase unveiled a second quarter profit of US$2.72bn., an increase of 36% on the same period the previous year.

17th – Ghana secured a US$600 m. three-year loan from the IMF and was given access to a further US$450 m. from the IMF through the special facility set up by the G20 summit to assist poor countries.

20th – Iceland announced a 270bn. kr. (US$2.1bn.) recapitalization plan for its banking system, issuing bonds to three new banks set up in 2008 following the collapse of the country's three main banks.

21st – UK government debt increased to £799bn., or 56.6% of UK GDP, its highest level since records began in 1974.

22nd – The National Institute of Economic and Social Research (NIESR) predicted UK GDP to fall by 4.3% in 2009 and UK GDP per capita to remain below its pre-recession levels until March 2014.

22nd – Morgan Stanley reported a loss of US$159bn. in the second quarter of 2009, compared to a US$698 m. profit for the same period the previous year.

23rd – Credit Suisse unveiled a 29% increase in second quarter net profits of 1.57bn. Swiss francs (US$1.48bn.).

23rd – The Asian Development Bank said growth in East Asia, excluding Japan, would double to 6% in 2010, compared to a 3% expansion in 2009.

23rd – The rate of decline of Japan's exports slowed in June, a sign that government stimulus spending around the world may be supporting demand. However, exports were still 35.7% lower than the same month the previous year.

24th – The IMF approved a 20-month Stand-By Arrangement for Sri Lanka worth US$2.6bn. to support the country's economic reform package.

24th – The UK economy contracted by 0.8% in the second quarter of 2009, much lower than the 2.4% decline in the previous quarter but above analysts' 0.3% prediction.

24th – The South Korean economy grew by 2.3% from April to June, its fastest expansion in five-and-a-half years.

28th – Deutsche Bank unveiled a net profit of €1.09bn. (US$1.56bn.) for the second quarter of 2009, a 67% increase in profits compared to the same period the previous year.

28th – BBVA, Spain's second largest bank, reported a net profit of €1.56bn. (US$2.23bn.) for the second quarter thanks to higher income from loans.

31st – Mizuho Financial Group revealed a net loss of 4.4bn. yen (US$46 m.) for the second quarter, its fourth consecutive quarterly loss.

31st – Japan's jobless rate increased by 830,000 in June to 3.48 m., its highest level in six years.

31st – Eurozone unemployment reached 9.4% (or 14.9 m. people) in June, its highest level in ten years.

August 2009

3rd – Barclays announced a pre-tax profit of £2.98bn. (US$5bn.) for the first six months of the year with an 8% increase in revenue.

3rd – HSBC saw pre-tax profits halve to £2.98bn. (US$5bn.) for the first half of 2009 compared to the same period the previous year, following the write-off of US$13.9bn. of bad debt in the USA, Europe and Asia.

3rd – World stock markets were boosted by brighter economic data – Standard & Poor's 500 index tipped beyond 1,000 for the first time since Nov. 2008, London's FTSE closed at its highest rate since Oct. 2008, the three major US indexes added over 1.25% by the end of trade after positive manufacturing survey results from July and European indexes also rose.

4th – UBS reported a loss of SFr1.4bn. (US$1.32bn.) in the second quarter, an improvement on the SFr2bn. loss made in the previous quarter.

4th – UniCredito, Italy's largest bank, unveiled better-than-expected second quarter earnings of €490m. (US$706 m.), 9.2% higher than the previous quarter.

5th – Société Générale announced a second quarter profit of €309m. (US$445 m.), 52% lower than the same period 12 months earlier.

6th – The Bank of England injected a further £50bn. into the UK economy as part of its quantitative easing program, bringing its total spending to £175bn.

6th – Commerzbank made a €763m. (US$1.1bn.) net loss in the second quarter, a small improvement on the h861m. loss registered in the previous quarter.

7th – RBS reported a pre-tax profit of £15m. for the first six months of the year.

7th – Italy's economy shrank by 0.5% in the second quarter, its fifth consecutive quarterly contraction but an improvement on the record 2.7% fall in Jan.–March.

7th – The IMF and Angola began talks on a loan to help the African country cope with the global economic slowdown.

12th – Dutch financial services group ING announced a €71m. (US$100 m.) profit in the three months to the end of June, its first profit in three quarters.

12th – Commonwealth Bank of Australia, the country's second largest bank by market capitalization, posted net earnings of A$4.72bn. (US$3.89bn.), 1% lower than the previous year owing to higher bad debt charges and reduced wealth management unit income.

12th – The UK unemployment rate increased to 7.8% in the second quarter, its highest level since 1995.

13th – France and Germany both recorded second quarter growth figures of 0.3%, bringing a year-long recession to an end. However, the Eurozone contracted by 0.1%, its fifth consecutive quarterly fall in output.

14th – Colonial BancGroup, a property lender based in Montgomery, Alabama, became the largest bank in the USA to collapse in 2009.

14th – The Nigerian Central Bank injected N400bn. (US$2.6bn.) into five banks and sacked their managers, after the regulator claimed the banks were undercapitalized and posed a risk to the entire banking system.

14th – Hong Kong posted growth of 3.3% between April and June following four consecutive quarters of contraction. Singapore also announced its emergence from recession, with annualized growth of 20.7% in the second quarter of 2009.

14th – South Africa's central bank slashed its lending rate by a half-point to a four-year low of 7%, its sixth cut since Dec. 2008.

17th – Japan's economy grew by 0.9% in the second quarter of 2009, ending a run of four consecutive quarters of negative growth.

18th – The South African economy contracted for the third quarter in a row as output fell at an annualized rate of 3% between April and June.

18th – The CPI measure of inflation in the UK remained at the same level of 1.8% in July,

although economists had forecast a decline to 1.5%.

20th – The UK's public sector net borrowing totalled £8bn. in July, the first July deficit for 13 years, as the government's overall debt reached its highest level since 1974 at 56.8% of GDP.

20th – Mexico's economy contracted by 10.3% in the second quarter owing to a decline in demand for exports and falling levels of tourism resulting from the outbreak of swine flu in April and May.

24th – Thailand posted growth of 2.3% in the second quarter of 2009 as it emerged out of recession.

26th – The Malaysian economy expanded by 4.8% in the second quarter of 2009 following two straight quarters of contraction.

27th – US GDP shrank at an annualized rate of 1% in the second quarter, lower than the 1.5% decline predicted by many economists.

27th – Credit Agricole, France's largest retail bank, announced a higher-than-expected second quarter profit of €201m. (US$286 m.).

28th – The Office for National Statistics (ONS) revised the rate of contraction in the UK economy for the second quarter to 0.7% from the original estimate of 0.8%.

28th – Unemployment in Japan hit a record high of 5.7% in July and consumer prices fell by 2.2% compared to a year earlier, its fastest recorded pace.

31st – The Eurozone's annual rate of inflation fell by 0.2%, its third consecutive monthly decline.

September 2009

1st – India's exports fell at an annualized rate of 28% in July, its tenth consecutive monthly contraction.

2nd – The *de facto* government of Honduras received US$150 m. from the IMF to boost its dollar reserves.

2nd – The OECD predicted that the recession in Iceland, marked by a large contraction in domestic demand, would be deeper than in most developed economies.

3rd – The OECD forecast the UK to be the only G7 economy to stay in recession at the end of 2009, while the eurozone and the USA would record two quarters of growth.

4th – The G20 group of nations agreed to continue fiscal stimulus until the recovery from recession was assured.

5th – The IMF sanctioned US$510 m. to Zimbabwe, its first loan to the country in a decade, to replenish the economy's dwindling foreign currency reserves.

8th – The EBRD announced it would invest a record €8bn. (US$11.6bn.) in central and eastern Europe in the course of 2009.

8th – Estonia's GDP shrank at an annualized rate of 16.1% in the second quarter of 2009, its sixth consecutive quarterly contraction. Latvia contracted by 18.7% and Lithuania by 19.5% in the same period.

8th – The gold price climbed above $1,000 per ounce for the first time since Feb. on the back of a weakening dollar and lingering concerns over the sustainability of the world economy's recovery.

9th – The FTSE 100 broke through the 5,000-point barrier for the first time since Oct. 2008.

11th – Brazil emerged from recession after it grew by 1.9% between April and June following two successive quarters of contraction.

14th – The European Commission predicted that the eurozone would grow by 0.2% in the third quarter and 0.1% in the fourth quarter, but GDP for the year would fall overall by 4%.

15th – Consumer Price Index inflation in the UK measured 1.6% in Aug., its lowest level since Jan. 2005.

15th – US Federal Reserve chairman Ben Bernanke claimed recession in the US was 'very likely over' but the economy would remain weak for some time owing to unemployment.

16th – Unemployment in the UK rose by 210,000 in the three months to July to take the total to 2.47 m., its highest level since 1995.

17th – The UK Office for National Statistics reported flat sales volumes in August compared with July, confounding analyst expectations of a 0.2% rise.

18th – The UK's public sector net borrowing totalled a record £16.1bn. in Aug., with government's overall debt standing at £804.8bn., or 57.5% of GDP.

20th – A further two US banks were closed by the country's federal regulator, taking the total number of US banks failing in 2009 to 94. Irwin Union Bank & Trust and Irwin Union Bank were shut down after their parent firm, Irwin Financial, failed to meet a Federal Deposit Insurance Corporation demand to boost their capital.

21st – The pound fell to its lowest level against the euro for five months as concerns continued about the underlying health of the British economy.

22nd – The Asian Development Bank made an upward revision of its growth forecast for India and China in 2009, with India expected to grow by 6.0% (up from an earlier forecast of 5.0%) and China by 8.2% (up from 7.0%).

23rd – The US dollar fell to a one-year low against the euro with traders switching to other currencies as signs of economic recovery emerged.

23rd – The World Bank announced it was to provide India with US$4.3bn. to fund infrastructure projects and support companies needing credit.

24th – Loss-making carrier Japan Airlines asked for a government bailout following recently announced plans to cut 6,800 jobs.

26th – Speaking at the end of the two-day G20 summit, US President Barack Obama said the world's leading nations had agreed to 'tough new measures' to prevent another global financial crisis, including regulation relating to the amount of money banks hold in reserve and a cap on pay for bankers.

29th – The Office for National Statistics revised growth figures for the UK in the second quarter from −0.7% to −0.6%.

29th – Core consumer prices in Japan fell 2.4% in Aug. year-on-year, the fourth successive month of contraction.

30th – The IMF slashed its forecast for the amount of bad debt likely to be written off globally between 2007 and 2010 from US$4.0trn. to US$3.4trn.

In Oct. 2009 US manufacturers reported that global output was growing at its fastest rate for five years. On 29 Oct. the Department of Commerce announced that the US economy was out of recession, growing by an annualized 3.5% in the third quarter. However, rising unemployment was an ongoing concern, standing at 10.2% in Oct. 2009 (its highest rate since 1983). US president Barack Obama responded to the news of the emergence from recession with caution, commenting: 'We anticipate that we are going to continue to see some job losses in the weeks and months to come.'

By the end of the third quarter of 2009, of the G7 economies only the UK remained in recession, having contracted by 0.4% in the period July–Sept.

Credit Cycle

P. Bridel

Abstract

It was with the post-First World War attempts to integrate marginalist value and monetary theory that theorists started pondering the possible (in Hayek's words) 'incorporation of cyclical phenomena into the system of economic equilibrium theory'. Hayck's own 'intertemporal equilibrium' approach overturned the traditional view of cycles as temporary deviations from long-period equilibrium

conditions. But the publication of Keynes's *General Theory* redirected research efforts towards the determination of output at a point in time. Since the late 1960s, with the search for 'microfoundations for macroeconomics', this line of thought has been back on the theoretical agenda.

Prior to Keynes's *General Theory*, the resolution of the question why, in capitalist economies, aggregate variables undergo repeated fluctuations about the trend was regarded by economists as a main challenge for the profession. What was then called business (or trade) cycle theory grew quite independently from the classical and subsequently neoclassical corpus of price theory. In fact, for all economists, a clear-cut distinction existed between the long-run forces at work in an economy – the subject of a rigorous value and distribution theory – and the more or less ad hoc explanations of the short-run oscillations around such an (equilibrium) centre of gravity. Of course, from Ricardo and Thornton down the 19th century to Overstone and Mill, money and credit played a substantial, but independent, part in these exogenous explanations of the business cycle. Along the same line, the founding fathers of marginalism (in particular Walras, Marshall and Jevons) failed to coordinate, even in a remotely satisfactory way, money and trade cycle with their then novel price theory.

Following Wickscll's and Miscs's lead, it is only with the post-First World War attempts to integrate marginalist value and monetary theory that theorists started pondering the possible 'incorporation of cyclical phenomena into the system of economic equilibrium theory' (von Hayek 1929, p. 33n.). The rediscovery of Tooke's (1844) income approach to the quantity theory of money is probably one of the earliest stepping-stones in the development of credit-cycle theories. This line of thought suggests that the explanation of money prices should start not from the quantity of money but from nominal income. Though another way of writing a Marshallian cash balance equation, Wicksell's (1898, p. 44) or Hawtrey's (1913, p. 6) emphasis on the 'aggregate of money income', on how it varies, is expanded or held, is a crucial turning-point on the road towards an analysis in terms of income, saving and investment. This shift of emphasis, together with the simultaneous progress in monetary theory proper (notably the development of a comprehensive and integrated monetary theory of interest), the 1914–1918 inflationary episode and the post-war cyclical upheavals provided in the 1920s and 1930s the right intellectual stimulus for credit-cycle theories to grow and multiply.

Explicitly or implicitly, to tackle this issue, Continental economists (for example, Mises, Cassel, Hayck, Schumpeter and Aftalion), members of the Cambridge School then dominating in England (Keynes, Robertson, Pigou, Hawtrey), Fisher and Mitchell in the United States all used the common analytical framework established jointly by Walras, Menger, Marshall and Jevons. This is made up of two basic (though familiar) propositions: on the one hand, there is an inverse relation between the volume of investment and the rate of interest (that is, a downward-sloping investment demand curve) and, on the other, despite short-run 'frictions', the interest rate is assumed to be sensitive enough to divergences between investment decisions and full employment saving.

The central theme of this argument (first expressed with great clarity in Wicksell's cumulative process) is that the market rate of interest oscillates in the short run around a natural rate of

interest determined in the long run by the supply of and the demand for capital as a stock, which, in turn, guarantees the equality between planned investment and full employment saving. Once this logic is understood, it then emerges that the entire development of interwar trade-cycle theories took place within the second proposition outlined above; namely, that, in the long run, the interest rate is assumed to be sensitive enough to divergences between investment decisions and full employment saving. Hence, since the twin concepts of an interest-elastic demand curve for investment and natural rate of interest were never called into question, the orgy of debates that took place in the 1920s and 1930s was conducted in terms of an analysis of various short-run forces which temporarily keep at bay the long-run forces of saving and investment.

These forces are, of course, of multiple nature. Of particular interest to interwar economists, and one of the essential features of business cycle, with its recurrence of upswings and downswings, is a *credit cycle,* an alternation of credit expansion and credit contraction. But it was assumed neither that an alternation of prosperity and depression would not exist in a barter economy (or in a purely specie system) nor that cycles could be viewed as functions of monetary factors only.

In fact, and thanks to their common capital theory, none of the leading interwar credit cycle theorists fell into either of these traps. Even Hawtrey who, with remarkable consistency kept claiming that business cycles are a purely monetary phenomenon, had clearly in mind a Wicksell-like cumulative process derived from Marshall's oral tradition in monetary theory. This common theoretical background and a deep interest in a then fast-developing monetary theory make similarities between credit cycle theorists.

> sufficiently pronounced to entitle us to speak of a single monetary theory [of the cycle], the votaries of which disagree on one issue only: whether bank-loan rates act primarily on 'durable capital' [Keynes, Robertson, Hayek] or via the stocks of wholesalers [Hawtrey]. (Schumpeter 1954, p. 1121)

In 1913, Hawtrey was amongst the first to provide a detailed analysis of the financial working of the cumulative process in an Anglo-Saxon environment. However, even if his theory usefully describes the ways in which money and credit behave in the cycle, the main weakness of his contribution is, of course, its almost exclusive emphasis on dealers' stocks in the course of a credit cycle. If Hawtrey does not deny altogether that a credit expansion/contraction has an influence on the volume of investment, he holds it however to be unimportant when compared with the direct influence on the wholesalers' stocks. He then logically disputes the existence of forced saving on the very ground of this availability of stocks and fails completely to link his credit cycle theory with the dominant Marshallian capital theory. Such a model led Hawtrcy not only to give Bank Rate the crucial part to play in any counter-cyclical policy but also to consider its fluctuations as the only explanation of cyclical fluctuations. To sketch British interwar depressions as almost exclusively functions of Bank Rate (itself a function of Britain's absorption of gold) is a rather bold simplification Hawtrcy was never quite ready to abandon.

If the theoretical apparatus underlying the *Treatise on Money* proceeds from the same logic, Keynes's fundamental equations introduce, however, a number of very sophisticated and new variations on the basic credit-cycle theme. In particular, causes of credit cycles are of non-monetary nature (they result from fluctuations in the rate of investment relative to the rate of saving), the influence of Bank Rate on investment is not limited 'to one particular kind of investments, namely, investments by dealers in liquid goods [stocks]' (Keynes 1930, vol. 1, p. 173), the cumulative process includes a theory of the demand for money beyond the traditional income motive (that is, an early version of liquidity preference), and, in the short run, there is no longer a direct relation between the quantity of money/credit and the price level: monetary or credit changes do not foster ipso facto a forced/abortive saving process. Despite the higher degree of sophistication shown in the *Treatise,* in a classic chapter on the modus Operandi of the Bank Rate, Keynes displays bold confidence in this mechanism to smooth any credit cycle, to fill the gap between saving and investment and to correct all temporary monetary

divergences from the long-run full employment equilibrium. However, Keynes's disaffection with the forced saving doctrine and the purely static nature of his fundamental equations drew sharp criticisms from Robertson and Hayek. Though from different standpoints, they both considered Keynes's credit cycle analysis as no more than an attempt to spell out the appropriate banking policy which could maintain a monetary equilibrium. In particular, Keynes's version of the credit cycle lacked, for the former, a proper sequential stability analysis and, for the latter, an explicit integration with capital theory.

Along lines very similar to Keynes's and, up to the late 1920s, in close cooperation with him, Robertson worked out a detailed sequential analysis of the interdependence of real and monetary magnitudes during the cycle. But clearly, for him, the cycle results from over-investment, this tendency to over-invest being a typical feature of decentralized economies stemming from the repercussions on the volume of investment of its gestation period. However, the largest part of Robertson's professional output was devoted to studying the monetary or credit symptoms of such economic fluctuations, that is, how banks may respond to an increased demand for credit during expansion.

This led Robertson to a redefinition of the concept of saving in a monetary economy and to the role of this new concept in the cycle. This approach was linked with a sequential analysis of the lagged adjustments of output to monetary flows. In the 'forced saving' debate, central to all credit cycle theories, and contrary to Hayek who considered it as the villain of the piece, Robertson saw that phenomenon as only a relatively minor component of his theory, the factors at the root to his 'credit inflation' being the *real* cause of this expansion. Dragged among others by Keynes into endless discussions in the realm of monetary and interest theory, Robertson never managed however to offer an articulate and full-blown version of his theory of industrial fluctuations. In particular, the problem of the alteration in the structure of production, a question forming the core of Hayek's cycle theory, never received more than passing comment.

Grounded of course in the Austrian tradition and Wicksell's cumulative process (first extended by Mises 1912, and Cassel 1918), the distortion of the production time structure is absolutely central to Hayek's monetary cycle theory. The divergence between 'natural' and market rates of interest is linked by Hayek to the variability in forced saving and considered as the cause of cyclical fluctuations. Hayek's 'additional credit' theory places the cause of this gap between these two rates upon newly created money. The increase in loan capital resulting from a 'trailing market rate' makes investment surpass voluntary saving: a cumulative expansion results. Such an increase in investment alters the relative prices of capital and consumer goods in favour of the former. The increased output of capital goods distorts the production time structure. At a later stage, higher factor incomes drive up the demand for consumption goods, which through increased withdrawals from bank accounts will raise the market rate of interest and, finally, make some investment unprofitable. Then, the turnabout that takes place in the cycle brings a change in the other direction in the production structure, this time in favour of consumer goods. Clearly, crises are caused by over-investment, that is, by a decline in the desire to purchase the flow of capital goods coming on the market. The reversal of the process initiated by credit inflation does take place (as in most credit cycle theories) whenever the market rate catches up with prices; and since, sooner or later, banks run up against the limits set to their lending by their reserves, this process cannot be explosive (Fisher 1911, also noticed, at least in his earliest writings, this stabilizing influence of the banking system).

Hayek's credit cycle theory thus marks a real break with what had come before. The theory of money is no longer a theory of the value of money 'in general' because relative prices may be changed by monetary influences and the Wicksellian full-employment assumption is dropped. The specific task of the trade cycle theorist is, for Hayek, to analyse short-period positions of the economy 'in successive moments of time' (1941, p. 23). The adoption of such an 'intertemporal equilibrium' approach to cycles

(conceptually not different from modern temporary equilibrium) marks not only a crucial methodological turning point, but also the swan song of credit cycle theories.

On the one hand, this new method of 'intertemporal equilibrium' heralds the abandonment of the traditional framework in which cycles (defined as short-run discquilibria) are seen as temporary deviations from long-period equilibrium conditions determined by systematic and persistent forces at work in decentralized economies. In the present case, the 'natural' rate of interest determined in the long run by the supply of and the demand for capital is no longer the norm towards which the system is tending. It is in fact a property of such an 'intertemporal equilibrium' that not only will the price of the same commodity be different at different points in time but also that the stock of capital will not yield a uniform 'natural' rate of interest on its supply-price.

On the other, the publication of Keynes's *General Theory* redirected research efforts away from this question into the problem of the determination of output at a point in time. It is only since the late 1960s, with the search for 'microfoundations for macroeconomics', and the subsequent advent of rational expectations and non-Walrasian equilibria, that this line of thought has been back on the theoretical agenda. However, given the extreme complexity of the problem and the relative crudeness of models still in their infancy, progress has so far been very modest.

Credit Rating Agencies

Joel Shapiro

Abstract

Credit Rating Agencies (CRAs) have been measuring the credit risk of debt for slightly over 100 years. The industry is characterised by artificial and natural barriers to entry and an issuer-pays system. The agencies' ratings performed poorly for structured finance products and have been criticised for being an important factor in the financial crisis of 2007–2009. The critique focuses on poor modelling techniques and conflicts of interest.

Credit rating agencies (CRAs) measure the credit risk of debt for all types of investors. Their measurement of credit risk includes default probabilities and they rate both corporate and public debt. In recent years they have also expanded dramatically into structured finance investments. In general, the CRAs use hard public information that is available to all investors, and hard private and soft private information that is provided by the issuer.

CRAs serve an economic purpose: they reduce asymmetric information about issuers that investors face when making investments, thus enhancing market liquidity. They also decrease wasteful duplication of research and information production. Reputation is critical in maintaining their incentives to produce

quality ratings: short-term gains from inflating an investment's quality can be smaller than long-term losses from jaded investors.

History

Bond rating and the establishment of formal CRAs began in 1909 when John Moody began rating US railroad bonds, soon expanding to utility and industrial bonds. Poor's Publishing Company followed in 1916 and Fitch Publishing Company in 1924. The business was characterised by the investor-pays model, where investors bought reports from the CRAs containing their ratings. This changed in 1970, for two reasons. First, with the advent of the photocopier free-riding became commonplace and CRAs found it difficult to sustain their business (White 2002). Second, in 1970 Penn Central defaulted on its commercial paper obligations, creating vast mistrust among investors and a large demand by issuers for certification. The business thus changed to an issuers-pay model (Cantor and Packer 1995). In 1975, the Securities and Exchange Commission (SEC) created the Nationally Recognized Statistical Rating Organization (NRSRO) category to designate credit ratings agencies whose ratings were recognised as being valuable for investment decisions. Standard & Poor's, Moody's and Fitch were given this designation immediately, and four other firms attained it in the following 17 years. By 2000, however, mergers returned the number of NRSROs to the big three. The SEC gave out a fourth NRSRO designation in 2003 (Dominion), a fifth in 2005 (A.M. Best), and in response to congressional legislation promoting transparency and entry in 2006 gave out three more designations (White 2010). All of these new NRSROs, however, remain very small players in the bond and structured finance businesses.

Important Aspects of Industry Structure

1. Many regulatory agencies use ratings in evaluation, e.g. to determine capital requirements. Moreover, certain entities such as banks, insurance and pension funds are restricted to invest only in *investment grade* securities, i.e. BBB and above (see Cantor and Packer 1995). This creates an artificial demand for ratings. Kisgen and Strahan (2010) demonstrate that the acquisition of NRSRO status for Dominion Bond Rating Service in 2003 changed the impact of its ratings on bond yields only in situations where this status was important. Coval et al. (2009) provide evidence that Collateralized Debt Obligations (CDOs) were inaccurately priced because ratings were overly weighted by investors. Adelino (2009) finds that while initial yields on tranches below AAA for mortgage backed securities predict future credit performance the initial yields on AAA tranches had no predictive power. This is consistent with the hypothesis that investors in AAA tranches had no other information beyond the credit ratings themselves.
2. There are large *barriers to entry* in the credit rating industry: Since Congress, local governments, and regulatory agencies adopted the NRSRO designation and used it for the determination of investment grade securities (point 1), this created an 'absolute barrier to entry' (White 2002). Moreover, the need to build a reputation in order to receive business is a natural barrier to entry.
3. The fact that Moody's and S&P rate some corporate bonds which they are not paid for by issuers using public information (*unsolicited ratings*) is controversial. While the firms state that they are providing a service demanded by investors, some parties have raised the point that these ratings may be used to discipline issuers. Poon (2003) demonstrates

that unsolicited ratings tend to be lower in general, but correcting for selection does not explain all of the variation.

4. CRAs have been able to avoid *liability* for problems with ratings. Under Section 11 of the Securities Act of 1933 they were immune from misstatements. Moreover, in court they have used the argument that ratings are speech and not recommendations on how to invest (Partnoy 2002). The Dodd-Frank Financial Reform Bill passed recently exposes CRAs to liability by defining them as experts.
5. The market for corporate bond ratings is different from the market for *structured finance* ratings. Standard & Poor's and Moody's rate all corporate bonds, while the percentage that Fitch rates has been increasing. Most structured finance products receive at least two ratings, but who is rating it depends on the deal (see Ashcraft et al. 2009). The corporate bond market is established and relatively simple, and the models used are well accepted. Structured finance products are fairly new but have grown rapidly; between 1997 and 2003 global structured finance issuance grew from about $280 billion to $800 billion (Committee on the Global Finance System 2005). These products are very complex and the methods for rating structured products have been imprecise. Errors in the ratings agencies' data, assumptions and modelling have been found. Moreover, agencies are not required to perform due diligence on underlying loans and have difficulties retaining their best employees (Partnoy 2002).
6. In the structured finance market, ratings *shopping* can occur. This means that if an issuer is unhappy with a rating, it may solicit another one, either from the same CRA or from another CRA. Moreover, 'typically the rating agency is paid only if the credit rating is issued' (US SEC 2008).

Evidence on CRAs in the Corporate Bond Market

There has been a large focus on the effect of announcements on the pricing of both bonds and stocks. The main finding is the asymmetry between downgrades and upgrades: downgrades have a significant negative impact on price, but there is virtually no price change following an upgrade. The effect of ratings changes on price is complex, as the impact of ratings changes is different for firms with low ratings than for firms with high ratings. Overall, there is a clear consensus that information provided by CRAs has an effect on price (Hand et al. 1992; Hite and Warga 1997; Berger et al. 2000; Kliger and Sarig 2000; Dichev and Piotroski 2001; Jorion and Zhang 2007). These findings suggest a role for CRAs in the allocation of capital process.

In terms of accuracy, Cantor and Packer (1995) show that ratings order corresponds to default rankings. Hilscher and Wilson (2009) argue that rating agencies do a poor job at forecasting default probabilities, but capture systematic default risk.

Fitch is generally thought of as having higher ratings than Standard & Poor's and Moody's (Jewell and Livingston 1999). Becker and Milbourn (2009) finding that increased competition from Fitch's increased market share in the corporate bond market led to more issuer-friendly ratings and also less informative ratings. Bongaerts et al. (2009) however, only find a certification role for Fitch in breaking ties between Moody's and Standard & Poor's.

Structured Finance Products and the Financial Crisis of 2007–2009

Much attention has been paid to CRAs as a potential contributor to the financial crisis. The structured finance market collapsed and even 'the highest rated (AAA) mortgage-backed securities (as measured by the corresponding credit default swaps prices) fell by 70 percent between January 2007 and December 2008' (Pagano and Volpin 2009), implying that ratings were not of high quality. There is debate over whether poor quality ratings were the fault of (i) conflicts of interest, (ii) imprecise modelling, or some mixture of both.

An SEC investigation found that senior analytical managers and supervisors participated in fee discussions with issuers and the analytical staff

also discussed ratings decisions and methodology in the context of fees and market share (US SEC 2008). In addition, CRAs offer related consulting services, such as pre-rating assessments (of what a rating might be).

A few recent theoretical papers study the implications of shopping for ratings. Bolton et al. (2010) demonstrate that competition among CRAs may reduce welfare due to shopping by issuers. Faure-Grimaud et al. (2009) look at corporate governance ratings in a market with truthful CRAs and rational investors. They show that issuers may prefer to suppress their ratings if they are too noisy. They also find that competition between rating agencies can result in less information disclosure. Skreta and Veldkamp (2009) also assume that CRAs truthfully relay their information and demonstrate how noisier information creates more opportunity for shopping by issuers to take advantage of a naive clientele.

In terms of conflicts of interest, Mathis et al. (2009) find that reputation cycles may exist where a CRA builds up its reputation by relaying information accurately only to take advantage of this reputation to later inflate ratings. Bolton et al. (2010) show that conflicts of interest for CRAs may be higher when reputation costs are lower and there are more naïve investors. Bar-Isaac and Shapiro (2010) demonstrate that CRAs incentives to produce accurate ratings are likely to be countercyclical, i.e. lower in a boom than in a recession. In Pagano and Volpin (2008), CRAs have no conflicts of interest, but can choose ratings to be more or less opaque depending on what the issuer asks for. They show that opacity can enhance liquidity in the primary market, but may cause a market freeze in the secondary market.

In empirical evidence, Mathis et al. (2009) show that, controlling for economic variables, the fraction of structured finance tranches that were rated AAA has increased over the period 2000–2008. Ashcraft et al. (2009) examine subprime and Alt-A mortgage backed securities (MBS) during the period leading up to the subprime crisis and find evidence that ratings become less conservative right at the height of the MBS market peak in 2005–2007. In particular, they demonstrate that ratings quality was worse on low documentation mortgages. Griffin and Tang (2009) look at CRA adjustments to their models' predictions of credit risk in the CDO market and find that the adjustments were overwhelmingly positive, were positively related with future downgrades, and the amount adjusted increased sharply from 2003 to 2007. Benmelech and Dlugosz (2009) find that securities rated by only one agency were 6.1% more likely to be subsequently downgraded and point to shopping as the reason.

Credit Rationing

Charles W. Calomiris, Stanley D. Longhofer and Dwight M. Jaffee

C

Abstract

Credit rationing – a situation in which lenders are unwilling to advance additional funds to borrowers at the prevailing market interest rate – is now widely recognized as a problem arising because of information and control limitations in financial markets. This article reviews various motivations behind research on credit rationing, traces the history of theoretical efforts to explain how this phenomenon can persist in equilibrium, and reviews recent empirical research on its prevalence and effects. In the process, credit rationing is shown to be simply an extreme case of the more general problem of capital market misallocation.

Broadly speaking, 'credit rationing' refers to any situation in which lenders are unwilling to advance additional funds to a borrower even at a higher interest rate. In the words of Jaffee and Modigliani (1969, pp. 850–1), 'credit rationing

[is] a situation in which the demand for commercial loans exceeds the supply of these loans at the commercial loan rate quoted by the banks'. Key to this definition is that changes in the interest rate cannot be used to clear excess demand for loans in the market. In essence, this definition treats credit rationing as a supply side phenomenon, with the lender's supply function becoming perfectly price inelastic at some point.

If the projects that are being funded by the loan are not scalable, however, then a distinction must be made between a situation in which a lender eventually restricts the size of loan it will provide to any individual borrower and one in which 'rationed' borrowers are denied credit altogether. This phenomenon arises in circumstances in which lending is not scalable. Stiglitz and Weiss (1981, pp. 394–5) therefore define credit rationing as follows:

> We reserve the term credit rationing for circumstances in which either (a) among loan applicants who appear to be identical some receive a loan and others do not, and the rejected applicants would not receive a loan even if they offered to pay a higher interest rate; or (b) there are identifiable groups of individuals in the population who, with a given supply of credit, are unable to obtain loans at any interest rate, even though with a larger supply of credit, they would.

According to this definition, lenders fully fund some borrowers but deny loans to others despite the fact that the latter are identical in the lender's eyes to those who receive loans.

Thus, there are two working definitions of credit rationing in the literature. The first focuses on situations in which increases in the interest rate cannot clear excess demand in the loan market, whether this excess demand reflects a single borrower (who would like a larger loan amount) or many. Under this definition, rationing would exist if every potential borrower received a loan but a smaller one than that desired at the equilibrium interest rate. The second definition – the Stiglitz–Weiss definition – restricts its attention to situations in which some borrowers are completely rationed out of the market, even though they would be willing to pay an interest rate higher than that prevailing in the market.

Both of these definitions focus on the supply side of the market. One could argue, however, that it is useful to think of non-price rationing as any phenomenon that limits the amount of funding used by firms such that firms are not able to use the price mechanism to successfully bid for additional funds, whether this is caused by supply-side constraints (as under the narrow definitions of credit rationing described above) or by other distortions in credit markets (related, for example, to regulation). This would allow a broader definition of 'credit rationing' in which regulatory constraints, rather than just informational problems, lead to non-price allocations of credit.

Why Care About Credit Rationing?

Early interest in credit rationing was driven in part by questions about the role that credit rationing might play in transmitting the macroeconomic effects of monetary policy, which was related to research on the so-called 'availability doctrine' in the 1950s and 60s (Scott 1957). To the extent that monetary policy operates through a 'credit channel' (in which contractionary policy affects the economy through a decline in the supply of funds available for banks to lend), and to the extent that changes in the terms of lending include not only changes in loan pricing but also changes in the quantities of credit available to borrowers, credit rationing may play an important role in the transmission of monetary policy's effects on the economy (Blinder and Stiglitz 1983).

In addition to the cyclical effects of rationing in credit markets related to monetary policy, development economists, especially Ronald McKinnon (1973), argued that a different credit rationing problem is more relevant for the long-term growth prospects of developing countries. High inflation, high zero-interest reserve requirements, government-mandated loan allocations to favoured borrowers, and interest rate ceilings on loans or deposits in developing economies (a combination which McKinnon termed 'financial repression') subjected many developing countries' banking systems to an extreme form of regulation-induced credit rationing. High

reserves, high inflation, and interest ceilings on deposits meant that banks were rationed in the deposit market, and thus had few funds to lend, while lending mandates and loan interest-rate ceilings meant that what funds were available to lend were often rationed by restrictions on who could bid for those funds.

Additionally, George Akerlof (1970), in his path-breaking article on the role of adverse selection in preventing market development, drew attention at an early date to the possible effects of information problems in retarding the development of lending markets, particularly in developing countries. In an ideal world, in the absence of any government policies limiting beneficial lending, all borrowers with positive net present value projects would be able to obtain outside funding (whether through debt or equity instruments, or bank or non-bank sources of funds). But Akerlof showed that, if markets were unable to distinguish good risks from bad ones, lending might not be feasible. The failure to develop institutions capable of producing credible information about borrowers and using that information to screen applicants could, according to Akerlof, play an important role in financial underdevelopment.

Many development economists have come to recognize that the failure to properly allocate funds in the loan market – a broad phenomenon, within which credit rationing is a special and extreme case – can be an especially important potential impediment to growth in developing countries because of the relative absence of institutions in those countries that allow effective screening of borrowers (to mitigate adverse selection) or ongoing monitoring of borrowers' actions (to mitigate moral hazard).

An additional motivation for an interest in credit rationing comes from the literature on bank fragility. Credit rationing can also apply to the market in which financial intermediaries raise their funds. Financial institutions go to great pains to attract and maintain deposits through (a) the structure of their contracts (which typically afford withdrawal options to depositors), (b) their long-term relationships with market monitors who track their progress, and (c) their established reputations for good management. But sometimes the market suddenly decides to ration credit to a particular bank or to the whole banking system; and when this happens the affected banks find it hard to attract and maintain deposits at any price. Thus, the literature on 'bank runs' as an historical phenomenon can be thought of as a literature on credit rationing in the markets in which financial institutions raise their funds. Depositors that decide to participate in a bank run ration credit to their bank in the sense that the decision to withdraw is a quantity, not a price, decision. They are simply unwilling to leave their money in the bank.

Finally, much of the current research on discrimination in credit markets is driven by evidence that black and Hispanic minority loan applicants are denied more frequently than comparable whites (for example, Munnell et al. 1996; Cavalluzzo and Cavalluzzo 1998; Cavalluzzo and Wolken 2005). Of course, this begs the question of why borrowers are denied loans in the first place, rather than simply priced according to their risk. In other words, understanding why there are differences in denial rates across groups necessarily entails exploring why rationing (loan denial) occurs.

The Development of Credit Rationing Theory

Early Views on Credit Rationing

The earliest discussions of credit rationing viewed it as a non-equilibrium phenomenon, arising either because of exogenous interest rate rigidities (for example, interest rate ceilings or usury laws) or because of a lack of competition in the loan market (Scott 1957). Soon authors made a distinction between temporary credit rationing, in which market interest rates are slow to adjust to exogenous shocks such as changes in the lender's cost of funds or borrower demand, and 'equilibrium' credit rationing, which persists after the market has fully adjusted to these shocks. Clearly the more interesting and difficult to explain phenomenon is equilibrium credit rationing.

Hodgman (1960) was the first to try to explain how credit rationing can persist in a rational, equilibrium framework. In this model, lenders

evaluate potential borrowers on the basis of the loan's expected return–expected loss ratio. In addition, it is assumes that there is a maximum repayment that the borrower can credibly promise, which effectively limits how much the lender will offer the borrower regardless of the interest rate: eventually the expected losses become too great relative to the expected return. This model was much debated in the ensuing years. In particular, Miller (1962) argued that Hodgman's analysis could be made consistent with rational expectations between the borrower and lender by incorporating bankruptcy costs that would be incurred by the lender upon the borrower's default. The real significance of the Hodgman article, however, was that it established as an important theoretical goal the objective of explaining how credit rationing could persist as an equilibrium phenomenon.

Freimer and Gordon (1965) resolved many of the issues regarding the structure of the Hodgman and Miller models by showing that credit rationing can occur with a risk-neutral lender if the borrower has a fixed-sized funding need. But this was done assuming an exogenous interest rate. Jaffee and Modigliani (1969) completed the picture by endogenizing the equilibrium interest rate by modelling both the supply and demand sides of the market. Credit rationing in their model, however, is the direct result of an exogenous assumption that borrowers within a given group must be charged the same interest rate, even though the lender can distinguish differences among them.

This early work was important in that it firmly established the idea that credit rationing could be a persistent equilibrium phenomenon. Ultimately, however, the solutions proposed relied on very restrictive assumptions about agent preferences or the contracts they could employ. More satisfactory explanations of credit rationing had to wait for the information economics revolution of the 1970s.

Modern Credit Rationing Theory

Akerlof's (1970) pioneering article on adverse selection was motivated in part by the desire to explain extreme cases of credit rationing (the absence of a credit market), but Jaffee and Russell (1976) provide the first explicit asymmetric information rationale for credit rationing in the general sense. In their model, lenders cannot distinguish *ex ante* between high-and low-quality borrowers (that is, those who will repay their loans and those who will default). Contracts are written to determine the size of the loan offered and the interest rate. As in the Rothschild and Stiglitz (1976) insurance framework, low-quality borrowers must accept the contract that is preferred by the high-quality borrowers, lest they be identified as the deadbeats they are. Although a market-clearing interest rate/loan amount combination does exist, high-quality borrowers prefer a contract that entails a slightly lower interest rate with a reduced loan amount. As a result, the pooling outcome entails credit rationing. The primary problem with this model is that the 'equilibrium' is not stable, in that unsustainable separating contracts dominate the pooling outcome.

In 1981, Joseph Stiglitz and Andrew Weiss published what has become the canonical model of credit rationing, because it was the first model that fully endogenized contract choices with a stable, rationing equilibrium. In the Stiglitz–Weiss framework, credit rationing occurs because the lender's expected return is not monotonically increasing in the interest rate. Instead, adverse selection or moral hazard problems eventually cause the lender's expected return to decline as the interest rate rises.

In the adverse selection version of the model, borrowers and lenders are both risk neutral. Borrowers are characterized by their projects, which are assumed to have the same expected returns but differ from one another in their risk. Specifically, borrower projects differ on the basis of mean-preserving spreads (Rothschild and Stiglitz 1970). These projects are also assumed to require a fixed investment (that is, they are indivisible) and borrowers have a fixed amount of internal equity that they can invest in the project. Limited liability upon default means that the lender's payoff is a concave function of the project's return, while the borrower's profit function is convex.

These assumptions imply that, at any given interest rate, a subset of the least risky borrowers

will drop out of the market, choosing instead to forgo their projects. In essence, the borrower's limited liability means that he reaps all of the project's gain (beyond the cost of debt service) when its return is high, but loses his collateral (his paid-in capital invested in the project, if any) only when the project's return is low. For low-risk projects, however, the potential upside gains are small. If those low-risk borrowers are pooled with high-risk borrowers, they will face higher than warranted interest rates. Low-risk borrowers will increasingly withdraw from the market as interest rates rise; as rates rise, borrowers with low-risk projects are better off withdrawing from the market and simply consuming their endowments rather than agreeing to invest and pay a high interest rate. As a result, increases in the interest rate cause more and more good borrowers to drop out of the market, lowering the average creditworthiness of the lender's remaining applicant pool. The size of the adverse selection premium faced by low-risk borrowers (the amount of interest low-risk borrowers have to pay in excess of what their project risks warrant) becomes larger with each interest rate rise because the interest rate must compensate for the default risk of an ever-worsening pool of borrowers.

Thus, increases in the interest rate affect lender returns in two ways. The first is the direct effect that a higher interest rate raises the lender's return (for a given pool of borrowers). Rising interest rates, however, also have the indirect effect of lowering the average quality of the lender's applicant pool, thereby lowering the lender's expected return from any given loan. Eventually, this secondary, adverse selection effect may outweigh the first interest rate effect, causing lender profits to decline as the interest rate rises.

Once the non-monotonicity of the lender's return in the interest rate is established, the possibility of credit rationing follows immediately. Profit-maximizing lenders will never voluntarily choose to raise the interest rate beyond where the adverse selection effect dominates. If excess demand exists in the market at this rate, credit rationing will be the equilibrium.

Paradoxically, in this model the very best credit risks do not seek funding because they do not find it worthwhile. This may seem odd, but it is important to remember that these borrowers are not rationed. Instead, they voluntarily drop out of the market because the cost of being pooled with higher-risk borrowers is too great. The rationed borrowers are the higher-risk borrowers who stay in the market and request funding.

Alternatively, Stigliz and Weiss show how changes in the interest rate may also affect the borrower's choice of project, so that moral hazard in project choice (sometimes referred to as 'asset substitution' in the finance literature) can be another reason that the lender's expected return is non-monotonic in the interest rate. Suppose that the borrower is able to choose among projects with different risk profiles. If, at a given interest rate, the borrower is indifferent between two projects, Stiglitz and Weiss show that an increase in the interest rate will cause the borrower to prefer the project that has the higher probability of default. Of course, the lender prefers the safer project. Thus (with slightly more restrictive distributional assumptions than in the adverse selection case), increases in the interest rate once again can eventually lower the lender's expected return, leading to credit rationing.

Models of credit rationing need not posit rationing for all borrowers. Realistically, some borrowers (certain firms for which information control problems are particularly acute) may be subject to rationing while other borrowers are not. Borrowers not subject to rationing may be able to avoid rationing because their prospects are more observable, or because their behaviour is more controllable.

Bank Runs as Credit Rationing

The theoretical literature on credit rationing in the deposit market (bank runs) has some features that distinguish it from the literature on credit rationing in the loan market. The ultimate causes of deposit market rationing can be similar to, or very different from, the causes of loan market rationing. As discussed above, loan market rationing can reflect either information and incentive problems in the loan market or exogenous

regulations. In the case of the deposit market, rationing can result either from incentive and information problems relating to the depositor–bank relationship or from exogenous liquidity needs of depositors.

With respect to the former, under some circumstances a bank run may reflect a loss of confidence in the market value of the bank's asset portfolio and changes in bank behaviour that attend such a loss. If the value of the portfolio falls sufficiently, and if the information and incentive problems are sufficiently severe, the perceived risk of losses in the bank can prompt depositors to ask for their money back because depositors have reason to be risk-intolerant (that is, to be unwilling to leave their money in a bank that has too high a level of risk). An example of such a model is Calomiris and Kahn (1991). Here the depositor withdraws funds in bad states of the world because doing so is necessary to prevent the banker from abusing his control over the bank's portfolio.

An alternative cause of credit rationing in the deposit market is a shock to the liquidity needs of depositors, which forces depositors to demand their funds from their banks irrespective of the portfolio performance of the banks. Diamond and Dybvig (1983) is an example of a model of this phenomenon.

Bank depositor runs are but one specific example of how financial intermediaries may be credit rationed due to creditor risk intolerance and/or liquidity shocks. During the 1998 Russian financial crisis, for example, it was widely reported that many emerging market hedge funds dumped their holdings of risky securities of all kinds in a scramble to reduce their risks and thus re-establish the high-quality credit ratings needed to retain their debtors. Intermediaries were also scrambling to accumulate liquidity, as many of their claimants needed to withdraw funds to meet other obligations related to the financial market upheaval.

The Limits of Credit Rationing

Credit rationing as a problem of information and control (as it was modelled by Jaffee and Russell 1976 and Stiglitz and Weiss 1981) is properly seen as an extreme case of the more general phenomenon of capital market misallocation, which includes cases where capital is misallocated (due to adverse selection and moral hazard) without any rationing occurring. It is important to recognize that, from the standpoint of either cyclical concerns about the transmission of monetary policy or developmental concerns about the efficiency of the allocation of capital, the important phenomenon is not rationing per se but rather the extent to which the market fails to allocate resources efficiently. Even a market that never suffers from credit rationing can be highly inefficient in its allocation of capital. In that sense, credit rationing may be somewhat beside the point. Indeed, the corporate finance literature is full of examples of models of market imperfections involving moral hazard and adverse selection in which credit is misallocated, and in which positive net present-value projects are not funded or negative net present-value projects *are* funded.

In some cases, firms may even be priced out of the market for funds entirely, so that they avoid funding profitable investments. For example, Jensen and Meckling (1976) show that the potential for asset substitution at the expense of creditors can make it much more costly for firms to access debt markets. Indeed, asset substitution can make it prohibitively expensive to issue debt. Note that this is not a case of credit rationing as defined by Stiglitz and Weiss, since suppliers are not refusing credit. Rather, the high asset substitution premium that firms would be charged if they sought credit can result in a decision by the firm not to fund a positive net present-value investment. Similarly, Myers and Majluf (1984) show that because of adverse selection problems – which are particularly acute in the public equity market – some firms may decide to avoid issuing equity to fund a positive net present-value investment. Here, again, a firm is not being rationed by suppliers, but is unwilling to seek financing because of its prohibitive pricing.

As the literature on capital market misallocations and credit rationing developed in the late 1970s and early 1980s, critics pointed out some limiting circumstances in which capital markets

did not have a tendency to underfund positive net present-value projects. For example, both adverse selection and moral hazard problems can be overcome by sufficient collateral. By placing collateral at risk a firm could signal its high quality, or commit itself not to abuse creditors by undertaking excessive risk (see Bester 1985). Of course, collateral is not always available, nor is it costless to place collateral at risk. In the case of a limited liability enterprise, the firm's net worth limits its available collateral. Firms that can finance themselves from internal funds and limited amounts of low-risk debt can avoid the adverse selection and moral hazard costs associated with external finance, but young, growing firms tend to be in need of substantial amounts of external finance, far in excess of their accumulated net worth. If borrowers use all of their available 'collateral', then, on the margin, collateral cannot mitigate adverse selection or moral hazard problems.

In the consumer context, it is also important to recognize that the moral hazard and adverse selection problems that arise in corporate lending may differ in importance across the various areas of consumer lending. For example, moral hazard may be limited in the context of mortgage lending where actions destructive to the lender's interest are likely to harm the homeowner as well (consider inadequate protection against the risk of fire, for example). Furthermore, the modern use of credit scores and loan-to-value ratios may make mortgage lenders more knowledgeable about an applicant's true credit risk than the applicant himself, particularly if that applicant has significant equity invested in the house and lacks experience in the credit market (Calomiris et al. 1994). Under such circumstances, the implications of adverse selection models (which depend on the superiority of the information of the borrower about his type) may be irrelevant, or even reversed. On the other hand, in the context of uncollateralized credit card borrowing based only on past credit records, unobservably high-risk borrowers (those who know that they are about to have major medical costs, lose their job, or become divorced) may have strong incentives to borrow, implying the possibility for severe adverse selection.

How Is Credit Rationing Measured Empirically?

Although credit rationing is a widely discussed phenomenon, there is a surprising paucity of evidence confirming its existence. The key problem is that, while the concept of a credit-rationed borrower is easy to understand in theory, under each of the various models of credit rationing discussed above it is extremely difficult to measure 'excess demand' of individual borrowers or the similitude of borrowers' creditworthiness.

Indirect Methods

Jaffee and Modigliani (1969) attempt to infer the presence of credit rationing by measuring the proportion of new commercial loans originated at the prevailing prime rate and/or with very large loan sizes. The intuition they use is that prime and/or large borrowers have the lowest risk and are therefore the least likely to be rationed. As a result, a larger proportion of loans will go to these low-risk borrowers when credit rationing is severe. Jaffee and Modigliani use this proxy to see how market factors affect the prevalence of credit rationing. Of particular interest is their result that increases in the average commercial loan rate are associated with higher levels of rationing, which seems to confirm the appropriateness of their proxy for credit rationing.

Other authors have attempted to measure whether commercial loan rates are 'sticky' in response to changes in open-market interest rates. The idea here is that in most credit rationing models there is an implicit cap above which lenders will ration credit. As open-market rates rise, this cap is more likely to become binding, meaning that commercial loan rates will not fully respond to changes in open-market rates. Following this approach, a number of authors, including Goldfeld (1966) and Jaffee (1971), have found that commercial loan rates are, in fact, slow to adjust to changes in open-market rates, and offer this as evidence in support of credit rationing.

Berger and Udell (1992), however, provide convincing evidence that, although commercial-loan rate stickiness does occur, it does so in a fashion that is inconsistent with information-

based credit rationing models. In particular, they find that nearly half of the observed loan rate stickiness occurs for loans made to borrowers who are exploiting a previously contracted bank loan commitment. Such borrowers are precluded from rationing by contract. Furthermore, they show that the fraction of loans made under commitment actually decreases during times of credit market tightness, exactly the opposite of what one would expect should credit rationing be an important phenomenon.

Direct Methods

Other authors have attempted to directly measure credit rationing using survey data to identify 'rationed' borrowers. For example, Cox and Jappelli (1990) and Chakravarty and Scott (1999) use data from the Survey of Consumer Finances (SCF) in which households are directly asked whether they recently have been denied credit or been unable to obtain as much credit as they requested. Although these articles purport to measure how some outside factor affects the likelihood of being rationed, it is not clear that borrowers who self-report being denied credit have, in fact, been 'rationed' in the Stiglitz–Weiss meaning of the term. After all, their denial of credit could simply reflect a failure to properly select into the right risk class in order to be approved, or the fact that the borrower was simply uncreditworthy at any interest rate.

With regard to business lending, Cressy (1996) uses a sample of new businesses that opened accounts with a major British bank to ascertain whether credit rationing affects the likelihood of business survival. He concludes that firms self-select for finance based on the entrepreneur's human capital, implying that no credit rationing is occurring.

One strand of the empirical literature on credit rationing, broadly defined, focuses on whether differential mortgage loan denial rates between white and minority borrowers constitutes evidence of discrimination (a much cited reference is Munnell et al. 1996; Ross and Yinger 2002, provide an excellent review of this literature). Although the discrimination literature does not specifically focus on the question of whether borrowers are credit rationed, any conclusion that one group is denied loans at a greater rate than others after creditworthiness is controlled for would imply that a form of credit rationing is occurring. This 'rationing', however, is distinct from that in Stiglitz–Weiss because the borrowers are not observably identical, and the underlying cause of 'rationing' is either lender preferences (Becker 1971) or some form of statistical discrimination (Calomiris et al. 1994; Longhofer and Peters 2005).

Evidence on 'Intermediary Rationing'

In contrast to the limited evidence of traditional borrower credit rationing, there is a significant body of evidence supporting the idea that financial institutions are rationed by their depositors. In recent years, a large literature has developed examining the determinants of deposit withdrawal from individual banks, and a parallel literature has developed on systemic banking panics. These articles find that in circumstances where the condition of banks is perceived to have deteriorated, depositors withdraw funds rather than simply demand a higher interest rate on deposits (Calomiris and Mason 2003; Calomiris and Wilson 2004). The links between bank characteristics and deposit withdrawals observed in these and other similar studies suggest that deposit rationing is related to information and incentive problems, rather than just liquidity shocks to depositors, although such shocks may still play a role.

Final Thoughts

It is worth noting that improvements in underwriting processes may have dramatically altered the practical impact of credit rationing in recent years. The use of risk-based pricing in consumer lending, including credit card loans and mortgages, has become widespread, reflecting the increased ability of lenders to

distinguish between borrowers with different risk profiles (see, for example, Edelberg 2003; Chomsisengphet and Pennington-Cross 2006). The same is true for commercial credit markets, in which instruments such as junk bonds, senior-subordinated securitization issues, and the like serve to provide financial market access to broader classes of instruments, borrowers and risks. As a result, 'sorting' among borrowers overall has increased, and today there is likely much less diversity in pools of 'observably identical' borrowers than there was when Stiglitz and Weiss first developed their model. While this suggests that in some markets credit rationing is a very different and perhaps less important phenomenon today than it once was, an important potential role remains for credit rationing, particularly as it pertains to financial allocations in emerging markets, the pricing of particularly opaque segments of the lending markets of developed economies, and the ways in which financial institutions may be rationed in response to shocks to their portfolios.

Crime and Punishment

Isaac Ehrlich

'Economics of Crime' revives an old tradition in economic thought in its reliance on the unifying power of economic analysis to explain human behaviour and resource allocation choices both within and outside the conventional market place. Classical economists such as Beccaria, Paley, and Bentham devoted considerable attention to the explanation of crime in rational economic terms, and to the formulation of optimal rules for punishing offenders, based on utilitarian principles. Motivated, in part, by the rapid growth of reported offences in recent decades, economists have regained interest in the issue. Several studies in the 1960s, notably the seminal work by Becker (1966), have inspired the development of the 'economic approach to crime'.

The essence of the approach lies in the assumption that offenders respond to incentives, both positive and negative, and that the volume of actual offences in the population is therefore influenced by the allocation of private and public resources to law enforcement and other means of crime prevention. For this approach to provide a useful approximation of the complicated reality of crime, it is not necessary that all those who commit specific offences respond to incentives, (nor is the degree of individual responsiveness prejudged); it is sufficient that a significant number of potential offenders so behave on the margin. By the same token, the theory does not preclude a priori any category of crime, or any class of incentives. Indeed, economists have applied this approach to a myriad of illegitimate activities, from tax evasion and violations of minimum wage laws to auto-theft, skyjacking, and murder.

Theory

In Becker's analysis the equilibrium volume of crime was produced through the interaction between offenders and the law enforcement authority, and the focus was on propositions concerning the socially optimal probability, severity, and type of criminal sanction. Later work centred on a more complete formulation of the components of the system, especially the supply of offences, the production of law enforcement activities, and the criteria for optimal law enforcement. Attempts have also been made to expand the notion and scope of the 'market' for illegitimate activities by expounding the roles played by offenders (supply), consumers and potential victims (private demand), and enforcement and prevention (government intervention), and by augmenting the relevant market equilibrium analysis.

Supply

The offender's choice is generally modelled to involve an optimal allocation of time among competing legitimate and illegitimate activities which differ in the mix of their uncertain pecuniary and

non-pecuniary consequences, and offenders are presumed to act as expected-utility maximizers. The basic opportunities affecting choice are identified as the (perceived) probabilities of apprehension, conviction, and punishment, and the marginal penalties imposed ('deterrence variables'); the deterrence variables associated with related crimes; the marginal returns on competing illegal and legal activities and the risk of unemployment; and initial wealth. Entry into a specific criminal activity is shown to be related inversely to its own deterrence variables, and directly to the differential return it provides. Moreover, a one per cent increase in the probability of apprehension is shown to generate a larger deterrent effect than corresponding increases in the conditional probabilities of conviction given apprehension, and specific punishments given conviction (see Ehrlich 1975). Essentially due to conflicting income and substitution effects, some results for active offenders are more ambiguous: a strong preference for risk may reverse the deterrent effect of sanctions (Ehrlich 1973) and the results are even less conclusive if one assumes (as do Block and Heineke 1975) that the length of time spent in crime, not just the moral obstacle to entering it, generates disutility. The results become less ambiguous at the aggregate level, however, as one allows for non-homogeneity of offenders due to differences in personal opportunities or preferences for crime: a more severe sanction can reduce the crime rate by deterring the entry of potential offenders even if it has little effect on actual ones.

Demand

The incentives operating on offenders often originate with, and are partially controlled by, consumers and potential victims. Transactions in illicit drugs and stolen goods, for example, are patronized by consumers who generate a direct or derived demand for the underlying offences (cf. Vandaele 1978). But even for crimes that inflict pure harm on victims there exists an indirect (negative) demand, which is derived from a positive demand for safety. By their choice of optimal self-protective efforts through use of locks, safes, and alarms, or selective avoidance of travel, potential victims influence the marginal returns to offenders, and thus the implicit 'demand' for crime. And since optimal self-protection generally increases with the perceived risk of victimization (the crime rate), private protection and public enforcement will be interdependent.

Public Intervention

Whereas crime is an external diseconomy and crime control measures are largely a public good, collective action is needed to augment individual self-protection. Public intervention typically aims to 'tax' illegal returns through the threat of punishment, or to 'regulate' offenders via incapacitation and rehabilitation programme. All control measures are costly. Therefore, the 'optimum' volume of offences cannot be nil, but must be set at a level where the marginal cost of each measure of enforcement or prevention equals its marginal benefit.

To assess the relevant net benefits, however, one must adopt a criterion for public choice. Becker (1966) and Stigler (1970) each chose maximization of a concept of 'social income' as the relevant criterion, requiring the minimization of the sum of social damages from offences and the cost of law enforcement activities. This approach can lead to powerful propositions regarding the optimal magnitudes of probability and severity of punishments for different crimes and different offenders, or, alternatively, the optimal level and mix of expenditures on police, courts, and corrections. It reaffirms the proposition that, in equilibrium, the deterrent effect of the optimal probability of apprehension will exceed that of the conditional probabilities of conviction and of specific punishments, and it makes a strong case for the superiority of monetary fines as a deterring sanction. Different criteria for public choice, however, yield different implications regarding the optimal mix of probability and severity of punishment, as is the case when the social welfare function is expanded to include concern for the distributional consequences of law enforcement and other concepts of justice in addition to aggregate income (see Polinsky and Shavell 1979; Ehrlich 1982). Furthermore, a positive analysis of enforcement must address the behaviour of the

separate agencies constituting the enforcement system and the constraints of the political market. Studies which focus on the production of and demand for specific agencies, such as police and courts (see, e.g., Landes 1971), have often adopted decision rules which deviate from the social welfare maximizing criterion.

Market Equilibrium

A general equilibrium analysis of the market for offences involving the joint determination of the volume of offences and the net returns from crime in a system of interrelated markets is still at an embryonic stage. One important implication of the market model already developed is that the efficacy of deterring sanctions cannot be assessed merely by reference to the elasticity of the aggregate supply of offences, but depends on the elasticity of the private demand schedule as well. Likewise, the efficacy of rehabilitation and incapacitation programmes cannot be inferred solely from knowledge of their impact on individual offenders. It depends crucially on the elasticities of the market supply and demand schedules, as these determine the extent to which successfully rehabilitated offenders will be replaced by others responding to the prospect of higher net returns (see Ehrlich 1981; van den Haag 1975). A market setting has also been applied by economists to analyse various aspects of organized crime.

Empirical Analyses

Largely due to the paucity of theoretically relevant data, little has been done thus far to implement a comprehensive market model of illegitimate activity (but see Vandaele 1978). In particular, few studies have sought to estimate the private demand for self-protection as part of a complete market system (see Bartel 1975; Clotfelter 1977). Many researchers have attempted, however, to implement a simultaneous equation model of crime and law enforcement activity consisting, typically, of three sets of basic structural equations (see Ehrlich 1973): supply-of-offences functions linking the rate of offences with deterrence variables and other measurable incentives; production functions of law enforcement activity linking conditional probabilities of arrest, conviction, and punishment with resource inputs and other determinants of productivity; and demand-for-enforcement functions linking resource spending with determinants of public intervention. The bulk of the econometric work concerns the first two structural relationships. (For surveys see Palmer 1977; Andreano and Siegfried 1980; Pyle 1983.)

The econometric applications have been hampered by a number of methodological problems. For example, FBI crime reports are known to understate true crime rates, and related errors of measurement in estimated punishment risks may expose parameter estimation to biases and spurious correlations. The inherent simultaneity in the data requires systematic use of identification restrictions to assure consistent estimation of structural parameters. In testing offenders' responsiveness to incentives, estimates of the deterrent effect of imprisonment must be distinguished from those of its incapacitative effect. Efficient functional forms of structural equations must be selected systematically. And then there is the ubiquitous possibility that results would be biased by 'missing variables' (including links to markets for illicit drugs or handguns). While these problems have been recognized from the outset, not all studies have attempted to resolve them by applying relevant statistical remedies.

Most studies of specific offences report similar findings: probability and length of punishment are generally found to be inversely related to crime rates, and the estimated elasticities of the latter with respect to the conditional risk of apprehension are often found to exceed those with respect to the conditional risks of conviction and punishment. Crime rates are often found to be directly related to measures of income inequality and community wealth (presumably due to the link between affluence and criminal opportunities). Estimates of unemployment effects are somewhat ambiguous, however, depending, in part, on whether they are derived from time-series or cross-section data (see the survey by Freeman

1983), and such is the case also with demographic variables. This pattern of results is derived from studies using aggregate data from different countries and locations, FBI as well as Victimization Survey statistics, and even individual crime data. There also is some evidence that police output measures are weakly responsive to additional resource inputs, although studies differ in their definitions of output and in their specification of the relevant production functions.

Not all research, however, is consistent with the deterrence hypothesis (e.g. Forst 1976; but see its critique by Wadycki and Balkin 1979). Also, criticism has been raised as to the validity of the estimated deterrent effects on grounds of potential biases due to errors of measurement and the identification restrictions used (see Blumstein et al. 1978). Critics have argued that the apparent deterrent effects may mask a deterrent effect of crime on punishment variables. These issues are clearly debatable (see Ehrlich and Mark 1977).

The applicability of the economic approach to the crime of murder, and whether the death penalty constitutes a specific deterrent have raised greater controversy. The centre of debate has been the study by Ehrlich (1975) in which the approach was found to be not inconsistent with time-series evidence (see Blumstein et al. 1978; Ehrlich and Mark 1977). The controversy has generated additional empirical research, some inconsistent with the deterrence hypothesis (e.g., Passell 1975; Forst 1977; Avio 1979; Hoenack and Weiler 1980) and some quite corroborative (e.g. Ehrlich 1977; Wolpin 1978; Phillips and Ray 1982; Layson 1983, 1985).

It is early to assess the degree to which the various econometric studies on crime have produced accurate estimates of critical behavioural relationships. Some studies attempting to test the theory have not, in fact, taken sufficient account of it. Both theory and econometric design, however, must be further developed to account for missing elements of the general market model, thereby facilitating the substantive identification of structural equations and, indeed, the explanation of observed crime variations. While a consensus seems to emerge among researchers regarding the potential power of the economic approach in studying both the illegal sector of the economy and its interaction with the legal economy, future progress will greatly depend on better data.

Crime and the City

Yves Zenou

Abstract

Crime is unevenly distributed across space and tends to be concentrated in poor areas. Recent theoretical advances show that social interactions and peer effects can explain this pattern because of contagion effects and social multipliers. An individual is more likely to commit crime if his or her peers commit crime than if they do not. Recent empirical findings suggest that, indeed, social interactions and networks are key to understand criminal behaviour in cities.

Crime is defined as an act committed in violation of a law forbidding it and for which punishment is imposed upon conviction. Crime is, however, not evenly distributed across space as it tends to be concentrated in specific areas where people are generally poor and uneducated. In both the United States and Europe, the typical urban pattern is that large cities have higher crime rates than smaller cities, and poor, largely minority neighbourhoods experience higher crime rates than more affluent white neighbourhoods (Raphael and Sills 2005). According to the United Nations Interregional Crime and Justice Research Institute, (see Alvazzi del Frate 1997), the percentage of population who are victims of burglary in urban areas with more than 100,000 inhabitants over a five-year period

(between 1992 and 1996) is: 16 for Western Europe, 24 for North America, 20 for South America, 18 for Eastern Europe, 13 for Asia and 38 for Africa. Another typical pattern common to both the United States and Europe is that ethnic minorities are overrepresented in criminal activities. In the United States, the proportion of 20–29-year-old black men directly in trouble with the law (in jail or prison or on probation or parole) reached 23 per cent in 1989 (Freeman 1999). There is, however, one notable difference. Since the mid-1980s, crime has declined in the United States but increased in Europe, especially in large urban areas (Blumstein and Wallman 2000).

Theories

In the standard crime model (Becker 1968), each individual has to implement a cost–benefit analysis in order to choose between becoming a criminal and participating in the labour market. The cost is the severity of punishment, which obviously depends on the probability of being arrested. The benefit consists in the proceeds from crime. If crime is localized, then criminals will trade off a lower probability of being arrested (since, in some areas, a host of criminals are active and the number of policemen is not sufficient) against lower proceeds from crime (more criminals also imply less booty). In this context, Sah (1991) examines the influence of the social environment on individuals' perceptions of the probability of arrest. Indeed, people develop their ideas about the relative benefits and costs of crime based on the observations they make every day. If a person lives in an area with a high crime rate, and particularly if the criminals are seen to be relatively successful, then that person is more likely to engage in criminal activity. The main result of this paper is that individuals in some areas tend to commit more crime than the Beckerian model would predict because of the gap between the perceived and the real cost of committing crime, which leads to a lower sense of impunity based on the information provided by their criminal friends.

Another approach (Verdier and Zenou 2004) proposes that distance to jobs plays a role in crime behaviour and provides a unified explanation for why blacks commit more crime, are located in poorer neighbourhoods and receive lower wages than whites. The mechanism is as follows. If everybody believes that blacks are more prone to crime than whites, even if there is no basis for this, then blacks are offered lower wages and, as a result, locate further away from jobs. Because distant residence implies more tiredness and higher commuting costs, the black–white wage gap is widened further. Blacks have thus a lower opportunity cost of committing crime (lower outside option) and become indeed more criminal than whites. The loop is closed and the beliefs are self-fulfilling.

Whereas the standard Beckerian approach focuses on individual behaviour, Glaeser et al. (1996) stress the role of peers and social interactions in criminal activities, especially in urban areas because of the high variance in crime rates. Two types of individuals are assumed: those who, as in the standard model, base their crime decision on a cost–benefit analysis, and those who only imitate their neighbours. Because of these social interactions, the benefits from crime are greater than in the Beckerian model. Moreover, if these interactions are localized (as is usually the case), then it becomes easy to explain very high levels of crime in some areas of the city. Indeed, if there are already a lot of criminals in a particular location, then crime becomes 'contagious' by spreading like a virus and amplifies the number of criminals in this location. There are social *multiplier* effects through a feedback loop: negative social behaviour such as crime leads to more negative social behaviour.

Calvó-Armengol and Zenou (2004), and Ballester et al. (2004) propose a model along these lines but represent social interactions in terms of a social network of criminal friends. People in a network not only imitate but also influence each other. Here, the cost of committing crime is reduced thanks to the network of friends. Indeed, delinquents learn from other criminals belonging to the same network how to commit

crime in a more efficient way by sharing the know-how about the 'technology' of crime. They show that the influence of peers on the individual's criminal activity depends on his or her position in the network, and each agent's criminal effort is proportional to his or her Bonacich centrality measure (see Bonacich 1987). For a given network, the Bonacich network centrality counts, for each agent, the total number of direct and indirect paths of any length in the network stemming from this agent. Such paths are weighted by a geometrically decaying factor (with path length). In other words, the 'location' of each individual in a network of friends, as measured by the Bonacich centrality measure, is a key determinant of his or her criminal activity.

As a result, in a spatial or social context, an efficient policy aiming at reducing crime would not be, as in the Beckerian model, to increase at random the cost of committing crime, but rather to target criminals according to their location in the urban or social space. Ballester et al. (2004) propose a policy that consists in finding and getting rid of the key player, that is, the criminal who, once removed, leads to the highest aggregate crime reduction. They show that the key player is not necessarily the most active criminal (that is, the one with the highest Bonacich centrality). Indeed, removing a criminal from a network has both a direct and an indirect effect. The direct effect is that fewer criminals contribute to the aggregate crime level. The indirect effect is that the network topology is modified, and the remaining criminals adopt different crime efforts. The key player is the one with the highest overall effect.

Empirical Studies

One of the first tests of the Becker model was undertaken by Ehrlich (1973), who used as explanatory variables the imprisonment rate and the average sentence for the crime in question. More recently, the focus has been on urban or social problems because this is particularly fruitful for understanding personal and property crime as opposed to white-collar crime. Cullen and Levitt (1999), using data for 137 US cities from 1976 to 1993, explore the relationship between crime and urban flight (that is, the flight of the white population from city centres to suburbs). They find that each additional reported crime in city centre is associated with a net decline of about one resident. Causality runs from rising crime rates to city depopulation. Pursuing this area of research, Glaeser and Sacerdote (1999) provide three reasons for higher crime rates in big cities. They report that 27 per cent of the difference between urban and rural crime rates in the United States is due to higher pecuniary benefits for crime in cities, 20 per cent to a lower probability of arrest and recognition in cities, and the remaining 45–60 per cent to the observable characteristics of individuals. This last number can be explained by a positive covariance across agents' decisions about crime, so that the variance of crime rate is higher than the variance predicted by local conditions. This implies that social interactions should matter, especially in cities.

Case and Katz (1991) were among the first to investigate this last issue. Using data from the 1989 NBER survey of youths living in low-income Boston neighbourhoods, they find that the behaviours of neighbourhood peers appear to substantially affect youth behaviours in a manner suggestive of contagion models of neighbourhood effects. The direct effect of moving a youth with given family and personal characteristics to a neighbourhood where 10 per cent more of the youths are involved in crime than in his or her initial neighbourhood is to raise the probability the youth will become involved in crime by 2.3 per cent.

Glaeser et al. (1996) find that, across crimes, crime committed by younger people has higher degrees of social interaction, while, across cities, for serious crimes in general and for larceny and auto theft in particular, the degree of social interactions is larger in those communities where families are less intact, that is, have more female-headed households. Ludwig et al. (2001) and Kling et al. (2005) explore this last result by using data from the Moving to Opportunity (MTO) experiment that assigned a total of 638 families from high-poverty Baltimore

neighbourhoods into three 'treatment groups': (a) Experimental group families receive housing subsidies, counselling and search assistance to move to private-market housing in low-poverty census tracts; (b) Section 8-only comparison group families receive private-market housing subsidies with no programme constraints on relocation choices; and (c) a Control group receives no special assistance under MTO. They show that relocating families from high- to low-poverty neighbourhoods reduces juvenile arrests for violent offences by 30–50 per cent of the arrest rate for control groups. This also suggests very strong social interactions in crime behaviours.

Using a very detailed data-set of friendship networks in the United States from the National Longitudinal Survey of Adolescent Health (AddHealth), Calvó-Armengol et al. (2005) test the main results of Ballester et al. (2004). Contrary to the standard approach, here peer effects are conceived not as an average intra-group externality that affects identically all the members of a given group, but as a collection of dyadic bilateral relationships, which constitutes a social network. The position and thus the centrality of each individual are thus crucial to understand criminal behaviour. Calvó-Armengol et al. (2005) show that, after observable individual characteristics and unobservable network specific factors are controlled for, the individual's position in a network (as measured by his or her Bonacich centrality) is a key determinant of his or her level of criminal activity. A standard deviation increase in the Bonacich centrality increases the level of individual delinquency by 45 per cent of one standard deviation.

C

Crises

P. Kenway

The term 'crisis' as used in economics is principally associated with Marx. While other writers use the term, Marx attempted rigorously to theorize crises as they occur in capitalism. It is therefore his work which will be discussed here.

In one sense, what Marx meant by an economic crisis accords perfectly well with the common use of the term: for example, it would be quite appropriate to use it to describe the liquidation of a company due to bankruptcy or a major financial disruption, involving the collapse of a number of banks. Marx however used the term 'crisis' rather more precisely, applying it to any situation where the process of renewal and expansion of capital was interrupted. Thus, for example, overproduction by one sector of the economy would cause a crisis, whether restricted to that one sector alone, or not. The term also includes the most general crises, affecting all branches of the economy and many national economies simultaneously.

For Marx, long periods of economic decline or stagnation were not 'crises'. Neither should it be thought that by *the* crisis is meant solely the final demise of capitalism. For crises were (and are) a normal and frequent feature of capitalism, and they represent not only a breakdown in the process of capital accumulation, but also the means through which capital reorganizes itself for a fresh burst of accumulation.

Two important points must be made about Marx's theory of crises. The first is that Marx identified the forces which give rise to the possibility of crisis within the process of capitalist production itself. While not disputing that economic crises could also arise as a result of disturbances from outside the economic sphere (such as natural disasters), these were not Marx's concern. Marx attempted to show that crises could be generated 'internally' by capitalism. The second point is to emphasize that there is a distinction within the theory between the analysis of the features of capitalism which give rise to the possibility of crisis, and the analysis of those conditions which turn this latent possibility into reality. Although the 'theory of the possibility of crisis' grows over into the consideration of crises proper, it inevitably precedes it and lays the foundation for this analysis.

Most analyses of the actual content of crises begin with the circuit of capital, M–C–M. The purpose of theory of the possibility of crisis is to show why that form, M–C–M, contains the *potential* for crisis. It is that theory which will be discussed here.

Capitalist production is the production of commodities. To show that crises were intrinsic to capitalism, Marx had therefore to develop the theory of the possibility of crisis from his analysis of the commodity.

A commodity, Marx observed, is a product produced for exchange. It is not produced to meet the needs of the person who produces it. The commodity has two sides to it, its use-value (or usefulness) which is entirely dependent on its physical properties, and its value, the magnitude of which is measured by the amount of socially necessary labour time required for its production. As it is produced for exchange, it has to pass through a series of distinct forms: firstly as 'commodity' then as money and then again as 'commodity'. This commodity circuit is usually depicted as C–M–C.

It is worth explaining this in a little more detail to avoid any ambiguity. Suppose that I manufacture an item for sale. At this stage, my commodity is in its natural or 'commodity' form. Suppose now that I succeed in selling it. My commodity now takes the form of money. It is still a commodity (money is a commodity) but it now takes the form of money where previously it took a physical form. If I now use this money to make a purchase, my commodity has now once more reverted to a natural, 'commodity' form. C–M–C refers to the phases through which the one commodity has to pass, though its circuit is of course intertwined with the circuits of other commodities. In accordance with common sense, the first phase (C–M) is the sale and the second (M–C), the purchase.

A number of observations may now be made. Since the commodity is produced for sale, it must undergo the metamorphosis from 'commodity' to money. Whether it succeeds in this depends on conditions which are external to the commodity, conditions which may or may not prevail. The fact that it must attempt this transformation, the success of which depends upon conditions external to the commodity, is what creates 'the germ of the possibility of crisis' (Marx 1861, p. 507). The possibility of crisis arises from the fact that the commodity may fail to complete this metamorphosis: it may fail to be sold.

It may seem that Marx was doing no more than state the obvious: a commodity must be sold. Such an assessment would be wrong for two reasons. It should be remembered that it is a result derived from his analysis of the commodity, not merely an assertion. Secondly, it is significant that those who deny that crises are an inevitable feature of capitalist production, do so essentially by ignoring or assuming away the very characteristics which Marx's analysis uncovered.

To illustrate this, it is worth looking at how Marx challenged Ricardo's denial of the possibility of general overproduction. Ricardo's position was that: 'Productions are always bought by productions, or by services; money is only the medium by which the exchange is effected' (Ricardo 1821, pp. 291–2). To this, Marx replied:

> Here ... the exchange of commodities is transformed into mere barter of products, of simple use-values. This is a return not only to the time before capitalist production, but even to the time before there was simple commodity production: and the most complicated phenomenon of capitalist production – the world market crisis – is flatly denied by denying the first condition of capitalist production, namely that the product must be a commodity and therefore express itself as money and undergo the process of metamorphosis. (Marx 1861, p. 501)

But if the possibility of crisis lies firstly in the simple metamorphosis of the commodity, in the commodity circuit C–M–C, it is far from fully developed. 'For the development of this possibility into reality', Marx observed, 'a whole series of conditions is required which do not yet even exist from the standpoint of the simple circulation of commodities' (Marx 1867, p. 209). Thus the theory of the possibility of crisis must be extended to take account of the implications of the circuit of capital.

Although the circulation of commodities is the starting point of capital, the circuit of capital is a dramatic transformation of that followed by the commodity. Instead of C–M–C, the capital circuit is M–C–M (Money–'Commodity'–Money). In the capital circuit, capital, as money, is firstly used to buy commodities (means of production, raw materials and labour-power). These are then put to use to produce items for sale which are then sold, if possible, at a profit. With this sale, capital has once more returned to the money form.

> It is worth noting that money plays a quite different role in C–M–C, compared with M–C–M. In the circulation of the commodity, money acts merely as money, as medium of circulation, whereas 'money which describes the latter course in its movement is transformed into capital, becomes capital, and from the point of view of its function, is capital'. (Marx 1867, p. 248)

Two more points of contrast between M–C–M and C–M–C should be mentioned. Firstly, the goal of the simple circulation of the commodity is the acquisition of further commodities for their use-value: the goal is consumption. In contrast, the driving force of the circulation of capital, its determining purpose, is exchange value (Marx 1867, p. 250). Secondly, although both C–M–C and M–C–M contain a sale phase and a purchase phase, the order of the two phases is inverted. In C–M–C, it is selling in order to buy. In M–C–M, it is buying in order to sell.

This inversion has a direct bearing on the development of the possibility of crisis. For obviously, if the circuit is broken, it will be during the sale phase. This creates a problem even under the simple circulation of commodities but its impact is likely to be limited. Once the circuit becomes a capital circuit, a failure to sell has more far-reaching consequences, because it means that the very purpose of production has been thwarted.

Marx illustrated this in his discussion on money as a means of payment. Essentially, a chain of mutual financial obligations develops: should the cloth fail to be sold, then many capitalists will be affected, not just the cloth merchant.

The weaver will not be paid; he in turn will be unable to pay the spinner; neither will be able to pay the machine manufacturer and he in turn will be unable to pay the suppliers of iron, timber and coal. 'This is nothing other than the possibility of crisis described when dealing with money as a means of payment; but here – in capitalist production – we can already see the connection between the mutual claims and obligations, the sales and purchases, through which the possibility can develop into actuality' (Marx 1861, p. 512).

Ricardo's denial of the possibility of general overproduction is now worth another look. His main argument was this:

> No man produces, but with a view to consume or sell, and he never sells but with an intention to purchase some other commodity, which may be immediately useful to him, or which may contribute to future production. By producing, then, he necessarily becomes either the consumer of his own goods, or the purchaser and consumer of the goods of some other person. It is not to be supposed that he should, for any length of time be ill-informed of the commodities which he can most advantageously produce, to attain the object which he has in view, namely, the possession of other goods; and therefore, it is not probable that he will continuously produce a commodity for which there is no demand. (Ricardo 1821, p. 290)

Marx found fault with this on three counts. Firstly, in saying that a man may produce in order to consume, Ricardo was again overlooking the fact that commodities are produced to be sold, and not to meet the needs of the producer. It is true that where production is for the direct satisfaction of the producer, there are no crises. But such a situation is not even simple commodity production, let alone capitalist production (Marx 1861, p. 502).

Marx's second criticism goes to the very heart of the matter:

> A man who has produced does not have the choice of selling or not selling. He must sell. In the crisis there arises the very situation in which he cannot sell or can only sell below the cost price or must even sell at a positive loss. What difference does it make to him or us that he has produced in order to sell? The very question we want to solve is what has thwarted that good intention of his? (Marx 1861, p. 503)

Finally, 'no man sells but with an intention to purchase'? Not so, said Marx, who added that a capitalist may sell in order to pay, especially during a crisis. And:

> During the crisis, a man may be very pleased if he has sold his commodities without immediately thinking of a purchase … The immediate purpose of capitalist production is not 'possession of other goods' but the appropriation of value, of money, of abstract wealth. (Marx 1981, p. 503)

In the circulation of capital, M–C–M, the possibility of crisis is developed to its fullest extent. Firstly, it is a development of the 'simple' circulation of commodities, C–M–C, and therefore contains the 'simple' possibility of crisis, namely that commodities must (yet may not be able to) undergo a sequence of transformations. Secondly, under capitalist production, money as means of payment introduces a far-reaching set of connections between capitals. Thirdly, the fact that the goal of capitalist production is the acquisition of abstract wealth, rather than other use-values, means that the presence of use-values for sale is no longer sufficient to ensure that sales will take place, let alone at prices which will give the desired return.

Marx's criticism of Ricardo has a wider significance. Ricardo was criticized here not for erring in his deductions, but rather because the starting point for those deductions, his 'model', was inappropriate. Leaving aside those unfortunate moments when he was using arguments relevant only to a barter economy, Ricardo's model was one of simple commoditiy production, characterized by the circuit C–M–C. This was inappropriate, said Marx, because the circulation of capital, M–C–M, contains new possibilities for crises, not contained in the simple circulation C–M–C.

If Marx was right about this, then any model of production and exchange where the objective is consumption (that is, the acquisition of use-values rather than value in general) by its very nature excludes those specifically *capitalist* causes of the possibility of crisis.

The converse of this is that a proper consideration of capitalist crisis must consider not only use-values but value too: 'value, abstract wealth, money'. In this respect, Keynes's introduction of effective demand into the orthodox theory of his time can be seen as an attempt to remedy the same

one-sidedness of that theory which Marx criticized in Ricardo. Indeed, the theory of the possibility of crisis can help show why 'effective demand' – a monetary quantity – is important in its own right and why Keynes was justified in elevating it to a place of considerable importance (Kenway 1980).

Ricardo denied that crises could arise out of the production process itself. In his defence, Marx commented that Ricardo himself did not actually experience any such crises (Marx 1861, p. 497). All the crises between 1800 and 1815 could be attributed to external conditions: poor harvest; interference with the currency by the authorities; the wars. After 1815, the crises could be explained quite readily by reference to the strains of the change from war to peace. Yet as Marx observed, these interpretations were not available to Ricardo's followers. And neither, of course, are they available today.

Critical Path Analysis

Kenneth R. MacCrimmon

When consumers plan vacations, manufacturers schedule production, and governments tackle budget deficits, each must deal with a myriad of interrelated activities. In large projects, managing these interrelationships is very difficult due to three major factors: the precedence ordering of activities, the uncertainty about activity durations, and the possibility of reallocating resources.

Even if there were only one way to perform an activity and if the time it took to complete it were known for sure, there would still be the problem of determining when an activity can begin. A book cannot be bound until it is printed, cannot be printed until it is edited, and cannot be edited until it is written. When one realizes that there are hundreds of activities in book publishing, it is clear that effective management requires some way of keeping track of the precedence order of activities.

A further complexity is the uncertain duration of activities. People get sick, buildings burn down, funds are scarce and so activities often take longer than expected. Although delays in some activities will be relatively unimportant, delays in others will delay the whole project. Effective project management must focus attention on such critical activities.

The third major complication is due to the multiplicity of ways in which things can be done. By allocating more resources, an activity can be speeded up. By allocating fewer resources, costs can be held down, although delays will probably occur. Project managers need a way of determining how resources can be effectively allocated.

Critical path analysis (CPA) is the generic name for a set of techniques to help people deal with the problems of managing projects. The basic elements in CPA are: (i) the specification of activities necessary to complete a project; (ii) their precedence order represented by a directed, acyclic network diagram; (iii) the identification of the critical activities, especially those activities on the longest path through the network (i.e., the critical path); and (iv) the determination of cost–time tradeoffs for the whole project.

Critical path analysis can be viewed as the consolidation and extension of the ideas of Henry Gantt and Vilfredo Pareto. In the early 1900s, Gantt proposed a graphical method for scheduling and controlling production activities.

A Gantt chart represents each production activity as a row with a bar drawn to scale representing how long the activity takes. The bar is positioned in calendar time by taking into account the precedence relationships among activities, although these relationships are not shown directly.

Pareto suggested that a small proportion of components had an undue effect on the performance of a system. For example, 10 per cent of a company's sales force often account for 90 per cent of the sales. This concept, sometimes under the label of the 'Pareto principle', became adopted as a regular management control technique. Both John Commons and Chester Barnard incorporated this concept of the 'critical factor' or 'strategic factor' in their economic theories of organization.

In the late 1960s two independent techniques, PERT (Program Evaluation and Review Technique) and CPM (Critical Path Method), were created to help manage very large projects. PERT was used in handling the tens of thousands of activities in developing weapon systems for Polaris submarines for the US Navy (Malcolm et al. 1959). CPM was developed for controlling large construction projects in industry (Kelley and Walker 1959). Both methods can be viewed as a Gantt chart embedded in a network that shows the interdependencies among activities. This representation shows how the expected start and completion times of any activity depend on the progress of the activities that precede it. By identifying which activities can delay the whole project and which can expedite the project, the concept of critical factors is developed into a concept of a 'critical path'. By associating time–cost trade-offs with each activity, it becomes clear that one speeds up a project by allocating resources to critical activities and one saves money by withdrawing resources from non-critical activities.

Even though both PERT and CPM used very similar ideas in network representation and the identification of critical paths, each technique had its own unique features. In PERT, the arcs in a network represented the activities and the nodes represented starting and ending points, while in CPM the nodes represented the activities and the arcs indicated the precedence relationships. A more significant difference was that PERT allowed for uncertainty in the duration of an activity while CPM exhibited time-resource trade-offs. Since both uncertainty and resource trade-offs are key elements of any large project, both PERT and CPM made distinctive contributions.

PERT assumed that the uncertainty in the duration of an activity could be represented by a Beta distribution, the parameters of which are derived from three time estimates, a most likely time, an optimistic time, and a pessimistic time provided by project managers. Using the Central Limit Theorem, the overall project time is normally distributed with a mean (variance) equal to the sum of the means (variances) of activity distributions along the critical path. The possible errors in the PERT assumptions, at both the level of individual activities and at the level of the whole project have been analysed (MacCrimmon and Ryavec 1959). The assumption of independence among activities (allowing means and variances to be summed) is particularly weak. Environmental events that delay one activity are likely to delay other activities and so the estimated completion time will tend to be optimistic. Methods have been proposed for grouping network elements to reduce bias and for using simulation techniques to overcome some of the analytical difficulties.

While PERT focuses on time management, CPM focuses on the cost of performing activities. Piecewise linear time–cost tradeoffs are developed from information provided by project managers. For any desired project completion time, linear programming can be used to ascertain the minimum project variable cost subject to resource availabilities. By varying the project completion time parameter, a frontier of tradeoffs of total variable cost and completion times is obtained. By focusing only on the cost of the resources, the allocation of specific resources remains to be determined separately. The resources for speeding up one activity may be committed elsewhere.

Clearly, both PERT and CPM can help to plan and control large projects. By combining the best features of each, there is promise for developing more powerful methods. One of the first modifications was the development of PERT–COST which took into account project costs, although

in more of a monitoring role than in CPM. Over time the original distinctions between PERT and CPM have become blurred and it is reasonable to focus on a generic CPA. Advances have taken place in two main areas, handling uncertainty and managing resources.

Handling project uncertainty has been improved by de-emphasizing the single most critical path. When delays occur, other paths may become the critical path, thus activities that are common to several of these paths should be monitored carefully. Methods allowing for a more flexible treatment of uncertainty in the activity durations have also been developed (Elmaghraby 1977).

There is also uncertainty in how a project can be carried out. As the project goes along, the results of early activities influence the way later activities are performed. For example, the outcome of research and development on a new kind of memory may have major implications for the construction of a computer. More advanced network models, then, allow for uncertainty in network structure such as disjunctive activities whereby one activity is performed in lieu of another (Pritsker and Sigal 1983).

A second major area of improvement has been in handling resources (Dean and Chaudhuri 1980). Procedures for resource smoothing were used to avoid costly fluctuations such as continual hiring and firing in the labour force. Methods have been proposed for splitting jobs, allowing for halting the performance of one activity and transferring resources to where they are most needed. More sophisticated techniques have been developed for handling multiple categories of resource types and for handling uncertainty about the availability of resources. Other advances have incorporated information about the quality of performance of the activity.

Critical path analysis is now widely used in one form or another. Many actual applications, however, involve only the most basic elements such as the network representation. Why aren't some of the more advanced methods used? As one manager is reported to have said about the time estimates required in PERT, 'activity durations are too uncertain to try to use more than one time estimate'! With better analytical training, with microcomputers, and with sophisticated computer programs, perhaps the uses of critical path analysis will begin to catch up with the developments in the methods.

Croce, Bendetto (1866–1952)

R. Bellamy

Croce was a southern Italian idealist philosopher and historian. His *Philosophy of Spirit* was intended as a secular religion capable of encompassing all aspects of human life. He regarded as his greatest innovation the addition of the category of the Useful to the classical triad of the Beautiful, the True and the Good. He elaborated this theory in the course of his early

writings on Marx (1900b) and a debate with Pareto 'On the Economic Principle' (1900a). He argued that human practical activity was orientated to solving the immediate problems of everyday life, and hence highly contingent. We only discover the moral worth of an act post facto, when the consequences can be evaluated. Our action is therefore directed at the Useful and only indirectly at the Good. Whilst all moral acts are economic, the reverse is not the case. He rejects hedonism and egoism as ethical theories, since happiness and self-interest may be good guides to the utility of an act to an agent at a given time, but not necessarily to its ultimate moral worth. He therefore disputed Pareto's contention that you could develop a science of economics based on certain constant features of human behaviour. All human activity is conditioned by chance and the diversity of beliefs different individuals hold. This fact similarly vitiated Marx's historical materialism. These ideas were later expanded into his *Philosophy of the Practical* (1908). However, in a later debate he denied Luigi Einaudi's conclusion that his theory implied classical liberal laissez-faire policies (1928). He asserted that certain conditions could warrant welfare socialism. A moderate conservative rather than a liberal, he belatedly opposed fascism, partly because his philosophy provided few action guiding principles in the present beyond the endorsement of whatever succeeds. The judgement of events is left to history.

Crosland, Anthony (1918–1977)

I. M. D. Little

Born in 1918, Crosland read classics at Trinity College, Oxford (1937–40). Always a socialist, he led the undergraduate faction that opposed the Communist creed embraced by many left-wing intellectuals of that period. War service, as a paratrooper, claimed him for the next five years. Returning to Oxford, he became President of the Union, took a first class degree in politics and economics, and was appointed to a Fellowship at Trinity College. He taught economics for three years, then in 1950 began a political career as a Labour Member of Parliament.

His most important book, *The Future of Socialism* (1956), sought to define the role of a Socialist government in a modern industrial state. Essentially anti-utopian and revisionist, it was as opposed to latter-day Marxism as to Toryism. Crosland insisted that Socialism was about equality, not the ownership of the means of production. Greater equality was facilitated by economic growth, and high levels of government expenditure and intervention were also required.

For 20 years his views strongly influenced the Labour Party. Between 1964 and his sudden death in 1977 when he had been Foreign Secretary only 10 months, he held four senior Cabinet posts in which he initiated measures born of his political philosophy, particularly in education and housing.

But government failure to achieve sufficient growth frustrated many of his aspirations. And after his death his blueprint for the future of socialism became less realizable. Always an optimist, he underestimated the economic and social forces that would obstruct his programmes.

Cross-cultural Experiments

Rob Boyd

Abstract

Experiments conducted in student populations suggest that people are not money maximizers, but also seem to have social preferences. To determine whether these social preferences are culturally variable, a group of economists and anthropologists undertook a series of economic experiments in a wide range of non-Western, small scale societies. Results in these societies were highly variable, and in some of them strikingly different from experiments in student populations. Variation in behaviour was correlated with societal characteristics, but not individual attributes. Finally, variation in punishment across societies predicted variation in cooperation across societies.

C9

A large number of well-replicated results using a wide variety of experimental games are inconsistent with the assumption that people are money maximizers. Instead, people's behaviour is consistent with choices based on social preferences in which people place a positive value on fairness, reciprocity, or equity (see Camerer 2003, for a review). For example, subjects typically make significant positive contributions in the public goods games, reject positive offers in the ultimatum game, and impose costly punishment in the third-party punishment game (see Camerer 2003, ch. 2, for descriptions of these games.) In some games these results are insensitive to framing and whether behaviour is anonymous to the experimenter ('double blind').

These experiments are open to two qualitatively different interpretations: It could be that pro-social behaviours like cooperation in the public goods game and punishment in the third-party punishment game reflect human nature. Cooperation in the public goods game could result from universal cognitive systems that cause people everywhere to behave as if all acts have reputational consequences, even when facts suggest no one will know what they have done. Punishment in the third-party punishment game could result from a pan-human motivational system that causes people to prefer outcomes that are fair or mutually beneficial, and to derive satisfaction from punishing unfair behaviour. However, with few exceptions experimental subjects have been university students in urbanized, industrial societies. Thus, it also could be that observed pro-social behaviour results from culturally evolved beliefs and values that are specific to such social environments. It is obviously of great importance to determine which of these two interpretations is correct.

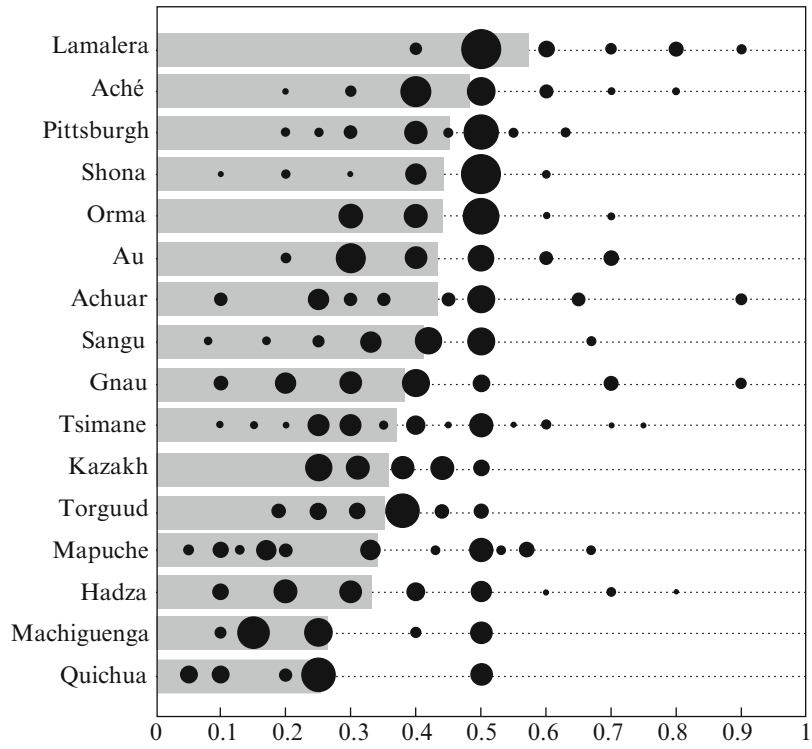
To answer this question, a team of anthropologists and economists performed two rounds of

experimental games in a wide range of cultural environments. The first round (Henrich et al. 2004, 2005) comprised a diverse group of 15 societies including peoples like the Aché and Hadza who live in nomadic foraging bands, the Achuar and Au who live in small villages and mix hunting and horticulture, Mongol and Sangu pastoralists, and sedentary Shona farmers in Zimbabwe. The ultimatum game was performed in all 15 societies, and the public goods game and the dictator game were performed in different subsets. The second round (Henrich et al. 2006) included a similar and overlapping range of 15 societies. Based on experience in the first round, experimental protocols were improved and standardized, and a greater effort was made to collect standardized data on individual characteristics. During the second round the ultimatum, dictator, and third-party punishment games were performed in all 15 societies. In addition complete strategies for second players in the ultimatum game and punishers in the third-party punishment game were elicited using the strategy method.

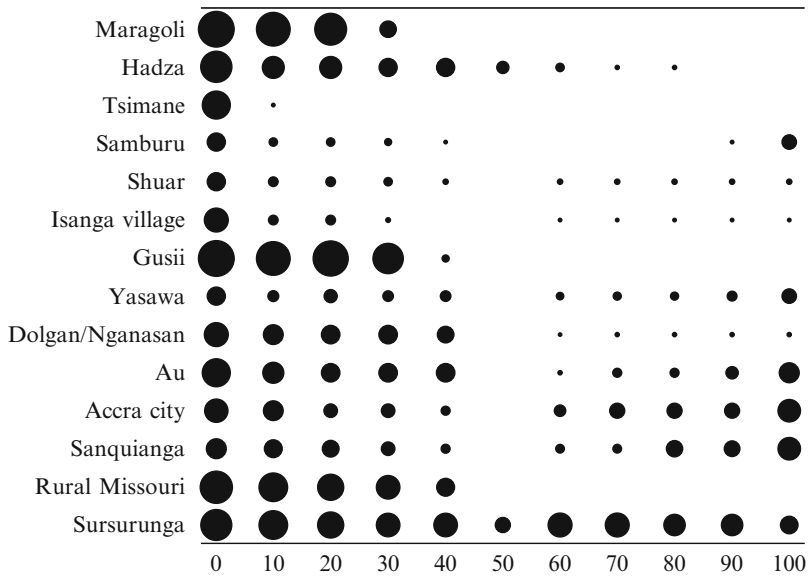
These experiments reveal a number of interesting results.

1. *Behaviour in non-Western populations can be quite different from that of Western university subjects.* Figure 1 shows the distribution of ultimatum game offers in the first round of experiments. The Pittsburgh data taken from Roth et al. (1991) are typical for university populations – the modal offer is 50 per cent but many subjects make somewhat lower offers. Behaviour in other populations can be very different. For example, modal offers are much lower among two lowland tropical forest groups; the Achuar and the Machiguenga are quite low. Interestingly, these very low offers were usually accepted, behaviour much closer to the predictions of money maximization than the behaviour of Western university subjects. Non-western populations also exhibited novel behaviours not seen in university populations.

   Figure 2 shows the rejection probabilities for different ultimatum game offers. Notice



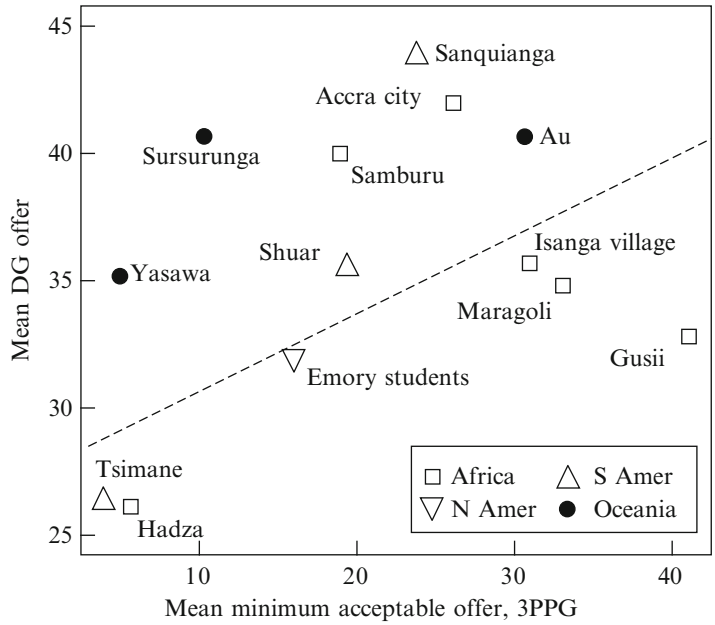
Cross-cultural Experiments, Fig. 1 Ultimatum game offer. *Note:* A *bubble plot* showing the distribution of ultimatum game offers for each group. The diameter of the circle at each location along each row represents the proportion of the sample that made a particular offer. The *right edge* of the *lightly shaded horizontal grey bar* is the mean offer for that group. In the Machiguenga row, for example, the mode is 0.15, the secondary mode is 0.25, and the mean is 0.26. *Source:* Henrich et al. (2005)



Cross-cultural Experiments, Fig. 2 Ultimatum game rejection rates. *Note:* The diameter of the *black circles* is proportional to the fraction of offers that would have been rejected in the ultimatum game during the second round of experiments plotted as a function of the offer as a percentage of the maximum offer. For scale, note that the Gusii and Maragoli rejected all offers of zero. Notice that in all societies offering 50% of the stake minimizes the probability of rejection, but that in a number of societies increasing offers above 50% increases the rate of rejection. *Source:* Henrich et al. (2006)

that in several populations increasing offer level above 50 per cent *increased* the rate of rejections, a phenomenon not observed among student subjects.

2. *Behavioural differences are correlated with group characteristics but not individual characteristics.* The ethnographers who performed most of these experiments have studied these groups for many years and have detailed data on subjects about income, wealth, education, market contact, and a variety of other factors. None of these factors was significantly correlated with ultimatum game offers within social groups in first round, or offers or rejections in the second round. Because measures of wealth, income, and so on are not comparable across groups, these measures could not be aggregated to derive group characteristics. However, during the first round, ethnographers who were blind to the results ranked each of the groups along five dimensions: extent of cooperation in subsistence, degree of market contact, amount of privacy, amount of anonymity, and social complexity. We also had comparable data on settlement size. It turned out that market contact, settlement size, and social complexity were all highly correlated, so these were collapsed into a single variable labelled 'aggregate market contact'. Multiple linear regression showed that increasing aggregate market contact and cooperation in subsistence significantly predicted increased ultimatum game offers, and together the two variables accounted for more than half of the variance among groups in average offers.
3. *Variation in punishment predicts variation in altruism across societies.* In the third-party punishment game, an individual, the 'punisher' observes a dictator game and can punish the dictator at a cost to him or herself. The average minimum offer acceptable to the punisher in this game provides a measure of the level of punishment in that society. As is shown in Fig. 3, this measure of punishment also predicts the level of altruism measured by dictator offers in the ordinary dictator game.



Cross-cultural Experiments, Fig. 3 Mean minimum acceptable offer, third-party punishment game. *Note:* The mean offer in the dictator game for a society plotted against the mean value of the minimum acceptable offer in the third-party punishment game. The different symbols indicate continents. The size of each symbol is proportional to the number of DG pairs at each site. The *dotted line* gives the weighted regression line, with continental controls of mean dictator game offers against mean minimum acceptable offer in the third-party punishment game. *Source:* Henrich et al. (2006)

Taken together these results indicate that pro-social behaviour in economic experiments does not result from an invariant property of our species, and instead suggest that there are significant cultural differences between societies. The fact that ultimatum game behaviour is predicted by the average level of cooperation and average level of market contact further indicates that these cultural differences are not arbitrary, but may reflect economic, ecological and social differences between societies. However, the lack of correlation between individual characteristics and individual behaviour indicates that the differences between societies are not likely to be explained as the simple aggregation of individual experiences. Instead, it is more plausible that cultures evolve over time in response to the average conditions which they face, and that individual behaviour is, in turn, shaped by these cultural differences.

Crowding Out

Olivier Jean Blanchard

Abstract

'Crowding out' refers to all the things which can go wrong when debt-financed fiscal policy is used to affect output. While the initial focus was on the slope of the LM curve, 'crowding out' now refers to a multiplicity of channels through which expansionary fiscal policy may in the end have little, no or even negative effects on output.

'Crowding out' refers to all the things which can go wrong when debt-financed fiscal policy is used to affect output.

A first line of argument questions whether fiscal policy has any effect at all on spending. Changes in the pattern of taxation which keep the pattern of spending unaffected do not affect the intertemporal budget constraint of the private economy and thus may have little effect on private spending. This argument, known as the 'Ricardian equivalence' of debt and taxation, holds only if taxes are lump sum (Barro 1974). Some taxes which induce strong intertemporal substitution, such as an investment tax credit for firms, will have stronger effects if they are temporary; for most others, such as income taxes, changes in the intertemporal pattern may have only a small effect on the pattern of spending.

The Ricardian equivalence argument is not settled empirically and its validity surely depends on the circumstances. A change in the intertemporal taxation of assets such as land or housing, leaving the present value of taxes the same, will have little effect on their market value, thus on private spending. An explicitly temporary income tax increase may have little effect on spending while the anticipation of prolonged deficits may lead taxpayers to ignore the eventual increase in tax liabilities. Evidence from specific episodes, such as the 1968 temporary tax surcharge in the United States, suggests partial offset at best.

Changes in the pattern of government spending obviously have real effects. But here again, various forms of direct crowding out may be at work. Public spending may substitute perfectly or imperfectly for private spending, so that changes in public spending may be directly offset, fully or partially, by consumers or firms. Even if public spending is on public goods, the effect will depend on whether the change in spending is thought to be permanent or transitory. Permanent changes, financed by a permanent increase in taxes, will, as a first approximation, lead to a proportional decrease in private spending, with no effect on total spending. Temporary changes in spending, associated with a temporary increase in taxes, lead to a smaller reduction in private spending and thus to an increase in total spending.

In summary, one should not expect any change in taxation or government spending to have a one-for-one effect on aggregate demand. An eclectic reading of the discussion above may be that only

sustained decreases in income taxation, or the use of taxes that induce strong intertemporal substitution, or temporary increases in spending, can reliably be used to boost aggregate demand. The focus in what follows will be on these forms of fiscal expansion.

Crowding Out at Full Employment

Not every increase in aggregate demand translates into an increase in output.

This is clearly the case if the economy is already at full employment (I use 'full employment' to mean employment when unemployment is equal to its natural rate). While tracing the effects of fiscal expansion at full employment is of limited empirical interest, except perhaps as a description of war efforts, it is useful for what follows. If labour supply is inelastic, output is fixed and any increase in aggregate demand must be offset by an increase in interest rates, leaving output unchanged. In the case of an increase in public spending, private spending will decrease; in the case of a decrease in income taxation, private spending will in the end be the same, but its composition will change as the share of interest sensitive components decreases. (If labour supply can vary, the story is more complicated. See, for example, Baxter and King 1993, for an analysis of changes in government spending in an otherwise standard RBC model.)

This is just the beginning of the story, however. Over time, changes in capital and debt lead to further effects on output. The decrease in investment in response to higher interest rates leads to a decline in capital accumulation and output, reducing the supply of goods. If fiscal expansion is associated with sustained deficits, the increase in debt further increases private wealth and private spending at given interest rates, further increasing interest rates and accelerating the decline in capital accumulation (see, for example, Blanchard 1985, for a characterization of these dynamic effects in an economy with finite horizon consumers). How strong is this negative effect of debt on capital accumulation likely to be? One of the crucial links in this mechanism is the effect of government debt on interest rates; empirical evidence, both across countries and from the last two centuries, shows surprisingly little relation between the two. This probably reflects, however, more the difficulty of identifying and controlling for other factors than the absence of an effect of debt and deficits on interest rates.

Worse can happen. It may be that the fiscal programme becomes unsustainable. There is no reason to worry about a fiscal programme in which debt grows temporarily faster than the interest rate. But there is reason to worry when there is a positive probability that, even under the most optimistic assumptions, debt will have to grow for ever faster than the interest rate. When this is the case, it implies that the government can meet its interest payments on existing debt only by borrowing more and more. What happens then may depend on the circumstances. Bond holders may start anticipating repudiation of government debt and require a risk premium on the debt, further accelerating deficits and the growth of the debt. If they instead anticipate repudiation through inflation, they will require a higher nominal rate and compensation for inflation risk in the form of a premium on all nominal debt, private and public. What is sure is that there will be increased uncertainty in financial markets and that this will further contribute to decreases in output and in welfare. The historical record suggests that it takes very large deficits and debt levels before the market perceives them as potentially unsustainable. England was able in the 19th century to build debt-to-GDP ratios close to 200 per cent without apparent trouble. Some European countries are currently running high deficits while already having debt-to-GDP ratios in excess of 100 per cent, without any evidence of a risk premium on government debt. The threshold seems lower for Latin American economies. But even if one excludes this worst-case scenario, fiscal expansion can clearly have adverse effects on output at full employment. The relevant issue, however, is whether the same dangers are present when fiscal expansion is implemented to reduce unemployment, which is presumably when it is most likely to be used.

Crowding Out at Less Than Full Employment

The historical starting point of the crowding out discussion is the fixed price IS–LM model. In that model, a fiscal expansion raises aggregate demand and output. The pressure on interest rates does not come from the full employment constraint as before but from the increased demand for money from increased output. Thus the fiscal multiplier is smaller the lower the elasticity of money demand to interest rates, or the larger the elasticity of private spending to interest rates. Fiscal expansion crowds out the interest-sensitive components of private spending, but the multiplier effect on output is positive. As output and interest rates increase, it is quite possible for both investment and consumption to increase. But what happens when the model is extended to take into account dynamics, expectations and so on? Can one overturn the initial result and get full crowding out or even negative multipliers?

Even within the static IS–LM, one can in fact get zero or negative multipliers. This is the case, for example, if money demand from agents is higher than that from the government and the change in policy redistributes income from the government to agents. While this case is rather exotic, a much stronger case can be made if the economy is small, open, and with capital mobility and flexible exchange rates, as in the 'Mundell–Fleming' model. In this case, with the interest rate given from outside, and fixed money supply, money demand determines output; fiscal policy leads only to exchange rate appreciation. Exchange rate-sensitive components are now crowded out by fiscal expansion. The multiplier is equal to zero.

When dynamic effects are taken into account, other channels arise for crowding out. The analysis of these dynamic effects, with the dynamics of debt accumulation taken into account, was initially conducted under the maintained assumption of fixed prices and demand determination of output (Tobin and Buiter 1976). Then, as debt was accumulating, private wealth and spending increased, leading to even larger effects of fiscal policy on output in the long run than in the short run. But the assumption of fixed prices, while debt and capital accumulation are allowed to proceed, is surely misleading; when prices are also allowed to adjust, the effects of fiscal policy become more complex, and crowding out more likely. This is because some of the full employment effects come back into prominence: if fiscal expansion is maintained even after the economy has reached full employment, then the perverse effects of higher interest rates on capital accumulation and full employment output come again into play. This is true even if deficits disappear before the economy returns to full employment; the economy inherits a larger level of debt, and thus must have higher interest rates and lower capital accumulation than it would otherwise have had. The fiscal expansion trades off a faster return to full employment for lower full-employment output.

Anticipations of these full employment effects are likely to feed back and modify the effects of fiscal policy at the start, when the economy is still at less than full employment. Anticipations of higher interest rates, perhaps also of higher distortions due to the higher taxes needed to service the debt, may dominate the direct effects of higher government spending on demand, and lead to an initial decrease rather than an initial increase in demand and output. Symmetrically, fiscal consolidation, to the extent that it implies lower interest rates and lower distortions in the future, may be expansionary. This is even more likely to be the case if fiscal consolidation decreases the risk of default on government debt, and thus decreases the risk of major economic disruptions. There is indeed some evidence that, when initial fiscal conditions are very bad, and the fiscal consolidation is large and credible, the net effect of consolidation may be expansionary (Giavazzi and Pagano 1990).

Crowding Out: An Assessment

Should one conclude from this that fiscal policy is an unreliable macroeconomic tool, with small and sometimes negative effects on output? The answer is 'no'. Fiscal policy is likely to partly crowd out some components of private spending, even in the

best circumstances, but there is little reason to doubt that it can help the economy return to full employment. Ricardian equivalence and direct crowding out warn us that not any tax cut or spending increase will increase aggregate demand. But there is little question that temporary spending or sustained income tax cuts will do so. Results of full crowding out at less than full employment, such as the Mundell-Fleming result, are simply a reminder that the monetary-fiscal policy mix is important.

In all cases, monetary accommodation of the increased demand for money removes the negative or the zero multipliers. That fiscal expansion affects capital accumulation, and output adversely at full employment, and that unsustainable fiscal programmes may lead to crises of confidence, is a reminder that fiscal expansion should not be synonymous with steady increases in the debt-to-GDP ratio even after the economy has returned to full employment. This shows one of the difficulties associated with fiscal expansion: if done through tax cuts, it has to be expected to last long enough to affect private spending, but not so long as to lead to expectations of runaway deficits in the long run. The room for manoeuvre is, however, substantial. Some taxes, such as the investment tax credit, work best when temporary. These can be used, as they work in the short run and have few adverse implications for the long run.

Crowther, Geoffrey (1907–1972)

R. J. Bigg

Crowther was educated at Leeds Grammar School, Oundle and Clare College, Cambridge, where after studying modern languages he proceeded to win a high first in Part II of the Economics Tripos. Lionel Robbins remembered one of his examination answers as being only a few sentences: 'the way he put it left nothing more to be said' (Robbins 1972, p. 23). This ability to go to the heart of the matter Crowther carried into his work at *The Economist*.

Prior to this however he went to Yale and Columbia Universities as a Commonwealth Fund Fellow (he married an American, Margaret Worth, in 1932) and then worked for two years in a London merchant bank. This led to his appointment as economic adviser on banking to the Irish government. Crowther gave up the Irish appointment to join *The Economist* in 1932, becoming assistant editor in 1935 and editor in 1938. Crowther was the longest major editor of the newspaper, holding the post from 1938 to 1956 – Robbins compared him to the paper's previous great editor, Walter Bagehot. After 1956 he maintained his contact with the journal, first as Managing Director and later as Chairman.

Under Crowther *The Economist* changed radically in its format so as to widen its appeal to a broader readership both in the UK and overseas, expanding its circulation from 10,000 to 55,000 and becoming one of the most influential weekly papers in the world. Crowther was also responsible for the establishment of the Economist Intelligence Unit just after World War II and for the

newspaper's successful development of its St James's property. He was also one of the first newspaper editors to appoint women, such as Barbara Ward, to the staff in significant positions.

His major theoretical work on economics was *An Outline of Money* (1940), which, like his journalistic writings, had 'a clarity and expository power which few academics could muster' (Robbins 1972, p. 23) as well as a lively style and was quickly popular with both students and the general public. His other works on economics, such as *Ways and Means* (1936) stemmed from broadcasts or lectures.

Crowther's magnetic personality and prodigious capacity for work made him an outstanding public servant (Goode 1974). His principal public interest was in education. He was Chairman of the Central Advisory Council for Education (England) from 1956 to 1960, whose report '15 to 18' was a landmark in the expansion of further education. As the first Chancellor of the Open University (1968) he played a major part in its early development. He then took on the joint responsibilities of chairing both the Royal Commission on the Constitution and the Committee on Consumer Credit, whose report (1971) recommended the complete reform of consumer credit law (embodied in the Consumer Credit Act of 1974) and of personal property security law. Crowther was knighted in 1957 for his services to journalism and in 1968 he became a life peer, taking his title from Headingley, the place of his birth.

Cryptocurrency

Eli Dourado and Jerry Brito

Abstract

For most of history, humans have used commodity currency. Fiat currency is a more recent development, first used around 1000 years ago, and today it is the dominant form of money. But this may not be the end of monetary history. Cryptocurrency is neither commodity money nor fiat money – it is a new, experimental kind of money. The cryptocurrency experiment may or may not ultimately succeed, but it offers a new mix of technical and monetary characteristics that raise different economic questions than other kinds of currency.

This article explains what cryptocurrency is and begins to answer the new questions that it raises. To understand why cryptocurrency has the characteristics it has, it is important to understand the problem that is being solved. For this reason, we start with the problems that have plagued digital cash in the past and the technical advance that makes cryptocurrency possible. Once this foundation is laid, we discuss the unique economic questions that the solution raises.

Technical Overview

Cryptocurrency is the name given to a system that uses cryptography to allow the secure transfer and exchange of digital tokens in a distributed and decentralised manner. These tokens can be traded at market rates for fiat currencies. The first cryptocurrency was Bitcoin, which began trading in January 2009. Since then, many other cryptocurrencies have been created employing the same innovations that Bitcoin introduced, but changing some of the specific parameters of their governing algorithms. The two major innovations that Bitcoin introduced, and which made cryptocurrencies possible, were solutions to two long-standing problems in computer science: the double-spending problem and the Byzantine Generals Problem.

Double Spending

Until the invention of Bitcoin, it was impossible for two parties to transact electronically without employing a trusted third party intermediary. The reason was a conundrum known to computer scientists as the 'double spending problem', which has plagued attempts to create electronic cash since the dawn of the Internet.

To understand the problem, first consider how physical cash transactions work. The bearer of a physical currency note can hand it over to another person, who can then verify that he is the sole possessor of that note by simply looking at his hands. For example, if Alice hands Bob a $100 bill, Bob now has it and Alice does not. Bob can easily verify his possession of the $100 bill and, implicitly, that Alice no longer has it. Physical cash transfers are also final, in the sense that to reverse a transaction the new bearer must give back the currency note. In our example, Bob would have to hand the $100 bill back to Alice. Given all of these properties, cash makes it possible for different parties, including strangers, to transact without trusting each other.

Now, consider how electronic cash might work. Obviously, paper notes would be out of the picture. There would have to be some kind of digital representation of currency. Essentially, instead of a $100 bill, we might imagine a $100 computer file. When Alice wants to send $100 to Bob, she attaches a $100 file to a message and sends it to him. The problem, as anyone who has sent an email attachment knows, is that sending a file does not delete it from one's computer. Alice will retain a perfect digital copy of the $100 she sends Bob, and this would allow her to spend the same $100 a second time, or indeed a third and fourth. Alice could promise to Bob that she will delete the file once he has a copy, but Bob has no way to verify this without trusting Alice.

Until recently, the only way to overcome the double spending problem was to employ a trusted third party intermediary. In our example, both Alice and Bob would have an account with a third party that they each trust, such as PayPal. Trusted intermediaries like PayPal keep a ledger of all account balances and transactions. When Alice wants to send $100 to Bob, she tells PayPal, which in turn deducts the amount from her account and adds it to Bob's. The transaction reconciles to zero. Alice cannot spend the same $100, and Bob relies on PayPal, which he trusts, to verify this. At the end of the day, all transfers among all accounts reconcile to zero. Note, however, that unlike cash, transactions that involve a third party intermediary are not final, as we have defined it, because transactions can be reversed by the third party.

In 2008, Satoshi Nakamoto (a pseudonym) announced a way to solve the double spending problem without employing third parties (Nakamoto 2008). His invention, Bitcoin, is essentially electronic cash. It allows for the first time the final transfer, not the mere copying, of digital assets in a way that can be verified by users without trusting other parties. This is accomplished through the clever use of public key cryptography, peer-to-peer networking and a proof-of-work system.

Like PayPal, the Bitcoin system employs a ledger, which is called the block chain. All transactions in the Bitcoin economy are recorded and reconciled in the block chain. However, unlike PayPal's ledger, the block chain is not maintained by a central authority. Instead, the block chain is a public document that is distributed in a peer-to-peer fashion across thousands of nodes in the

Bitcoin network. New transactions are checked against the block chain to ensure that the same bitcoins have not been previously spent, but the work of verifying new transactions is not done by any one trusted third party. Instead, the work is distributed among thousands of users who contribute their computing capacity to reconcile and maintain the block chain ledger. In essence, the whole peer-to-peer network takes the place of the one trusted third party.

Byzantine Generals Problem

Bitcoin's solution to the double spending problem – distributing the ledger among the thousands of nodes in a peer-to-peer network – presents another problem. If every node on the network has a complete copy of the ledger that they share with the peers to which they connect, how does a new node connecting to the network know that she is not being given a falsified copy of the ledger? How does an existing node know that she is not getting falsified updates to the ledger? The difficult task of reaching consensus among distributed parties who do not trust each other is another longstanding problem in the computer science literature known as the Byzantine Generals Problem, which Bitcoin also elegantly solved.

The Byzantine Generals Problem posits that a number of generals each have their armies camped outside a city that they have surrounded. The generals know that their numbers are large enough that if half their combined force attacks at the same time they will take the city, but if they do not attack at the same time they will be spread too thinly and will be defeated. They can only communicate via messenger, and they have no way of verifying the authenticity of the messages being relayed. They also suspect that some of the generals in their ranks are traitors who will send fake messages along to their peers. How can this large group come to a consensus on the time of attack without employing trust and without a central authority, especially when there will likely be attempts to confuse them with fake messages?

In essence, this is the same problem faced by Bitcoin's 'miners', the specialised nodes that verify new transactions and add them to the distributed ledger. Bitcoin's solution is to require additions to the ledger to be accompanied by the solution to a mathematical problem that is very difficult to solve but simple to verify. (This is much like calculating prime factors; costly to do, but easy to check.) New transactions are broadcast in a peer-to-peer fashion across the network by parties to those transactions. Miners look at those transactions and confirm by checking their copy of the ledger (the block chain) that they are not double-spends. If they are legitimate transactions, miners add them to a queue of new transactions that they would like to add as a new page in the ledger (a new block in the block chain). While they are doing this, they are simultaneously trying to solve a mathematical problem in which all previous blocks in the block chain are an input. The miner that successfully solves the problem broadcasts his solution to the problem along with the new block to be added to the block chain. The other miners can easily verify whether the solution to the problem is correct, and if it is they add that new block to their copy of the block chain. The process begins anew with the new block chain as an input of the problem to be solved for the next block.

The mathematical problem in question takes an average of 10 minutes to solve. This is key because the important thing is not the solution itself, but that the solution proves that the miner has expended 10 minutes of work. On average, a new block is added to the block chain every 10 minutes because the problem that miners must solve takes on average 10 minutes to solve. However, if more miners join the network, or if computing power improves, the average time between blocks will decrease. To maintain the rate at which blocks are added to six per hour, the difficulty of the problem is adjusted every 2016 blocks (every two weeks). Again, the key here is to ensure that each block takes about 10 minutes to discover.

How does this solve the Byzantine Generals Problem? Suppose that a miner is confronted with two competing block chains (just as a general might receive messages with different attack times). To choose which chain to accept and work to extend, a miner can look to see which is

longer; that is, which chain has had the most processing power devoted to it. By always choosing the longest chain, an honest miner can ensure that he is in the company of at least 51% of the other honest miners. The gap between the longest chain and competing chains will grow as time passes, since the longer chain will have more processing power behind it.

New blocks contain not just the new transactions that have been broadcast on the network, but also a transaction that assigns the winning miner 25 newly created bitcoins, which incentivises them to dedicate their computing capacity to the network. The size of the reward to miners that accompanies new blocks also halves every 210,000 blocks (every four years). The reward began at 50 bitcoins with each block when the network was launched in 2009. Today the reward is 25 bitcoins and will halve again to 12.5 in 2016. This means that the total number of bitcoins that will ever exist will not exceed 21 million. As mining rewards diminish, what incentive will miners have to lend their computing power to verify transactions? The answer is that parties to a transaction can include a transaction fee to be paid to the miner who successfully adds their transaction to a block in the block chain.

The Economics of Cryptocurrency

Governance

Cryptocurrencies do not have central banks to regulate the money supply or oversee financial institutions, but no one should neglect the importance of cryptocurrency governance institutions. We focus our discussion on two separate but interrelated ways that cryptocurrencies can be said to be governed.

Algorithmic Governance

Rules for what are considered valid cryptocurrency transactions are embedded in the peer-to-peer software that cryptocurrency miners and users run. One valid kind of transaction is the creation of new coins out of thin air. Not everyone can execute this kind of transaction – miners compete for the right to execute one of these transactions per block (on Bitcoin, every ten minutes or so). When a miner discovers a valid hash for a block, they can claim the new coins.

A transaction in which a miner claims new coins, like any other transaction, has to conform to the expectations of the network. The network will reject a block that contains a transaction in which a miner awards themselves too many new coins. The growth of coins is limited by a pre-determined amount per block.

On Bitcoin, the pre-determined amount is not scheduled to be constant over time, but rather is set to halve every 210,000 blocks, or about every four years, as described above. The total supply of bitcoins will asymptotically approach, but never exceed, 21 million. It will reach 20 million in 2025 and stop growing altogether in 2140.

Open Source Governance

The astute reader will note that the Bitcoin software that enforces particular rules about valid transactions and the rate of money creation does not appear out of thin air. Rather, the rules embedded in the software emerge from an interplay between leaders of the open source project that manages what is known as the ‘reference client’, other developers, miners, the user community and malicious actors. The dynamic between these players is as crucial to understanding Bitcoin as that of central banks, traditional monetary institutions and monetary politics is to understanding fiat currency.

Bitcoin, like all other even moderately successful cryptocurrencies to date, is a non-proprietary open source project. Users tend to look with suspicion on cryptocurrency projects that are closed source, that feature significant pre-mining in order to reward insiders, or that have other proprietary features. Other expectations of the user community also impose a check on developers. For example, the hard cap of 21 million bitcoins, while in principle subject to change through a software update, appears to be non-negotiable for Bitcoin,

although other cryptocurrencies have different money supply rules.

The division of Bitcoin software into a 'reference client' and so-called 'alt-clients' also has implications for Bitcoin's evolution. The community looks to the Bitcoin Core team for leadership as to the direction of the network. An alternative approach would be for the community to agree on the specification for the network, and then let independent teams write clients that implement the specification. The fact that Bitcoin has such a dominant reference client means that evolution can occur more quickly, although it may also have hidden costs. For example, the community has to put a lot of trust in the Bitcoin Core developers not to make bad changes to the network. A less concentrated approach to cryptocurrency development would slow down development, which would prevent any changes to the network without full deliberation of the community. It's possible that over time Bitcoin could move more to this model, but for now, the advantages of rapid evolution might outweigh the costs.

Miners also play an important role in governance. Because miners cryptographically guard against double spending, their consensus on what counts as a valid transaction is necessary for a cryptocurrency to function. A majority of miners must adopt any change to Bitcoin, and therefore the miners are able to impose a check on developers. Miners also exert influence through mining pools. Miners join pools in order to earn a more consistent payout. A single miner working alone might go for some time without discovering a block. But if miners pool their work and split their rewards, they can earn daily payouts.

Mining pools raise complications. For example, the biggest Bitcoin mining pool often has a third or more of the computing power of the Bitcoin network. If a pool ever obtained more than half of the network's computing power, it could double-spend. Double spending would destroy confidence in the Bitcoin network and would likely cause the price of bitcoins to plummet. Consequently, we observe some self-regulation by the mining pools, which are heavily invested in the success of Bitcoin. Whenever the top pool starts to approach 40% or so of computing power of the network, some participants exit the pool and join another one. So far this norm has persisted, but many in the community are concerned about mining pool concentration. Recently, the GHash.IO mining pool briefly exceeded 50 percent of Bitcoin's mining power. There is no evidence that the pool used its position to double spend, but many observers were alarmed that it was able to happen.

Concentrated mining pools have benefits as well as risks. In a crisis, it is useful to be able to assemble the key players. Such a crisis occurred on the night of 11 March 2013, when it became clear that a change in version 0.8 of the reference client introduced an unintentional incompatibility with version 0.7. As a result of the incompatibility, the two implementations of Bitcoin rejected each other's blocks, and the block chain 'forked' into two versions that did not agree on who owned which bitcoins. Within minutes of the realisation that there was a fork, the core developers gathered in a chat room and decided that the network should revert to the 0.7 rules. Over the next few hours, they were able to confer with the major mining pool operators and persuade them to switch back to 0.7, sometimes at a non-trivial cost to the miners who had mined coins on the 0.8 chain. The fact that mining pools are relatively concentrated meant that it was relatively easy to coordinate in the crisis. Within about seven hours, the 0.7 chain pulled permanently ahead and the crisis was resolved.

Another problem occurred in February 2014 when Mt. Gox, the oldest and largest Bitcoin exchange, claimed that its bitcoin holdings had been depleted through 'transaction malleability' attacks. Although it remains unclear whether Mt. Gox losses were really due to attacks, it became clear over the next several days that misunderstandings about transaction malleability were creating vulnerabilities. Some Bitcoin sites temporarily suspended withdrawals while the issues were addressed by the core development team, which updated the Bitcoin software and helped educate the community about transaction malleability, which, when properly understood, is a feature of Bitcoin, not a bug.

There is considerable scope for further study of cryptocurrency governance.

Medium of Exchange Versus Unit of Account

Bitcoin's lack of a central bank and fixed-trajectory money supply have earned it some criticism from economists concerned about macroeconomic stabilisation. Countercyclical inflationary stimulus is impossible.

However, this criticism may be misplaced. On most Keynesian and monetarist theories of monetary non-neutrality, the macroeconomic properties of money inhere in its unit-of-account function. Bitcoin is typically used as a medium of exchange without serving as a unit of account; that is, transactions will be denominated in dollars or another currency, but payment will be made using bitcoins. Unless prices, wages and contracts come to be denominated in Bitcoin, we would expect use of Bitcoin to have little cyclical impact.

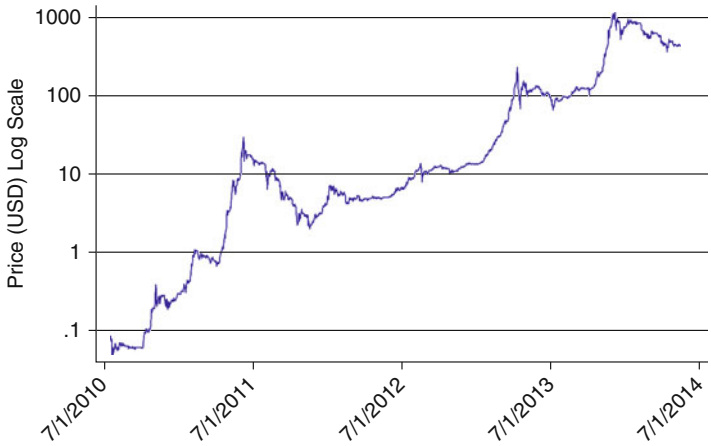
Cryptocurrencies have a number of properties that make them especially useful as media of exchange, if not as units of account. Unlike paper money, they can be transacted online as well as in person, if an Internet connection is present. Unlike credit cards, the network fee for a simple cryptocurrency transaction is low and voluntary; it is used to incentivise rapid processing of transactions by the miners. Credit card networks typically charge a swipe fee of 25 ¢ *plus* about 3% of the value of the transaction. On the Bitcoin network, transaction fees are at most a few pennies. Some retailers use merchant services to accept Bitcoin-denominated payments and have the equivalent amount of dollars deposited directly in their bank accounts. The service providers commonly charge a 1% fee for this convenience, though this may decrease as hedging costs go down (discussed below). Even with this conversion fee, merchants save 2% or more on transactions via the Bitcoin network. Another feature that could attract merchants is that customers who disavow a purchase cannot reverse most Bitcoin transactions, as they can credit card transactions.

In its separation of the medium of exchange and the unit of account, cryptocurrency brings to life some creative research from the 1970s and 1980s by economists such as Fischer Black (1970), Eugene Fama (1980), Robert Hall (1982) and Neil Wallace (1983). These authors regard the received monetary economics as highly contingent on legal and institutional arrangements; under *laissez faire*, they argue, we would observe explicit or implicit prices on media of exchange and a breakdown in the distinction between money and other financial assets. While cryptocurrency remains a niche payment mechanism and existing monetary institutions remain dominant, experimentation at the edges of our current monetary system with Bitcoin and other new cryptocurrencies could be fertile ground for new research in this tradition.

Pseudonymity and Censorship Resistance

Early news reports on Bitcoin focused on its use on the online black marketplace Silk Road. These reports propagated the misconception that Bitcoin transactions are anonymous. In fact, Bitcoin's ledger (called the block chain) is a completely public document. There is therefore a publicly accessible record of every Bitcoin transaction ever made. Bitcoin transactions occur between Bitcoin addresses, which are strings of random numbers and letters (a cryptographic hash of the address's public key). While there is no meaningful name attached to a transaction on the block chain, Bitcoin addresses function as pseudonyms for users. If a Bitcoin address can be identified as belonging to a particular individual, then all of the transactions on the block chain using that address can be attributed to that individual.

Users can take several steps to obfuscate identities and preserve some measure of financial privacy. They can generate and use a virtually unlimited number of addresses (there are 2^{160} valid Bitcoin addresses). It is considered best practice for merchants to generate a new receiving address for every transaction in order to protect their customers from scrutiny and to prevent



Cryptocurrency, Fig. 1 The price of Bitcoin (Source: Bitcoin Price Index data from CoinDesk http://www.coindesk.com/price/)

espionage from competitors. It is also becoming increasingly common for transaction processors to collate several transactions into a single one so that no one knows which address is paying which. If Alice wishes to pay Bob and Charlie wishes to pay David, a single transaction in which Alice and Charlie put in money and Bob and David take it out can make it unclear who is paying whom.

Despite the availability of these steps, the Bitcoin network remains vulnerable to sophisticated analysis. Meiklejohn et al. (2013) were able to trace bitcoins from well-known thefts through the network to centralised services such as exchanges, which in principle could be subpoenaed to reveal the identities of the criminals. They used only publicly available data; a well-equipped law enforcement agency could de-anonymise the network even further.

Although transactions are not fully anonymous, Bitcoin represents a significant shift in the enforcement burden for illegal transactions. Because non-cryptocurrency electronic payments pass through financial intermediaries, governments can enforce restrictions on transactions by regulating those intermediaries. A drug dealer cannot generally accept Visa payments because Visa will not approve a merchant whose business is dealing drugs. Illegal Bitcoin transactions may be subject to *ex post* punishment, but they are not subject to prior restraint through the regulation of financial intermediaries. This could have a significant effect on the number and kind of laws that governments are able to economically enforce.

Future developments in cryptocurrency technology could bring strong anonymity to Bitcoin or another currency. Zerocash is one proposed anonymisation system that could either be added to a future iteration of Bitcoin or released as its own currency. The strong anonymity provided by Zerocash or a similar system could have significant implications for governments who rely on controlling the financial system to enforce laws.

Pricing and Volatility

Bitcoin traded over $1 for the first time in February 2011, for $30 in June 2011, below $7 in July 2011, below $2.50 in October 2011, climbed back up to $10 by August 2012, to over $230 in April 2013, fell to below $70 within a week and rose to over $1100 in November 2013 before falling by several hundred dollars again (see Fig. 1). This volatile trend raises questions about the price of cryptocurrencies: What is the fundamental value of a Bitcoin? Why is Bitcoin so volatile? What could increase or decrease the volatility of Bitcoin in the future?

Since Bitcoin is not asset-backed, its value as a currency can only lie in its usefulness as a medium of exchange. As we have discussed, in some contexts, Bitcoin is superior to cash (e.g. it can be used online) and credit card payments (it is cheaper). In addition to its technical characteristics, its usefulness depends on the network effects that it can generate. The extent of future network

effects remains uncertain, which is perhaps the biggest reason for the volatility of Bitcoin prices so far. Some of this uncertainty will necessarily resolve itself over time, as Bitcoin is revealed either to be valueless or to have enduring value. Bitcoin is always likely to be more volatile than fiat currencies, however, because it lacks a central bank and its supply is not responsive to changes in demand.

Cryptocurrencies also raise in a new way questions of exchange rate indeterminacy. As Kareken and Wallace (1981) observed, fiat currencies are all alike: slips of paper not redeemable for anything. Under a regime of floating exchange rates and no capital controls, and assuming some version of interest rate parity holds, there are an infinity of exchange rates between any two fiat currencies that constitute an equilibrium in their model.

The question of exchange rate indeterminacy is both more and less striking between cryptocurrencies than between fiat currencies. It is less striking because there are considerably more differences between cryptocurrencies than there are between paper money. Paper money is all basically the same. Cryptocurrencies sometimes have different characteristics from each other. For example, the algorithm used as the basis for mining makes a difference – it determines how professionalised the mining pools become. Litecoin uses an algorithm that tends to make mining less concentrated. Another difference is the capability of the cryptocurrency's language for programming transactions. Ethereum is a new currency that boasts a much more robust language than Bitcoin. Zerocash is another currency that offers much stronger anonymity than Bitcoin. To the extent that cryptocurrencies differ from each other more than fiat currencies do, those differences might be able to pin down exchange rates in a model like Kareken and Wallace's.

On the other hand, exchange rate indeterminacy could be more severe among cryptocurrencies than between fiat currencies because it is easy to simply create an exact copy of an open source cryptocurrency. There are even websites on which you can create and download the software for your own cryptocurrency with a few clicks of a mouse. These currencies are exactly alike except for their names and other identifying information. Furthermore, unlike fiat currencies, they don't benefit from government acceptance or optimal currency area considerations that can tie a currency to a given territory.

Even identical currencies, however, can differ in terms of the quality of governance. Bitcoin currently has high quality governance institutions. The core developers are competent and conservative, and the mining and user communities are serious about making the currency work. An exact Bitcoin clone is likely to have a difficult time competing with Bitcoin unless it can promise similarly high-quality governance. When a crisis hits, users of identical currencies are going to want to hold the one that is mostly likely to weather the storm. Consequently, between currencies with identical technical characteristics, we think governance creates something close to a winner-take-all market. Network externalities are very strong in payment systems, and the governance question with respect to cryptocurrencies in particular compounds them.

Cryptocurrency volatility could also be reduced by the introduction of exchange-traded futures and options markets. At present, the CFTC has still not opined on the legality of cryptocurrency derivatives. However, a number of Bitcoin-based businesses have been calling for the normalisation of hedging instruments for Bitcoin, which could also have the advantage of lowering merchant processing fees. Greater access to cryptocurrency derivatives is necessary for the health of the ecosystem. Some developers have begun work on decentralised derivatives exchanges, which could be important if financial regulators refuse to approve ordinary derivatives.

Conclusion

Cryptocurrency is an impressive technical achievement, but it remains a monetary experiment. Even if cryptocurrencies survive, they may not fully displace fiat currencies. As we have tried to show in this article, they provide an interesting new perspective from which to view economic

questions surrounding currency governance, the characteristics of money, the political economy of financial intermediaries, and the nature of currency competition.

Cultural Transmission

Alberto Bisin and Thierry Verdier

Abstract

The economic literature analyses cultural transmission as the result of interactions between purposeful socialization decisions inside the family ('direct vertical socialization') and indirect socialization processes like social imitation and learning ('oblique and horizontal socialization'). This article reviews the main contribution of these models from theoretical and empirical perspectives. It presents the implications regarding the long-run population dynamics of cultural traits, and discusses the links with other approaches to cultural evolution in the social sciences as well as in evolutionary biology. Applications to economic problems are also briefly surveyed.

Preferences, beliefs, and norms that govern human behaviour are partly formed as the result of genetic evolution, and partly transmitted through generations and acquired by learning and other forms of social interaction. The transmission of preferences, beliefs and norms of behaviour which is the result of social interactions across and within generations is called *cultural transmission*. Cultural transmission is therefore distinct from, but interacts with, genetic evolution.

Cultural transmission is an object of study of several social sciences, such as evolutionary anthropology, sociology, social psychology and economics, as well as of evolutionary biology. The theoretical contributions of Cavalli-Sforza and Feldman (1981) and Boyd and Richerson (1985), who apply models of evolutionary biology to the transmission of cultural traits, as well as the empirical study of cultural socialization in American schools by Coleman (1988), had a great multidisciplinary impact. Recently, economists have also studied the determination and the

dynamics of preferences, beliefs, norms and, more generally, cultural and cognitive attitudes.

Cultural transmission arguably plays an important role in the determination of many fundamental preference traits, like discounting, risk aversion and altruism. It plays a central role in the formation of cultural traits and norms, like attitudes towards the family and fertility practices, and in the job market. It is, however, the pervasive evidence of the resilience of ethnic and religious traits across generations that motivates a large fraction of the theoretical and empirical literature on cultural transmission. For instance, the fast assimilation of immigrants into a 'melting pot', which many social scientists predicted until the 1960s (see, for example, Gleason 1980, for a survey), simply did not materialize. Moreover, the persistence of 'ethnic capital' in second- and third-generation immigrants has been documented by Borjas (1992), and recently also by Fernandez and Fogli (2005) and Giuliano (2007) for norms of behaviour regarding, respectively, work and fertility practices and living arrangements. Orthodox Jewish communities in the United States constitute another example of the strong resilience of culture (see Mayer 1979, and the discussion of a 'cultural renaissance' rather than the complete assimilation of Jewish communities in New York in the 1970s). Outside the United States, Basques, Catalans, Corsicans, and Irish Catholics in Europe, Quebecois in Canada, and Jews of the diaspora have all remained strongly attached to their languages and cultural traits even through the formation of political states which did not recognize their ethnic and religious diversity.

Models of cultural transmission have implications regarding the determinants of the persistence of cultural traits and more generally regarding the population dynamics of cultural traits. In the economic literature in particular, cultural transmission is modelled as the result of purposeful socialization decisions inside the family ('direct vertical socialization') as well as of indirect socialization processes like social imitation and learning ('oblique and horizontal socialization'). Therefore, the persistence of cultural traits or, conversely, the cultural assimilation of minorities is determined by the costs and benefits of various family decisions pertaining to the socialization of children in specific socio-economic environments, which in turn determine the children's opportunities for social imitation and learning.

Evolutionary Biology Models

L. Cavalli-Sforza and M. Feldman are the first to formally study the transmission of cultural traits. Their formal models are adopted from evolutionary biology. In a baseline version of these models, they obtain a simple differential equation which describes the population dynamics of cultural traits. Consider the dynamics of a dichotomous cultural trait in the population; formally, a fraction q^i of the population has trait i, and a fraction $q^j = 1 - q^i$ has trait j. Families are composed of one parent and a child, and hence reproduction is asexual. All children are born without defined preferences or cultural traits, and are each first exposed to their parent's trait, which they adopt with probability d^i. If a child from a family with trait i is not directly socialized, which occurs with probability $1 - d^i$, he or she picks the trait of a role model chosen randomly in the population (that is, he or she picks trait i with probability q^i and trait j with probability $1 - q^i$). Therefore, the probability that the child of parents of trait i will also have trait i is $\prod^{ii} = d^i + (1 - d^i)q^i$; while the probability that he or she will have trait j is $\prod^{ij} = (1 - d^i)(1 - q^i)$. It follows that the dynamics of the fraction of the population with trait i, in the continuous time limit, are characterized by:

$$\dot{q}^i = \left(d^i - d^j\right)q^i\left(1 - q^i\right) \tag{1}$$

The dynamics that eq. (1) describes implies that the distribution of cultural traits in the population converges to a degenerate distribution concentrated on trait i whenever $d^i > d^j$ (and on trait j when $d^i < d^j$), while any initial distribution is stationary in the knife-edge case in which $d^i = d^j$. This model therefore predicts the complete assimilation of the trait with weaker direct vertical socialization. Moreover, it predicts faster

assimilation for smaller minorities. Both predictions are at odds with the documented strong resilience of cultural traits discussed above. Cavalli-Sforza and Feldman show how these extreme predictions can be relaxed by considering other effects like mutations, migrations and horizontal cultural transmission among peers. Boyd and Richerson (1985) in turn extend the analysis of Cavalli-Sforza and Feldman (1981) by considering forms of direct vertical socialization called *frequency dependent* biased transmission, which depend on the distribution of the population by cultural trait. Formally, they allow d^i to be a function of q^i.

Bisin and Verdier (2001a) study the same differential equation for the population dynamics of cultural traits, with the objective of characterizing the conditions which give rise to culturally heterogeneous stationary distributions, that is, limit population with a positive fraction of either cultural trait, $0 < q^i < 1$. They show that the crucial determinant of the composition of the stationary distribution consists in whether the socio-economic environment (oblique socialization) acts as a substitute or as a complement to direct vertical socialization. More precisely, when direct vertical socialization and oblique transmission are *cultural substitutes*, parents by definition socialize their children less the more widely dominant are their cultural traits in the population. In such a case, $d^i(q^i)$ is a strictly decreasing function in q^i, and in the long run a non-degenerate stable stationary distribution exists. It is characterized by a qi such that the direct vertical socialization of the two cultural types are equalized (that is, $d^i(q^i) = d^j(1-q^i)$): Intuitively, when family and society are substitutes in the transmission mechanism, in fact families socialize children more intensely whenever the set of cultural traits they wish to transmit is common only to a minority of the population. Conversely, families which belong to a cultural majority spend fewer resources directly socializing their children, since their children adopt or imitate with high probability the predominant cultural trait in society at large, which is the one their parents desire for them. *Cultural substitutability* tends to preserve cultural heterogeneity in the population because in this case minorities directly socialize their children more than majorities. The other typical situation is the opposite one in which direct vertical transmission is a *cultural complement* to oblique transmission; that is, when parents socialize their children more intensely the more widely dominant their cultural trait is in the population. In such a case, $d^i(q^i)$ is a strictly increasing function in qi and in the long run the dynamics converges to a culturally homogeneous cultural population (with either $q^i = 0$ or $q^i = 1$ depending on the initial distribution).

Economic Models of Cultural Transmission

Economic models of cultural transmission induce testable restrictions on the form of the function $d^i(q^i)$. In their baseline specification, for instance, Bisin and Verdier (2001a) assume that parents are altruistic towards their children and hence might want to socialize them to a specific cultural model if they think this will increase their children's welfare. If we let V^{ij} denote the utility to a type i parent of a type j child, $i, j \in \{a, b\}$, the formal assumption is

$$\text{for all } i, j \text{ with } i \neq j, V^{ii} > V^{ij}$$

This assumption, called *imperfect empathy*, can be interpreted as a form of myopic or paternalistic altruism. Parents are aware of the different traits children can adopt and are able to anticipate the socio-economic choices a child with trait i will make in his or her lifetime. However, parents can evaluate these choices only through the filter of their own subjective evaluations and cannot 'perfectly empathize' with their children. As a consequence of imperfect empathy, parents, while altruistic, tend to prefer children with their own cultural trait and hence attempt to socialize them to this trait. (Some justifications of imperfect empathy from an evolutionary perspective are provided by Bisin and Verdier 2001b. The assumption can be relaxed, as for example in Sáez-Martí and Sjogren 2005). Assume

socialization is costly and let costs be denoted by $C(d^i)$. Parents of type i then choose di to maximize:

$$-C(d^i) + \left(\prod^{ii} V^{ii} + \prod^{ij} V^{ij}\right) \tag{2}$$

$$s.t \prod^{ii} = d^i + (1 - d^i)q^i, \prod^{ij} = (1 - d^i)(1 - q^i) \tag{3}$$

Under standard assumptions, the solution to this problem provides a continuous map $d^i = d(q^i, \Delta V^i)$, where $\Delta V^i = V^{ii} - V^{ij}$ is the subjective utility gain of having a child with trait i. It reflects the degree of 'cultural intolerance' of type i's parents with respect to cultural deviations from their own trait. Given imperfect empathy on the part of parents, $\Delta V^i > 0$. The dynamics of the fraction of the population with cultural trait i is then determined by eq. (1) evaluated at $d^i(q^i) = d(q^i, \triangle V^i)$ It is straightforward to demonstrate that this class of socialization mechanisms generates cultural substitutability and therefore the preservation of cultural heterogeneity. Other micro-founded specifications and examples are provided in Bisin and Verdier (2001a), some of which illustrate the contrary possibility of cultural complementarity and the tendency of cultural homogenization over time.

Direct Socialization Mechanisms and Socio-Economic Interactions

Several specific choices contribute to direct family socialization and hence to cultural transmission. Prominent examples are education decision, family location decisions, and marriage choices While education choices have been studied by Cohen-Zada (2004), and marriage choices by Bisin and Verdier (2000), the literature has to date shown little interest in the socialization effects of location choices, for instance, the socialization effects of urban agglomeration by ethnic or religious trait.

The simple analysis of the economic model of cultural transmission of Bisin and Verdier depends crucially on the assumption that the utility to a type i parent of a type j child, V^{ij} is independent of the distribution of the population by cultural trait, that is, independent of q^i. Many interesting analyses of cultural transmission require this assumption to be relaxed. In many instances the adoption of the cultural trait of the majority in fact favours children, for example in the labour market; a typical example is language adoption. In this case altruistic parents, even if paternalistic, might favour (or discourage less intensely) the cultural assimilation of their children. If we allow for interesting socio-economic effects interacting with the socialization choices of parents, the basic cultural transmission model of Bisin and Verdier has been applied to several different environments and cultural traits and social norms of behaviour, from preferences for social status (Bisin and Verdier 1998) to corruption (Hauk and Sáez-Martí 2002), hold-up problems (Olcina and Penarrubia 2004), development and social capital (François 2002), intergenerational altruism (Jellal and Wolff 2002), labour market discrimination (Sáez-Martí and Zenou 2005), globalization and cultural identities (Olivier et al. 2005), and work ethics (Bisin and Verdier 2005).

Empirical Analysis of Cultural Transmission Models

While an interesting literature has documented the relevance of cultural factors in several socio-economic choices, much less is known about cultural transmission per se. Nonetheless, several important questions are beginning to be answered. First of all, several important correlations have been documented in sociology, in particular with regard to the role of marriage in socialization (see, for instance, Hayes and Pittelkow 1993; Ozorak 1989; Heaton 1986). The literature in economics has instead concentrated more specifically on the direct empirical validation of the economic approach to cultural transmission surveyed above, thereby estimating the relative importance of direct and oblique socialization for different specific traits and the prevalence of cultural

substitution or complementarity in specific socio-economic environments. Patacchini and Zenou (2004) find evidence of cultural complementarity in education in the United Kingdom. Cohen-Zada (2004) finds instead for the United States that the demand for private religious schooling decreases with the share of the religious minority in the population, in accord with cultural substitution. Fernandez et al. (2004) find evidence of an important role for mothers in the transmission to their sons of attitudes favouring the participation of women in the labour force and acquisition of higher education. Finally, Bisin et al. (2004a), using the General Social Survey data for the United States over the period 1972–96, estimate for religious traits the structural parameters of the model of marriage and child socialization in Bisin and Verdier (2000). They find that observed intermarriage and socialization rates are consistent with Protestants, Catholics and Jews having a strong preference for children who identify with their own religious beliefs, and taking costly decisions to influence their children's religious beliefs. The estimated 'relative intolerance' parameters are high and asymmetric across religious traits, suggesting an interestingly rich representation of 'cultural distance'.

Genetic and Cultural Evolution

Cultural transmission possibly has a role also in the determination of fundamental preference parameters, such as time discounting, risk aversion, altruism, and interdependent preferences. Purely evolutionary models have been complemented by alternative models of cultural transmission and genetic and cultural co-evolution. The wealth of different approaches proposed is best exemplified by the study of preferences for cooperation. The observation that humans often adhere to collectively beneficial actions which are not in their private interest (or which are not rationalizable as strategic equilibria) has led to a theoretical literature explaining how psychological 'preferences for cooperation' can be sustained in the context of genetic and/or cultural evolution (this is called the *puzzle of pro-sociality* by Gintis 2003a). For instance, in the context of the Prisoner's Dilemma, Becker and Madrigal (1995) exploit the ability of habits to induce preferences; Guttman (2003), Stark (1995), and Bisin et al. (2004b) show how cooperation can be sustained by different modes of cultural evolution; Gintis (2003b) shows that a general capacity to internalize fitness-enhancing norms of behaviour can be genetically adaptive, and hence that cooperation can also be internalized by 'hitchhiking' on this general capacity.

The empirical evidence on the nature–nurture debate (see Ceci and Williams 1999, for a review) has not yet been systematically taken to the point of distinguishing the genetic from the cultural factors in the determination of fundamental preference parameters. Similarly, the empirical evidence distinguishing the different cultural transmission models of fundamental preference traits is almost non-existent. The only exception is by Jellal and Wolff (2002), who study the implication of the pattern of *inter vivos* transfers within the family in France for the transmission of intergenerational altruism. They argue that the evidence is more consistent with a cultural transmission model such as that of Bisin and Verdier (2001a) rather than with a 'demonstration effect' model, as in Stark (1995), where parents take care of their elders in order to elicit similar behaviour in their children.

Culture and Economics

Raquel Fernández

Abstract

Modern neoclassical economics has, until recently, ignored the potential role of culture in explaining variation in economic outcomes, largely because of the difficulty in rigorously separating the effects of culture from those of institutions and traditional economic variables. This article selectively reviews some recent attempts to empirically identify the effects of culture on economic outcomes and to answer the question, 'does culture matter and, if so,

how much?' Open theoretical and empirical questions are discussed, including the relationship between culture and institutions.

Economic decisions are made within a social context; as Aristotle reminds us, man is a social animal. The relevance of this statement to economics, however, is far from clear. In what ways, if any, do we need to consider the social nature of man in order to study economic questions? This article attempts to provide a partial answer to this question.

Traditionally, economists seek to explain differences in economic outcomes by studying how agents, with given preferences and beliefs, react to changes in the policy environment, institutions and technology. At a deeper level than the taste for apples versus oranges, however, few would deny that preferences and beliefs must be, to some extent, endogenous. Our level of trust in others, the determinants of status in society, our beliefs about the correct trade-off between efficiency and equity, or the 'proper' roles for men and women, are all examples of beliefs or preferences that have differed across societies and over time. These beliefs and preferences impact on individual behaviour and how society allocates scarce resources. At the individual level they help determine whether a woman participates in the formal labour market and the career she follows, the extent to which racism is tolerated, or the degree of assortative matching on wealth in marriages. At a collective level, they help determine, for example, the range and depth of the welfare state, the legality of slavery, or the proportion of the budget that is dedicated to foreign aid.

Although at some general level few may disagree that preferences, beliefs, or values of the type discussed above are endogenous (and may therefore differ across societies), whether they have a quantitatively significant impact on economic outcomes is another matter. Do differences in beliefs and preferences that vary systematically across groups of individuals separated by space (either geographic or social) or time – what I shall henceforth term *culture* – play an important role in explaining differences in outcomes? (For the purposes of this article, I will not give a more rigorous definition of culture than the abbreviated one here. See Elster 1989, for a discussion of social norms and culture and Manski 2000, for a discussion of peer effects and social interactions.) Modern economics (as opposed to sociology or anthropology) has largely been, until recently, reluctant to investigate this question. Although in principle there is nothing non-standard about positing preference/belief heterogeneity among individuals to explain differences in outcomes, the Stigler–Becker dictum *de gustibus non est disputandum* (Stigler and Becker 1977) and its assertion that 'no scientific behavior has been illuminated by assumptions of differences in taste' has cast a long shadow in economics. Thus, the main challenge faced by those who believe that culture might matter has been to find a convincing way to show that culture can be studied rigorously and, in particular, that it is possible to separate the influence of culture from institutions and standard economic variables. In this sense, running, say, cross-country regressions on variables that one suspects reflect cultural attitudes (for example, different savings patterns may reflect attitudes towards thrift) to study the effect of culture has long (and correctly) been considered unsatisfactory. Despite one's best efforts to control for differences in countries' economic environments, identifying the residual with culture is ultimately unconvincing. It is difficult, if not impossible, to summarize the economic environment faced by agents with a few aggregate variables. Thus, there are bound to be omitted

variables and problems of endogeneity, which are all further confounded by mismeasurement.

Hence, despite a long history of writers on the relationship between culture and economics (which includes Marx, Weber, Gramsci, Polanyi, Banfield and, more recently, Putnam and Landes, among others), modern neoclassical economics has been by and large silent on the topic of culture and only in recent years have economists started to think seriously again about how culture may help explain economic phenomena. In this article I will selectively review some recent attempts to empirically identify the effects of culture on important economic outcomes and to answer the question, 'does culture matter?' Answering this question affirmatively naturally leads one to explore the propagation mechanisms of culture, to theorize about the relationship between institutions and culture, and to investigate the dynamic of culture – all topics that I will briefly touch upon at the end.

Empirical Evidence on Culture

In this section I examine some of the recent evidence on the importance of culture for economic outcomes. For expository ease, I have divided the empirical evidence into that which uses survey data, evidence based on immigrants or their descendants (what I call the 'epidemiological approach'), and historical case studies. There is also a small body of experimental work that, by showing that across societies there exist marked differences in how individuals play games such as the ultimatum, public good or dictator game, has also shed light on the relationship between culture and economics (see, for example, Henrich et al. 2001).

Survey-based Evidence

Perhaps the most natural approach to doing empirical work on culture consists in using the beliefs expressed by individuals in surveys (for instance, the World Value Surveys) on a variety of issues as expressions of culture and correlating them with economic outcomes. This approach, however, must overcome the problem of reverse causality. That is, differences in beliefs may be solely a consequence of different economic and institutional environments. Hence, the use of instrumental variables is required in order to identify causality. Overall, this has been difficult to achieve.

As shown by Guiso et al. (2003), the intensity of religious beliefs and religious denomination are correlated with a variety of individual attitudes such as trust in others, government's role, views of working women and the importance of thrift. Guiso et al. (2006) show that these attitudes, aggregated at the country level, are correlated with cross-country aggregate outcomes (for example, savings, redistributive versus regressive taxation, and trade). In order to ensure that the reverse causality is not at play, the attitudes are instrumented, usually by the religious composition in the country. This work is suggestive but there are several concerns associated with it. In addition to questions about omitted variables, it is not clear that religious composition is a valid instrument since it may also help explain the aggregate outcome through other channels. (Indeed, the coefficients on the instrumental variable results tend to look very high relative to the ones obtained by ordinary least squares. Running regressions at the individual outcome level would be more convincing, but opinion surveys unfortunately tend not to have high-quality economic data (the World Value Survey, for example, classifies income levels into ten categories). Recent work by Guiso et al. (2005) on the relationship between trust and trade, instead instruments trust with the genetic distance between indigenous populations. This seems a promising avenue of research.

Tabellini (2005) takes a significant step towards overcoming some of the weaknesses discussed above. To study whether culture affects economic development across European regions, he also aggregates (at the regional level) individual responses from the World Value Surveys to questions about trust, respect and the link between individual effort and economic success. The scope for omitted variables is reduced by focusing on within-country variation in Europe (by including country fixed effects). The attitudes are then

instrumented with historical variables, such as regional literacy rates at the end of the 19th century and indicators of political institutions in the period from 1600 to 1850. The author finds that the proxies for culture are quantitatively significant determinants of per capita GDP levels and growth rates across regions. It is possible of course that the instruments are not valid. For example, they could affect output directly via sectoral composition or public investment. The paper contains a good discussion of these and other alternative hypotheses.

The Epidemiological Approach

A very different approach to relying on opinion data is to examine the economic outcomes of immigrants or their descendants. This is reminiscent of the epidemiology literature that, in order to attempt to identify the contribution of the environment broadly defined (namely, physical and cultural) relative to genes in disease, studies various health outcomes for immigrants and compares them to outcomes for natives (see, for example, the classic study by Marmot et al. 1975).

To understand the strengths and weaknesses of such an approach, suppose that the level of, say, heart disease differs markedly between two countries (the source and host countries). If heart disease in immigrants converges to that of natives in the host country, the difference between the two countries is unlikely to be driven by genetics and instead results from the environment. Failure to find convergence, on the other hand, does not imply the opposite. There are many reasons why the environment may be solely responsible and still sustain differential levels of heart disease. For example, cultural assimilation may occur slowly (for instance, if immigrants maintain the same dietary patterns as in the source country), or living in the source country at a young age may confer some degree of immunity, or selection into immigration may be correlated with a particular health outcome.

The epidemiological strategy in economics has its own set of problems. In particular, it is important to recognize that immigrants may be subject to many shocks (language difficulties, worse employment opportunities, greater uncertainty and so forth) which cause them to deviate from their traditional behaviour. Culture, furthermore, is socially constructed: to be replicated, the behaviour may require the incentives – rewards and punishments – provided by a larger social body such as a neighbourhood, school, or ethnic network. Furthermore, immigrants are unlikely to be a representative sample of their home-country's population. Their beliefs, preferences, and unobserved differences in their economic circumstances may differ significantly from the country average. Lastly, the exposure of immigrants (or their descendants) to a different culture from the one prevalent in their country of heritage presumably weakens the latter's impact on their behaviour. Note that all the factors mentioned above introduce a bias towards finding culture to be insignificant. Thus, on the whole, comparisons of behaviour or outcomes across different immigrant groups are a very demanding test of the importance of culture. In epidemiology, when differences across groups remain, one must be careful not to conclude that genetics is determinative when the underlying cause may be cultural; in economics, when significant differences are not observed, one must be careful not to rule out cultural forces.

In economics, the paper by Carroll et al. (1994) is the first that, to my knowledge, follows an approach similar to the one described above. The authors are interested in exploring whether cross-country differences in savings rates may be culturally driven. Using individual-level data on immigrants to Canada, they estimate individual consumption levels as a function of permanent income (as captured by labour and asset income), the interaction of this variable with demographic variables, some measures of wealth, and finally the interaction of a region of origin dummy (and years since arrival to Canada) with their measure of permanent income. If there exist different cultural attitudes towards savings, and if this attitude is maintained in immigrants, then one should observe different propensities across immigrants, by region of origin, to consume out of permanent income (that is, the regional dummies should be significantly different from one another). The authors find that the saving patterns of immigrants

do not vary significantly by region of origin. Recent immigrants as a whole save less than native-born Canadians, but there is no statistically significant difference in behaviour across immigrant groups.

There are several weaknesses in the data-set used in the study above that may bias it against finding results that show a significant impact of culture. Wealth, for example, is not well measured. In particular, as only South East Asia's saving rate differed markedly from those of other regions in the immigrant population (31 per cent relative to 18–20 per cent across the remaining regions), the small number of immigrants from this group in the sample limits the power of the test. Note also that, if the motivation to save more stems from the desire to provide one's child with greater status via a larger bequest, the incentive to do this may be much less marked in a society in which savings are generally low or in which status stems from consumption behaviour.

Fernández and Fogli (2005, 2006) use a similar, but arguably less problematic, methodology by studying second-generation Americans in order to investigate the quantitative importance of culture. Their research focuses on the fertility and work behaviour of married second-generation American women (that is, women who were born in the United States but whose parents were born elsewhere). The use of second-generation immigrants attenuates the problems associated with the first generation's adjustment to a foreign setting (for example, language difficulties) and even some selection problems are less likely to play a role for the second generation. On the other hand, second-generation individuals have been more exposed to the new culture, and that will tend to diminish the role of culture from the country of heritage. Our hypothesis is that attitudes towards woman's 'proper' role in society and towards ideal family size are culturally different across countries and that this culture is likely to be transmitted intergenerationally and show up in systematic differences in female labour force participation (LFP) and fertility, even if individuals were raised in the United States.

In our 2005 paper, the challenge was how to best capture the attitudes towards women and family size in the parents' country of origin. We chose not to use country dummies (as in Carroll et al. 1994) but to instead examine whether past values of economic variables in the country of origin that should reflect this culture – in particular, past values of female LFP and total fertility rates (TFR) – are able to play a quantitatively significant role in explaining differences in outcomes across second-generation women in the United States. Our argument is that these economic variables reflect the institutions (for example, markets, legal framework, minimum wages and so on), the strictly economic environment (demand and supply, transportation costs, access to day care, for example), as well as the preferences and beliefs (that is, the culture) of individuals in the country making decisions at that time. If these variables are able to explain the behaviour of women who, by virtue of living in the USA and in a different time period, face different institutions and economic variables, then solely the cultural component of these variables should affect their choices. This is a more demanding test that is superior to the 'black box' approach of using country dummies which leaves open the question of what it is about the country that matters to outcomes.

In individual level regressions, we find that our cultural proxies – past values of female LFP and TFR – help explain both how much second-generation American women work and their fertility. As our data-set – the 1970 US Census – does not allow us to control for family factors such as parental wealth, income, and education, we include the woman's education, her spouse's education, and total personal income (as well as location, age, and so on) in our regressions. By including these variables, the coefficient on the cultural proxy only captures the direct effect of culture rather than its full direct and indirect effects (for example, a woman who wants engage in market work is more likely to invest in education and hence, by controlling for education, we are eliminating the effect of culture on this variable), but this is preferable to not controlling for differences in parental background, other than culture, that may affect women's work and fertility outcomes. We find that the cultural proxies still

matter even after including these additional variables. Furthermore, the cultural proxies are quantitatively significant: a one standard-deviation increase in the corresponding cultural proxy is associated with approximately an eight per cent increase in hours worked per week and about a 14 per cent increase in the number of children. The forces of assimilation means that these numbers should be taken, if anything, as a downward biased estimate of the true power of culture in the original setting (that is, in the country of ancestry).

We also examine the most compelling alternative economic explanation for our results, namely, the hypothesis that these are driven by unobserved human capital. We do this by showing that the results are robust to the inclusion of the country of ancestry's level of per capita GDP in various years and to the years of education of immigrants (by country of ancestry) in 1940 (this remains the case when Hanushek and Kimko's (2000) measures of education quality in the parents' country of origin are included). We also demonstrate that the work cultural proxy does not have explanatory power in a Mincer wage regression which it would be expected to have if it captured unobserved human capital. Lastly, we show that the work cultural proxy is insignificant in explaining how much married second-generation American men work whereas the fertility cultural proxy retains its explanatory power. (If the work cultural proxy had a negative effect on how much these men work, that might indicate a substitution effect. In our regressions, the coefficient is basically zero and insignificant.) This is important because it implies that there does not exist some omitted economic variable at the parental country-of-origin level that affects the productivity of both men and women and that helps explain how much they work.

The methods used in Fernández and Fogli (2005) could be profitably extended to examine other issues, such as entrepreneurship or savings behaviour. It might also be interesting to elaborate upon the recent approach by Algan and Cahuc (2006) that attempts to combine survey evidence with the epidemiological approach in order to study the effects of culture on cross-country labour market outcomes. Although this work is too preliminary to discuss in depth, using the attitudes of, say, second-generation Americans to instrument for the attitudes of individuals in the home country seems cleaner than relying on variation in religious denominations. As usual, the question will be whether there is some omitted background economic variable correlated with the country of origin (particularly given the quality of the survey data-sets) that could be driving the results, but it seems a promising avenue of research (see also the interesting work on culture and migrants within regions in Italy by Ichino and Maggi 2000. As shown recently in Fernández (2007a) using the World Value Survey, the attitudes of individuals in the country of ancestry towards women's market work and housework have explanatory power for the work outcomes of second-generation American women in 1970.

Historical Case Studies

The analysis of historical episodes in which changes in either culture or environment yield 'natural experiments' is likely to add richness and depth to our understanding of culture and the economy. Greif's 1994 paper is probably the best-known work in economics that makes the link between culture and institutional development. In brief, Greif argues that cultural beliefs (collectivist versus individualist) are reflected in the different ways in which in the 11th century Genoese traders and Maghrebi traders set up their trading institutions. Both groups of merchants required agents to conduct their business overseas, and in both cases there was an agency problem as the overseas agent might be tempted to cheat the merchant. Maghrebi traders set up 'horizontal' relations in which merchants served as agents for traders and vice versa. Information was shared among merchants/traders and an agent who was dishonest with one merchant could expect to be shunned by other merchants. The Genoese, on the other hand, set up 'vertical' relationships in which individuals specialized as merchants or agents. Information was not shared among merchants. This led the Genoese to set up more formal enforcement institutions. The two different responses, argues Greif, then had important consequences once trading opportunities

were expanded in previously inaccessible areas. The Maghrebi expanded trade using other Maghrebi agents whereas the Genoese were able to establish agency relations with non-Genoese, leading to very different economic development paths thereafter (see also Greif's 2005, recent book on the topic).

Another compelling example is provided by Botticini and Eckstein (2005) who present the thesis that an 'exogenous' cultural change gave rise to the pattern of Jewish occupational selection that we see to this day. They argue that with the destruction of the Temple in Jerusalem in 70 CE, the Pharisees became the dominant religious group and transformed Judaism from a religion based on sacrifices to one whose main rule required each male to read and to teach his sons the Torah. This reform was implemented in places where most Jews were farmers who would not gain anything from investing in education. When urbanization expanded many centuries later, Jews had a comparative advantage in the skilled occupations demanded in the new urban centres. Thus, culture – the religious requirement of reading skills for other than human capital reasons – gave rise to the pattern of Jewish occupational selection seen since the ninth century.

Theories of Culture

Is it necessary to modify the standard economic model in order to incorporate culture? The answer definitely is 'no'. What appear to be societal differences in preferences may only be choice of equilibrium strategies in a game with multiple equilibria and standard preferences. This is in fact the most common way to think about the role of culture in economics, and is fully in keeping with our working definition of culture as systematic differences (across groups) in preferences or beliefs. Here the heterogeneity lies in the expectations (beliefs) over the strategies that will be played in equilibrium. Hence differences in culture can be identified with, for example, which equilibrium we play in a static game (for example, do we drive on the right- or left-hand side of the road) or the degree of cooperation ('trust') sustained in a repeated Prisoner's Dilemma game.

Within the 'culture as multiple equilibria' literature, I find particularly interesting the research that attempts to generate behaviour that looks like social norms (such as determinants of status). Take, for example, a dynamic matching model in which individuals who differ in wealth choose a partner with whom to match and obtain utility from joint consumption and the utility of their child. As shown in Mailath and Postlewaite (2003), in addition to an equilibrium in which there is assortative matching on wealth, there may also be an equilibrium with imperfectly assortative matching that depends also on non-economic characteristics such as whether one has blue eyes. In this equilibrium, blue eyes matter not because of their intrinsic value, but simply because the matching rule allocates, for the same wealth level, a wealthier partner to individuals with blue eyes. Thus, a woman would be willing to match with a man with blue eyes and slightly lower wealth than another man without blue eyes, because although she obtains lower joint consumption, there is a 50 per cent chance that her child would inherit blue eyes and hence a better match and higher consumption in the future. To an outside observer, it might therefore appear that in this society people had an intrinsic preference for blue eyes, although this inference would be incorrect.

Although the example above is interesting, its explanation for a particular social norm seems incomplete and intuitively less than compelling. The preference for blue eyes or light skin may perhaps initially come about as a choice among many equilibria and involve solely a calculation about the trade-off between one's own consumption and that of one's child (though that too seems doubtful and is more likely the result of a history in which these traits are correlated with higher status). Over the longer run, however, one may conjecture that what sustains these equilibria – what makes these cultural traits less fragile to perturbations – is that these calculations are embodied in the individual and in society as preferences and beliefs about the inherent superiority/desirability of such features. People come to

prefer blue eyes; people become racist. Thus, what is missing more generally in the theory of culture is an analysis of how preferences and beliefs (about things other than equilibrium strategies) themselves evolve.

The hypothesis that certain features of culture (those that have greater depth than driving on the left or the right side of the street) become part of preferences and beliefs implies that they cannot be discarded easily simply because they are no longer useful or beneficial, though over time this will certainly lessen their appeal. In this way, the operation of culture may be clearest to perceive when it no longer serves any useful societal purpose or particular group interest but nonetheless, at least for some time, persists – for example, religious prohibition on eating pork. (One reason speculated for this prohibition is that consumption of undercooked pork is linked to trichinosis. It is now known that this problem can be eliminated, however, by thoroughly cooking the meat.) In the context of the matching example above, individuals may eventually be willing to match with lower wealth people with blue eyes because this matching rule is incorporated into preferences/beliefs over what type of mate is intrinsically better even if the benefit derived by passing this trait on to their offspring is no longer substantial (say, because family size falls and decreases the payoff from the inheritable trait relative to the decrease in immediate joint consumption).

So far, we have discussed differences in culture as systematic differences in preferences and beliefs without distinguishing much between the two. This is not accidental, since, in general, the distinction between preferences and beliefs for our purposes is rather fuzzy. Even for simple preferences such as the trade-off between apples and oranges, what one knows (or believes) about the nutritional contents of the two may affect how one 'feels' about them, as may any other mental associations (for example, whether one is considered more exotic, how they were grown and so forth). In general, there are few pure (or naive) preferences – what one thinks or believes influences how one feels (and the same may be true vice versa. See Damasio 1995, for an interesting exposition of evidence in favour of the hypothesis that emotions affect – and in fact are necessary for – the ability to think well). This is not to deny that people have some inherent tastes (for example, it is believed that human beings have a taste for fat, probably because of the evolutionary advantage associated with an inclination to eat meat in an environment in which protein and iron were not easily obtained).

For more complex questions the above is even more likely to be true. Consider, for example, the large increase in female labour force participation in the 20th century. Is it that woman's disutility from market work decreased or that her beliefs about the meaning or consequences of her working that changed over time? The dichotomy between the two alternatives does not seem very useful in this case. If the focus is on understanding why actions change over time, then using standard preferences and modelling the evolution of beliefs as giving rise to changes in expected payoffs may be the more useful strategy (the latter is the approach taken by Fernández 2007b, who shows that a model of the evolution of female LFP as an intergenerational learning process does a good job of replicating a century of US female LFP data). If instead one wished to understand the utility from a given action, particularly one in which identity is concerned, then incorporating cultural beliefs into preferences may be a better route (see, for instance, Akerlof and Kranton 2000). For example, wearing a dress or having a woman as a boss may decrease a man's utility, independently of any expectations of future consequences, simply because it makes him feel (culturally) less masculine.

Culture and Institutions

As seen previously, the main challenge faced by most empirical work on culture is to convincingly isolate its effects from the incentives provided by traditional economic variables and institutions. This should not be taken to mean that culture and institutions are independent variables. Indeed, one way to think about institutions is as congealed culture: that is, which institutions are set up and how these evolve depends not only on the problems faced by society (or by a particular group in society) at a particular moment in time but also the

beliefs/preferences – the culture – that are prevalent. As elaborated on in our earlier discussion of Greif (1994), cultural beliefs (collectivist versus individualist), for example, were reflected in the different ways in which in the 11th century Genoese traders and Maghrebi traders set up their trading institutions, leading to very different economic development paths thereafter. My hypothesis is that the reverse causality is also likely to hold: that is, not only does culture affect institutions but also institutions affect the dynamic evolution of culture. In this sense, work that attempts to establish whether institutions or culture are the most important determinants of economic development seems misconceived (see Fernández 2007c, for a theoretical analysis of the dynamic dependency of culture and institutions; also Bowles 1998, for a review of some of the theoretical and empirical evidence on the effect of markets on culture).

Concluding Remarks

The rigorous study of culture and economics is in its infancy. We would like to understand, for example, how culture propagates and evolves. In particular, what is the relative importance of family versus other institutions as cultural transmission mechanisms for different beliefs or in different environments? To what extent is cultural transmission purposeful, that is, optimizing on the part of an individual or her parents (as in Bisin and Verdier 2000) or for a social group, and to what extent is it involuntary? (Fernández et al. 2004, show that whether a man's mother worked while he was growing up is correlated with whether his wife works, even after controlling for a whole series of socioeconomic variables. They interpret this as preference transmission, but whether it is voluntary – optimizing – or simply by example is an open question.) When and why does culture change abruptly whereas at other times it proceeds glacially?

The relationship between technology and culture also needs to be investigated. How does technology influence culture and how does culture shape technological change? Some papers (for instance, Greenwood and Guner 2005; Greenwood et al. 2002) argue that sexual norms and female LFP changed because of changes in technology. These papers ignore, among other things, the endogeneity of demand for new technology. Despite the convenient simplification of treating technology as a primitive, it too is endogenous. The extent to which societies put resources into developing technology that 'liberates' individuals from household work, for example, depends on things such as whether slavery is available or whether women expect to work in the market or at home. Put differently, both the relative price of market versus household labour and the elasticity of labour supply depend on the institutions (for example, slavery) and expected division of labour (for example, clearly differentiated gender roles) that are in place. The opposite is also true – the extent to which one can substitute capital for labour, whether at work or at home, helps determine which institutions are viable and may determine the pace and ease with which beliefs or preferences change.

From a theoretical perspective, the endogeneity of preferences and beliefs raises difficult questions for welfare. How should we evaluate policies once we recognize that preferences can change? While this is indeed a vexing and problematic question for welfare economics, recognizing that man is a social animal that is (perhaps uniquely) capable of reflecting upon, and hence changing, his preferences and beliefs greatly enriches our view of ourselves and the world and within it the potential role of economic discourse. In the words of A.O. Hirschman, *'de valoribus est disputandum'*.

Cumulative Causation

Carlos J. Ricoy

The notion of 'cumulative causation' constitutes a basic hypothesis on the workings of the market mechanism. The operation of markets is conceived as a continuous process in which economic forces interact upon one another in a cumulative way, thus making for changes in one direction to induce supporting changes which push the system further away from its initial position. In essence, this is the notion which Myrdal refers to as the 'principle of circular and cumulative causation' and which plays an organizing role in his analysis of 'uneven development' (Myrdal 1957).

Although the term 'cumulative causation' is due to Myrdal, the basic hypothesis appears in Young's analysis of 'economic progress' (Young 1928). It is on this basis that Kaldor puts forward a definite 'cumulative causation' approach to the

'economic process' (Kaldor 1966, 1967, 1970, 1972, 1974, 1975, 1978a, 1978b, 1981a, 1981b, 1985); a similar approach, even if less developed, is found in Svennilson's analysis of economic growth (Svennilson 1954).

Young's Increasing Returns

Young's increasing returns constitute the dynamic counterpart of Adam Smith's dictum 'the division of labour – cause of the increased productive powers of labour – is limited by the extent of the market' (Smith 1776). In Young's interpretation, the expansion of markets leads to an 'increasing use of roundabout methods of production' and to a 'progressive division and specialization of industries' which result in a rising 'efficiency of production' (Young 1928).

The 'progressive division and specialization of industries' refers to the tendency (implied by the expansion of markets) for industries to be broken up into more specialized concerns which concentrate on a narrower range of output.

The growth of markets makes possible a progressive 'horizontal diversification' of consumer goods industries that relates to the introduction of new products and the increasing differentiation of basically the same type of goods. As for intermediate and capital goods industries, the process of specialization is both 'horizontal' and 'vertical' ('vertical disintegration', Stigler 1951). To a large extent, this process depends on the occurrence of 'technological convergence' which itself depends on the expansion of markets. (Hirschman, 1957; Rosenberg 1976; Kaldor 1985). This notion refers to the accumulated backward linkages of industries at a given stage in the network of interindustry relations which come to share basically the same process of production, thus allowing and inducing the progressive specialization of industries at successive lower stages.

In this view, 'efficiency' appears as a '*dynamic, macroeconomic-structural*' phenomenon; for it relates to the processes of mechanization and structural transformation which, in turn, refer to the expansion of manufacturing as a whole. This, however, does not imply that efficiency is uniform across industries. On account mainly of the differential incidence of the process of mechanization and of technical progress, the '*opportunity for efficiency*' varies widely across industries which, indeed, gets reflected both in the level and in the rate of change of efficiency. Notionally, for each industry, 'opportunity' defines a 'standard' both for the level and for the rate of change of efficiency. The actual performance of the different industries can then be measured relative to the respective standards.

Relative efficiency gains in a given industry depend on mechanization and specialization which depend on the growth of markets. On account of manufacturing's internal linkages and of 'technological convergence', the growth of markets depends on the growth and specialization of other industries which, in turn, depend on the growth and specialization of yet other industries, and so on; thus, the relative rise in efficiency in an industry depends on the overall expansion of manufacturing. At the same time, the specialization of an individual industry is but the result of the general process of 'division and specialization of industries'; to a large extent, an industry gets specialized, comes to concentrate on a narrower range of output insofar as other industries do. (complementary and subsidiary industries).

On this account, therefore, an industry's (relative) rise in efficiency depends on the expansion and internal development of manufacturing as a whole as much as it depends on the internal development of the industry itself. Moreover, due to the interindustry linkages internal to manufacturing, the rise in efficiency that notionally refers to a particular industry gets spread to other industries and, eventually, to the whole sector. In this sense, the development of particular 'key' industries characterized by a high 'opportunity' for efficiency and/or by rapidly growing markets benefits the development and efficiency of other industries across the sector; in this way, 'mature' industries may benefit and receive a new 'lease of life' from developments initiated elsewhere within the sector.

Efficiency, as macroeconomic phenomenon, reflects the process of growth in terms of capital accumulation and structural transformation; in the

process, as different 'tensions, disproportions and bottlenecks' are continuously being solved, the efficiency of production rises all across manufacturing. At any one time, the level of efficiency is the reflection of the structure of manufacturing in terms of the degree of mechanization and of specialization and diversification of industries as well as in terms of the strength of the network of interindustry relations. In this sense, the level of efficiency is an index of the level of development and the rate of change is an index of the growth and development performance over a period.

On this basis, a given industry located in different countries will tend to show in each country a level and a rate of change of efficiency in correspondence with the overall development (and efficiency) and the rate of output growth (and efficiency gains) of the respective national manufacturing sectors. Thus, countries experiencing (relative to their competitors) higher rates of growth and transformation and, therefore, higher rates of efficiency as regards manufacturing as a whole will tend to experience higher corresponding rates as regards individual industries as well (see Eatwell 1982). Yet, a proviso must be made here; for 'opportunity for efficiency' varies across countries as well. The degree of 'opportunity' is related to the dependence of efficiency on learning, on the accumulation of experience and mastery and on technical progress. As regards individual industries, a high degree of opportunity results from the industries' efficiency being dependent on (intensive in) learning, mastery and technical progress. As regards countries, the opportunity for efficiency, as it depends on learning and technical progress, is related to the growth and development of manufacturing. Thus, the intercountry differential in 'opportunity' is related to the interindustry differential; the lower the opportunity of the industry is, the lower the intercountry differential and, vice versa, the higher the opportunity of the industry, the higher the intercountry differential. Thus, the correspondence between the rate of change of efficiency in manufacturing and that in individual industries will tend to be more accurate for high opportunity industries.

Say's Law as 'Closure' of the System

In Young's analysis, based on the 'classical version' of Say's Law, the growth of markets is defined by the rise in the volume of production, which, in turn, is determined by the rise in efficiency; on account of increasing returns, the latter is determined by the growth of markets itself. Hence, 'the growth of markets is determined by the growth of markets'. This, as Young points out, 'is more than mere tautology'; the expansion of markets leads to the rise in efficiency through mechanization and structural transformation which open up '*new opportunities for further change which would have not existed otherwise*'. In the normal operation of markets any given 'impulse' is amplified cumulatively, the growth of demand results in an endless 'chain reaction' of sectoral supplies and demands all through the network of interindustry relations. In the process, 'each sector receives impulses' for change and, in turn, 'sends impulses' for further change. Thus, '*change becomes progressive and propagates itself in a cumulative way*' (Young 1928; Kaldor 1972, 1973).

Young's analysis embodies the essence of the principle of cumulative causation; however, what is essentially a matter of impulses and inducements what is a 'potentiality' is transformed into 'actuality'; for, by definition, demand always responds to the inducement to further growth provided by structural change and the all-round improvement in efficiency; the actuality of an endless chain of circular and cumulative causation is thus ensured. Due to Say's Law, there is no 'degree of freedom', no independent leading element in the system. In this sense, the analysis remains as it were 'hanging in the air'.

Learning and Technical Progress

(a) To a large extent, economic growth is to be seen as a '*learning process*' (Rosenberg 1976). Economic growth involves a series of ongoing activities, decisions and events, ranging from the operation of plant and equipment and decisions taken about production and investment to the

occurrence of structural change and the introduction and development of technology. As those activities, decisions and events materialize, different problems, 'tensions, disproportions and bottlenecks', are encountered. Successful growth requires that solutions be found to those problems; and learning results from discovering and facing problems and from searching for and finding solutions to them. Moreover, the faster growth takes place, the more will problems assert themselves, the more will the need to solve them be felt and, therefore, the stronger will the inducement to learn be (see Arrow 1962). To the extent that learning is effective, experience and knowledge are accumulated and skills and capabilities developed. On this basis, each successive step in the normal process of growth and transformation becomes (potentially) easier. As a result, the efficiency of production and that of the growth and learning processes themselves are raised. Thus, learning depends on the growth of output, results in efficiency gains and induces further growth and transformation.

(b) Within the cumulative causation framework, normal technical progress is conceived of as a *non-random, evolutionary* process; it is '*non-random*' in that the direction of change is defined by the 'state of the art of the technologies already in use' and it is '*evolutionary*' in that it normally involves the 'rejection of parts of the old technology' rather than its total rejection. Moreover the process tends to be *cumulative*; for the likelihood of success in the completion of a new technology depends on past developments and on the accretion of experience, knowledge and technological mastery that results from the 'learning process' that the development of technology implies (see Dosi 1984; Rosenberg 1976; Nelson and Winter 1982).

A new technological concept (product, equipment, technique) does not come about as a 'perfectly known', 'fully grown' output of R&D activities. At this stage, there is a fundamental lack of understanding and a great deal of uncertainty as to the actual performance of the new concept. Most commonly the resolution of that uncertainty and the acquisition of knowledge require experience in the production and operation of the new concept as well as further research and development.

At the same time, the introduction of a new technological concept faces fundamental uncertainties as to the nature of demand. Consumers are both uncertain about their preferences and unaware of the characteristics of new products and of how they compare with possible substitutes. Users of capital equipment are, in turn, uncertain as to the exact nature of their requirements and lack basic knowledge and face fundamental uncertainty as to the characteristics of new technological alternatives and as to how they fit in the process of production. It is only through actual experience in consumption (Pasinetti 1982; 'product-cycle'model: Vernon 1966) and in the effective use of equipment in production that uncertainty can be resolved and knowledge increased. ('learning by using': Rosenberg 1982).

Technical progress manifests itself in a *sequence of problem-solving activities* along the chain '*demand–production–R&D*'. In this sequence, faults, weak spots and technical problems of a new technological concept will be discovered. To the extent that solutions are found and that, through operating experience, consumers/users are able to improve the specification of their preferences/requirements, there will be frequent modifications and improvements of the new concept. At the same time the discovery of problems, the search for and the actual finding of solutions will result in a better understanding of the new technology and in the accumulation of skills, experience and knowledge; in this sense, technical progress is in itself a '*learning process*'.

So technical progress depends on the dynamics of demand in a fundamental manner. On the one hand, technical progress is, to a large extent, *induced* by the expectation of demand. As regards capital goods industries there is an 'external impulse', signalled by the rate of investment, to accommodate specific requirements of different industries, particularly, of fast growing, highly innovative ones (see Schmookler 1966; Rosenberg 1976). As for consumer goods, technical change is induced by the expected evolution of consumer's 'wants' and by the expectation of extending given patterns of consumption to

lower brackets of the income distribution structure. At the same time, the success (and further development) of technological advances depends on the actual dynamics of demand; the effective development of technology requires that the expectations of demand be fulfilled, i.e. it requires the *validation* of the effective growth of markets.

On the other hand, the *efficiency* and *effectiveness* of the process of technical change depend largely on the growth of markets. A faster growth of markets makes it easier to ascertain the 'new ways of expansion' as well as to switch from one path of expansion to another; in this sense, it provides the innovative process with a '*higher degree of flexibility*' which lowers the risks and costs involved, thus leading to a higher rate of innovative effort. In addition, a faster growth of markets leads to a faster and more effective learning process; it leads to a higher rate of accumulation of skills, knowledge and mastery and, therefore, to a more efficient and effective handling of the sequence of problem-solving activities that the process of technical change entails.

The process of technical progress appears intrinsically connected to Young's increasing returns; for, both through the introduction and differentiation of goods and through the development of new technologies of production, it induces and, at the same time, is induced by the processes of mechanization and of division and specialization of industries.

Effective Demand

By combining the dynamics of 'efficiency' as it results from Young's increasing returns and from learning and technical progress with the principle of effective demand in a dynamic setting, Kaldor provides the definitive development of the principle of cumulative causation. On this account, the growth of demand constitutes the 'leading factor' of the 'self-reinforcing dynamics' internal to manufacturing. The growth of demand determines the growth of output and leads to a rising efficiency of production; whether the process keeps its momentum and becomes cumulative or gets stopped (and probably reversed) depends on the 'next round' of demand, on the response of demand to the *inducement* to further growth provided by the rise in efficiency. In this sense, the growth of demand (as 'leading factor') is the 'weak-link' of the internal dynamics of manufacturing. Thus, effective demand provides the circular process of cumulative causation with a 'degree of openness' that contrasts with the 'continuity' that, owing to Say's Law, Young's analysis implied.

In the last analysis, the key role of demand rests on the 'independence' of capital accumulation as the driving force of the process of economic growth; capital accumulation is central to technical progress and adds both to demand and to capacity, i.e. it 'provides the incentives and the means of further expansion' (Kaldor 1966). On this basis, the *potential* for a continuous self-expansion of the system finds no limit; as Joan Robinson puts it, 'carrying itself by its own bootstraps is just what a capitalist economy *can* do' (Joan Robinson 1962).

The fact that investment is the fundamental independent variable of the system does not mean that the rate of accumulation is fixed, invariant with respect to economic conditions; actually, the assumed degrees of freedom in investment behaviour are to a large extent the reflection of the many factors, economic and non-economic, that influence investment decisions. In the context of the 'self-reinforcing dynamics' of manufacturing it is the response of investment to the growth of markets and to the resulting rise in efficiency along with the more direct dependence of consumption on industrial expansion that accounts for the 'reverse link' and, thus, for the circular and cumulative nature of the dynamics itself.

The rise in (quantitative) efficiency that results from industrial expansion, leads to the growth of consumer demand through the rise in real income and through the expansion of consumption to lower brackets of the income distribution structure. Owing to the different growth elasticities of demand for different goods and for different income levels, the overall growth of consumption and, therefore, the overall growth effect of the interaction 'industrial expansion–consumption' depend largely on the composition of

consumption in terms both of goods and of income groups. In this regard, at high income levels there is a tendency for the growth of demand to slow down and, even, to stagnate; this tendency, however, is continuously being overcome by the 'innovation' and 'quality-differentiation' effects of efficiency (technical change, structure diversification); these effects are, thus, crucial to keep the 'drive' for expansion alive (Pasinetti, 1982). As regards capital goods, the 'price' and 'quality-obsolescence' effects of technical change constitute fundamental determinants of investment activity. In addition, investment is induced by industrial growth itself both through the interindustry expansion of markets and through the growth of consumption it entails.

In the sequence 'industrial growth – consumption – investment – industrial growth', the growth of real wages is of special significance; for wages are both income and cost of production. (Kalecki, 1939). As income, the growth of real wages leads to demand and output growth which lead to productivity growth; as a result, it may lead to higher rates of investment. As cost, the growth of wages has two contradictory effects. On the on hand, it may induce a process of dynamic substitution à *la* Marx, thus, leading to a higher rate of investment and productivity. On the other hand, to the extent that the growth of real wages 'eats up' in profits, it may result in a lower rate of investment. On the basis of the 'substitution' and 'demand' effects, the growth of real wages can be seen to imply a 'cumulative causation' pattern of growth. The growth of real wages leads to demand growth and to dynamic substitution, therefore to investment and to productivity growth which, in turn, lead to higher growth of wages and so on and so forth.

Manufacturing as the Engine of Growth

If capital and labour, as resources used in production, were exogeneously given in fixed quantities, the circular and cumulative dynamics of manufacturing would not materialize; economic growth would be effectively 'resource-constrained'. Yet the quantity and quality as well as the sectoral distribution of labour and capital cannot be taken as 'given' independently of the growth progress itself.

Insofar as the effective labour force (participation) varies in direct relation with demand and, most significantly, insofar as there is *surplus labour* in other sectors such as agriculture and services, at no time can the labour force be considered fully and optimally employed. As manufacturing expands, labour is drawn from those 'reserves' and gets allocated to other uses where its contribution to the economy's output is greater than before; moreover, in the process, 'efficiency' in the surplus labour sectors is enhanced. As for capital, in no significant sense can it be regarded as a 'scarce' resource; capital, as produced means of production, is output and, as such, is the result of economic activity. The quantity, quality and sectoral distribution of capital and labour, as determined by investment, learning and technical progress, are the 'effect' of the process of development as much as the 'cause' of it (see Kaldor, 1978).

In the course of its expansion, manufacturing *generates* its own resources, it mobilizes labour and produces capital; thus, the expansion of manufacturing represents a net addition to the effective use of resources and, therefore, to the overall growth of the system. The growth of manufacturing and, thus, overall economic growth, are not constrained by resources; rather, they are led by the expansion of markets, by the growth of demand for manufactures. Moreover, as other sectors depend largely on manufacturing for the provision of their inputs, the overall efficiency of the economy is mainly determined by that of manufacturing.

Economic growth, centred on the 'self-reinforcing dynamics' internal to manufacturing, is a circular process of cumulative causation governed by the growth of demand. The growth of demand for manufactures leads to the growth of output and to efficiency gains both in manufacturing and in the economy as a whole (capital accumulation-mechanization, structural transformation, reallocation of resources, learning and technical change) which *induce* further growth of demand and so on. In this view, a 'pause' in

the expansion of the system may well lead to (structural) stagnation; for, on account of dynamic economies of scale, a shortage of effective demand tends to get amplified throughout the economy. Such a cumulative downturn is but the manifestation of the free workings of the market as mechanism that *transmits impulses and inducements*; in the same way as change calls forth supporting change, the absence of change leads to stagnation; for it is in the nature of the manner of operation of markets and competition that 'growth requires growth', 'success requires success'; the market system is prone to cumulative movements, once in a growth path it tends to cumulative self-expansion; yet should growth lose its momentum and slow down, a tendency towards a cumulative downturn ensues; 'a capitalist economy cannot afford to stay still because, it it stops expanding, it falls back' (Pasinetti, 1982). This is circular and cumulative causation. (Compare Marx's account of the process of capitalist development and of competition as a dynamic process.)

Foreign Trade

At a more concrete level of analysis, as regards the 'open economy', foreign trade in manufactures asserts itself as a 'built-in' element making for the continuity of the circular process of cumulative causation. The growth and composition of net exports (exports minus imports) are fundamental elements in shaping the process of growth and structural change of the economy and, in turn, as determined by competitiveness which results from efficiency, they are mostly determined by economic growth itself. The growth and the change in the composition of demand, including those of net exports, lead to 'efficiency gains' which, via price and non-price factors, give competitiveness which leads to growth and changes in the composition of net exports and, thus, of demand and output and so on and so forth.

On the other hand, foreign trade, through the balance of payments position, may impose an 'effective constraint' on growth. But for the possibility of attracting a continuous net inflow of capital, in the long run an economy's growth rate cannot be higher than the rate of growth consistent with balance of payments equilibrium on current account. This growth rate Thirlwall (1980) refers to as 'balance of payments equilibrium growth rate'. This rate depends fundamentally on the trade balance in manufactures and, therefore, on the growth rate and on the 'normal' competitiveness of manufacturing (given the 'normal' time paths of the other components of the current account). The significance of the equilibrium rate as ceiling to the actual rate is to be understood in relation to the growth rate that can be considered as 'socially necessary' in terms of economic development (output and employment growth, structural transformation learning and technical progress) (cf.Singh's notion of an 'efficient manufacturing sector': Singh 1977). In this regard, a situation in which, due to a 'weak' competitive position, the 'equilibrium' rate is lower than the 'socially necessary' rate tends to be 'self-perpetuating', as it will result in a lower rate of efficiency gains, lower growth of net exports, and, eventually, in a lower equilibrium rate.

The dynamics of foreign trade and, thus, economic growth in a given economy depend also on economic growth and efficiency abroad. Foreign growth 'complements' domestic growth insofar as it widens the opportunities for the expansion of domestic net exports. At the same time foreign growth enlarges the supply of commodities which can 'compete' with domestic production, and, by raising foreign efficiency, lowers domestic competitiveness, thus making for a lower growth of domestic net exports (Sayers 1965; Singh 1977). In addition, the competitive process in world markets entails a fundamental 'composition effect'; fast growing countries tend to gain market shares particularly in those trades with the highest 'opportunity for efficiency' and with the highest potential for market expansion while 'weak' countries tend to be pushed out of those trades. (cf. above, 'bias' in the correspondence across countries between efficiency in manufacturing and in individual industries). In this regard, if, in the course of growth, the 'competitive' aspects of growth elsewhere come to dominate, the ensuing disequilibrium may develop into a cumulative

downturn in which a lower growth of net exports leads to lower growth of output, lower rates of investment, lower rates of transformation and technical change, thus leading to a still lower growth of net exports and so on; eventually, the country will find itself 'balance of payments constrained' as the equilibrium rate falls below the 'socially necessary' rate. This is a '*vicious circle of cumulative causation*'. The cumulative fall in competitiveness and the resulting 'vicious circle' are worsened as other countries will be experiencing a '*virtuous circle*' in which high rates of growth of demand result in high rates of investment, transformation and technical progress, high growth of net exports (increasing market shares) and so on. A fundamental feature of this process rests in the fact that the 'vicious circle' results from developments initiated elsewhere, i.e. by the rise in growth rates and in efficiency elsewhere in the world system; thus, the need to expand, the need to keep the pace in the process of structural transformation and technical change appears more stringent in the presence of foreign trade. On the foregoing account, the dynamics of the world economy, as regulated by the free operation of markets, appears characterized by an inherent tendency towards *unequal growth* across countries; for, in a dynamic world where the expansion of manufacturing is characterized by the operation of 'dynamic economies of scale', where technology is 'developed' and not universally accessible, where technical progress unfolds as an evolutionary and cumulative learning process and where the dynamics of effective demand determine the dynamics of the system, any given 'competitive advantage' in terms of growth, transformation and technical change tends to be compounded through the interdependence that exists among countries via foreign trade.

The tendency towards 'unequal growth' entails a '*deflationary bias*' and an intrinsic and progressive instability in the dynamics of the world economy. As the growth of 'weak' countries is held back, the overall expansion of the world economy tends to slow down. This is normally offset by the faster growth of 'strong' countries which actually enables weak countries to grow faster than would otherwise be the case. In this sense, the long-rung deflationary tendency embodied in the dynamics of the system remains as it were 'disguised' in the very process of expansion. Yet, the pattern of uneven growth makes for the cross-country 'differential' in competitiveness to grow wider over time; in this respect, the dynamics of the world economy appears inherently and progressively unstable. Over time, a tendency develops for weak countries to experience a 'fundamental disequilibrium' (constraint) in the balance of payments. In these circumstances, an exogenous 'deflationary shock' or, simply, a slowdown in the expansion of the 'leaders', would make the constraint binding. But, even in the absence of any such shock, as long as the weak countries' loss of competitiveness is left 'to look after itself' and actually becomes cumulative, the tendency towards 'fundamental disequilibrium' will eventually materialize. In the event, a general slowdown in the expansion of markets could only be avoided by enabling weak, 'structural' deficit countries to grow at rates higher than the respective balance of payments equilibrium rate, thus effectively allowing them to run continuous current account deficits. If, on the contrary, the burden of adjustment were brought to bear upon weak countries by forcing them 'to live within their means', a generalized contraction of effective demand would ensue; the lower growth and weak countries and, thus, the lower growth of effective demand, would be spread from country to country through the operation of the dynamic foreign trade multiplier. In this way, a generalized deflationary process would set in. The fundamental point to stress here is that the occurrence of such a process constitutes the long-run consequence of the progressively increasing differential of competitiveness implied by the pattern of unequal growth, transformation and technical progress inherent in the normal dynamics of the world economy as regulated by the free operation of markets.

At the same time, the normal dynamics of the world economy are characterized by a pattern of

uneven development. In this regard, the sectoral structure of the economy is of the utmost significance. The dynamics of the different countries' net exports, as determined by relative efficiencies, reflects the process of development. At any one time, the structure of net exports reflects the past process of development in terms of Young's increasing returns, learning, technical change and both the potential for market expansion and the opportunity for efficiency characterizing the existing economic structure. In turn, the process of development and, thus, the economic structure reflect the dynamics of foreign trade.

As regards a 'representative' underdeveloped country, the economy is characterized by a low degree of mechanization, by a lack of inter- and intra-industry diversification and specialization and by a low degree of sectoral interdependence; in this sense, underdevelopment can be described in terms of the market-induced structural inability to realize Young's increasing returns. In addition, production processes are characterized by a very low intensity in skills, knowledge and technical progress which result in the absence of induced learning. On this basis, the export composition appears basically centred on primary commodities and a few 'mature' manufactured products for which the growth of demand tends to be rather low and unstable while the 'opportunity for efficiency' is practically nil.

As for a 'representative' advanced country, its economic structure, centred on the manufacturing sector, is highly diversified and interdependent; in turn, the different industries are highly specialized in terms of products and methods of production; the latter are further characterized by a high average degree of mechanization and by a high average intensity in accumulated experience, knowledge and technological mastery.

In the normal (free) operation of markets the pattern of 'specialization' as between advanced and 'poor' countries tends to be perpetuated and the corresponding differential and efficiency tends to be grow wider over time; due to the operation of dynamic economies of scale, industrial activities tend to concentrate in a few 'established centres' which benefit from the 'freeing' and 'widening' of markets at the expense of the industrial development of 'backward' countries; 'the free play of market forces works towards inequality' (Myrdal 1957).

Cumulative Processes

Björn Hansson

The first well-known analysis of cumulative processes was developed by Knut Wicksell in his book *Interest and Prices*, which was published in 1898. It grew out of an attempt to reformulate the quantity theory of money. In this context the cumulative process is intimately connected with the development of the saving–investment approach, which is one mechanism through which a change in the quantity of money can influence prices and quantities.

Wicksell considered the main proposition of the quantity theory, namely, that the value of the purchasing power of money varies in inverse proportion to its quantity, to be basically correct. At the same time the quantity theory was in its original formulation too restrictive and in conflict with reality, since it was based on the assumption that everybody uses their own cash, which is both legal tender and the monetary base, for buying and selling and all have to maintain a cash balance. Therefore the followers of the quantity theory sometimes argued 'as though the quantity of money, or of that part that at any moment finds itself in the hands of the public, must act as a *direct* and *proximate* price-determining force' (Wicksell 1898, p. 43). This is the so-called direct mechanism, which works via a real-balance effect and it is still stressed by Friedman in his development of modern monetarism. However, in a developed credit economy the keeping of individual cash-balances has almost faded away and it has been replaced by current and deposit accounts and the use of claims of various kinds in monetary transactions. The banks, in their turn, only hold a smaller part of the deposited sums as cash, which shows that Wicksell developed the quantity theory for a banking system based on fractional reserves.

The Background to the Cumulative Process

The following quotation gives the analytical basis for the cumulative process:

> Every rise or fall in the price of a particular commodity presupposes a disturbance of the equilibrium between the supply and the demand for that commodity, whether the disturbance has actually taken place or is merely prospective. What is true in this respect of each commodity separately must doubtless be true of all commodities collectively. A general rise in prices is therefore only conceivable on the supposition that the general demand has for some reason become, or is expected to become, greater that the supply. This may sound paradoxical because we have accustomed ourselves, with J.B. Say, to regard goods themselves as reciprocally constituting and limiting the demand for each other. And indeed ultimately they do so; here, however, we are concerned with precisely what occurs, in the first place, with the middle link in the final exchange of one good against another, which is formed by the demand of money for goods and the supply of goods for money (Wicksell 1935, pp. 159–60).

Wicksell proceeded from an approach based on Marshallian partial equilibrium to an aggregate approach for analysing secular changes in the general price level. Furthermore, the central problem is the analysis of a system out of equilibrium (i.e. a disequilibrium analysis), which implies criticism of the quantity theory for analysing and comparing equilibrium situations only and leaving out the dynamic process itself.

The cumulative process takes its point of departure in an analysis of the relation between the actual rate of interest on loans, the money rate, and the natural rate or the normal rate. The *natural rate* is defined as the anticipated profit to be made by the use of a bank loan. The *normal rate* is defined as that particular level of the money rate which guarantees the equality of the demand for loan capital from investors and the supply of savings or loan capital from lenders; this rate corresponds to the natural rate.

The level of the *money rate* of interest is ultimately determined by the normal rate. But in the first instance, the money rate of interest is a separate variable which is set autonomously by the banks in the market for borrowing and lending of money. In this institutional setting, where bankers fix the money rate, the money supply is assumed to be endogenous and determined by demand. Therefore disturbances emanate from variations in the demand for money due to changes in the natural rate, which is then passively supported by an expansion of the money supply from the private banks, and it is not active changes in the monetary base initiated by the Central Bank which are the source of the disturbance. The equality of the money rate with the normal rate, which, according to Wicksell's analysis, implies stability of the price level and that saving equals investment, is thus a separate equilibrium condition, which was later called monetary equilibrium.

The Mechanism of the Cumulative Process

In the following example it is supposed that the natural rate increases, which may be due to an increase in productivity, while the money rate as fixed by the banks stays the same. It implies that the value of the total product at the end of the production period – the duration of the period is the same in all lines of production – has increased, but the entrepreneurs have to pay back less to the bank. They now have a surplus profit, which eventually will lead to an attempt to expand production. An expansion in real quantities is ruled out since full employment is assumed (Wicksell's analysis was concerned with changes in the price level and not with changes in quantities.) In any case, even if capital accumulates, it would still take some time before the results accrue, so there would be no immediate counteracting effects. However, the entrepreneurs will try to increase their demands for inputs and these prices will rise, and it is assumed that the increase is equal to the value of the expected surplus profit. The owners of inputs, in their turn, will increase their demand for consumer goods and the price level will rise proportionately. At the end of the year, the entrepreneurs have in their hands, at the new

price level, consumer goods of a higher value than at the end of the previous period, while their debts to the banks are the same. Hence, they will still have a surplus profit, and the tendency to expand output will persist despite the change of the price level. The whole process will repeat itself. This is the minimum requirement for denoting a process as cumulative: it should have an endogenous mechanism which keeps the process going.

If it is assumed that the entrepreneurs always anticipate that the price level for consumer goods will be the same at the beginning as well as the end of the period, then we can imagine that a steady and more or less uniform rise in the price level will ensue. In the case of entrepreneurs expecting future rises in prices, then the actual rise will be higher and the cumulative process will be more and more rapid.

In the reverse case, where the money rate is larger than the natural rate, the process will be similar since Wicksell assumed that prices and wages have the same flexibility in both directions. It is likely that full employment could be preserved during the downward process; the fall in entrepreneurial demand for labour and land will induce workers and landlords to reduce their claims for wages and rents and the activity will be maintained at its former level. Wicksell did not rule out the existence of unemployment during a downward cumulative process, but it would not be a cumulative change.

The cumulative process may come to an end through internal causes. The changes in the price level will act as an equilibrating mechanism via its effect on the level of bank reserves. The increase in prices will lead to a higher requirement of means of exchange, which implies that to maintain a rate of interest permanently below the natural rate it is necessary to increase continually the amount of reserves. The Central Bank can therefore play a role by changing the monetary base.

In the new equilibrium the current price level will not change since the entrepreneurs can pay the increased wages etc. and still earn the normal profit. This is the basis for Wicksell's discussion of the difference between a stable equilibrium of relative prices and a *neutral/indifferent equilibrium* for the general price level, which implies that there is no tendency to resume the old equilibrium position of the price level. In fact, in an equilibrium situation value theory will determine relative prices while the quantity theory of money gives the absolute height of the price level. Wicksell did not challenge the classical dichotomy as long as it is a comparison of equilibrium situations. However, during a cumulative process, which is a disequilibrium phenomenon, the connection between value theory and monetary theory proceeds via the difference between the money rate and the normal rate. This difference determines changes in the price level and not the level itself. Thus the cumulative process is in the first instance an analysis of changes in the general price level and its main concern is not with changes in output and employment. This is explicit in the formal analysis of *Interest and Prices*, where it is assumed that the real system is in a stationary equilibrium even during the cumulative process.

The Cumulative Process and Monetary Policy

Wicksell applied his reconstruction of the quantity theory to Tooke's criticism of the quantity theory; rising prices mainly coincide with rising or high interest rates, which Keynes called Gibson's paradox. The object of this debate is the secular increase in the price level, which may be exemplified by the period 1850–1873. Wicksell explained this fact by the tardiness of the banks to change the loan rate in relation to changes in the natural rate. It is thus changes in the natural rate which often trigger off the cumulative process. It has already been seen that Wicksell did not put the blame on the Central Bank and the private banks are now exempted from initiating disturbances, which are mainly due to changes in real factors affecting the private demand for money. This analysis obviously has a place for an active monetary policy where the Central Bank tries to influence the money rate so as to dampen the cumulative process.

Further Development of Cumulative Processes

It is of fundamental importance for later developments that Wicksell analysed movements in the general price level via the effects of changes in the rate of interest (both money and normal) on savings and investment, that is, the indirect mechanism.

The Wicksellian influence on Keynes's *Treatise on Money* came probably not through Wicksell's works but via Cassel's *The Theory of Social Economy*, which was translated in 1923. Keynes used the idea of a difference between the natural and the market rate or between savings and investment, and its influence on profit, which is defined as windfall gains, as the basis for his attempt to find the dynamical laws of the disequilibrium process. Like Wicksell, he criticized the long run equilibrium character of the propositions of the quantity theory, since it did not distinguish the factors which operated during the transition process between two equilibrium positions. Keynes's theoretical constructions, the Fundamental Equations, were not supposed to be a complete substitute for the quantity theory, but to add an analysis of short period situations which was most important, from a practical point of view, for studying monetary phenomena. Keynes extensively studied, in particular in the Fundamental Equations, the dynamics of the price level, but he went beyond Wicksell by analysing credit cycles, which involve the mechanics of the wage-price-employment structure. However, the incorporation of quantity changes in the disequilibrium process does not imply that Keynes had determined an equilibrium level of output and employment which is different from full employment.

Mises stressed that the difference between the two interest rates had differential impacts on the prices of consumption goods and the prices of capital goods, that is, an analysis of relative prices was incorporated in the dynamic process. Hayek started from Mises's contribution. He was not interested in the dynamics of the price level as such, because this magnitude, which is a statistical artifact, has no influence on the decisions of individuals. It is the direct influence on relative prices from changes in the money supply and the money rate which is important. These changes determine the level and the direction of production. This is a clear rejection of the proposition that changes in the money supply can only lead to disturbances via the general price level. Hayek's position is linked to the substitution of the old notion of a long run equilibrium by intertemporal equilibrium. The central problem is therefore not changes in the price level but disturbances of the equilibrium relation between the rates of intertemporal exchange. This spills over into the problem of neutral money: to define the conditions under which changes in the money supply might leave intertemporal price relationships unchanged, which is one development of the notion of monetary equilibrium.

Wicksell's Swedish followers, Lindahl and Myrdal in particular, used the notions of ex ante and ex post to determine the factors which constitute the ex post equality between saving and investment during a cumulative process. This analysis puts the difference between ex ante saving and ex ante investment as the main condition for monetary equilibrium, where the latter is a criterion of a cumulative process. They also made a thorough analysis of the definition of the normal rate which would guarantee monetary equilibrium, in an attempt to make this rate practically useful in a monetary analysis. In this analysis they used new equilibrium concepts like temporary equilibrium and sequence analysis, which became one of the hallmarks of the Stockholm School.

During the 1930s two different strands of thought superseded the cumulative process as an approach to the relation between savings and investments. On the one hand there is the macrodynamic analysis developed by Frisch and Tinbergen, which is centred on cyclical behaviour in prices and quantities and on the existence and stability of equilibrium in a dynamic system. On the other hand Keynes's *General Theory* focused on the determination of a short run equilibrium of output and employment. Comparative statics was used to study the effects of changes in

exogenous factors and Keynes showed very little interest in the accommodation process outside equilibrium.

In the wake of the neo-Walrasian interpretations of Keynes (e.g. Clower and Leijonhufvud), which imply a disequilibrium approach, there have been attempts to reinterpret and develop Wicksell's cumulative process from this point of view (e.g. Laidler 1972). The neo-Walrasians stress income-constrained aggregate demand functions and a dynamic process with trading at disequilibrium prices, which is opposed to the traditional tâtonnement process with an auctioneer and recontracting. From this angle, Wicksell's modern element lies in the explicit analysis of the behaviour of an economy in disequilibrium and with no recontracting, which generates an income constrained process. However, the assumption of flexible wages and prices, in particular downwards, leads only to a cumulative process in the price level while output is constant. According to Laidler (1972), it is enough to introduce the Keynesian assumption of rigid wages and sticky prices into Wicksell's cumulative process and a Keynesian income constrained process would follow immediately. In this process changes in quantities do all the adjusting necessary in disequilibrium, which may produce cumulative forces that tend to move employment away from full employment equilibrium.

Cunningham, William (1849–1919)

O. Kurer

Keywords

Cunningham, W.; Economic history; English historical school; Imperialism; Marshall, A.; Protectionism

JEL Classifications

B31

A member of the English Historical School, Cunningham was educated at the Universities of Edinburgh and Cambridge. He held various posts as lecturer at Cambridge and was elected Fellow of Trinity College in 1891. From 1891 to 1897 he was Tooke Professor of Statistics of King's College London. In addition, he pursued a religious career. He was ordained in 1874 and rose to be Archdeacon of Ely (1907–19).

Cunningham was one of the most important pioneers in economic history. His *Growth of English Industry and Commerce* (1882) was the first textbook in the field, widely used for several decades and an important foundation on which English economic history was to be constructed, and he relentlessly fought for the recognition and establishment of economic history as an independent discipline.

Cunningham became increasingly hostile towards economic theory. He felt that its assumptions about human behaviour and the institutional framework were leading to insufficiently complete analyses and were blatantly unrealistic for most periods in history. In 1892 he started the English Methodenstreit by attacking Marshall for constructing economic history from general principles instead of empirical data. The debate was partly the result of his personal and professional antagonism towards Marshall and his wish to apply economics to politics.

Cunningham shifted from an internationalist and free trader to a nationalist and protectionist, making the preservation and strengthening of the nation-state his most weighty political and economic objective. By the time of the fiscal controversy in 1903 he fully endorsed the tariff reform movement and subscribed to imperialism, with the great empire securing peace and order.

Cunynghame, Henry Hardinge (1848–1935)

John K. Whitaker

Soldier, lawyer, civil servant, polymath and amateur economist, Sir Henry Cunynghame was born of distinguished forebears on 8 July 1848 at Penshurst. He died at Eastbourne on 3 May 1935, having been knighted in 1908. In 1870 he entered St John's College, Cambridge, to study law, throwing over a promising military career. There he became a favourite of Alfred Marshall and was infected by an enthusiasm for 'geometrical political economy', a topic on which he was eventually to publish one of his many books (1904). There too he invented for Marshall a

machine (now lost) for drawing a grid of rectangular hyperbolae (Guillebaud 1961, Vol. II, pp. 37–8).

Called to the Bar in 1875, Cunynghame had a varied career in law and government, but always retained his interest in economics. He occasionally lectured on the subject (his *Notes on Exchange Value* (1880) were printed for one such course) and in the later 1880s belonged to the economic discussion group which met at the Hampstead home of Henry Ramée Beeton. (P.H. Wicksteed, G.B. Shaw, H.S. Foxwell and F.Y. Edgeworth were among the regulars.) There he presented a paper (1888) defending Marshall's supply curve against Wicksteed's criticisms. The analysis of external effects in production and consumption, his most significant theoretical contribution, first appeared here, the arguments being amplified, but not much clarified, in Cunynghame (1892). His other notable contribution, the use of back-to-back demand–supply diagrams to analyse markets linked by trade, appeared in Cunynghame (1903). The 1904 book, although lively and praised by J.M. Keynes, added little and, indeed, rather compounded earlier ambiguities by a certain flabbiness of thought. Cunynghame's last economic publication (1912) was a valedictory address on methodology. For further biographical detail see Keynes (1935) and Ward and Spencer (1938). Consult also letters by Marshall (reproduced in Pigou 1925, pp. 447–452; Guillebaud 1961, Vol. II, pp. 809–813) and Edgeworth's review (1905) of Cunynghame (1904).

Currencies

C. A Gregory

Any commodity is capable of being used as a medium of exchange and history furnishes us with an almost endless list of commodities that have been used in this way: cattle, cacao, beans, salt, silk, furs, tobacco, dried fish, wheat, rice, olive oil, cloth, cowry shells, iron, copper, silver and gold. However, not all of these commodities are efficient means of exchange and the natural properties of cowry shells, gold, silver and copper led to their emergence as the most popular form of currency. The relative scarcity of gold and its indestructibility made this form of money highly desirable as a store of value; the relative abundance of cowry shells, combined with their uniformity and divisibility, made them an ideal medium of exchange for low valued transactions;

silver and copper have natural properties that made them useful for transactions intermediate between these two extremes.

The rise of nation states and the emergence of paper money and metallic tokens led to a decline in the use of commodity monies as currency. The principal problem with gold, silver, copper and cowries was that even though their relative values remained remarkably stable for centuries these ratios were incapable of being fixed. For example, the exchange ratio of silver to gold in Europe deviated little from its average of 13 to 1 in the eight hundred years prior to the emergence of the gold standard towards the end of the 19th century (Shaw 1895); in West Africa the cowry/gold ratio varied between 15,000 and 20,000 to 1 over the period 1700 to 1850 (Johnson 1970, p. 334). The ratios were determined by the conditions of production, unlike the relation of the English penny to the pound which was fixed by government fiat at 240 to 1.

Fixed ratios of the various units of a currency are essential if it is to perform its function as a standard of price efficiently. Thus 'bad' state money, which has no intrinsic value but fixed ratios between its subordinate parts, forced out the 'good' commodity monies according to the principles of Gresham's Law. Cowry shells were first to go and they disappeared from Africa and Asia in the mid to late 19th century following the colonization of the regions by the British empire and the establishment of the Sterling currency area. Silver followed next but only after much resistance from the European countries whose currencies were based on the silver or bimetal standard. Gold, too, disappeared from circulation but only to take up residence underground where central banks clung to it as a store of value. It too seemed to be on the way out in the post World War II period as the US dollar emerged as world currency. However, the rapid rise in the US dollar price of gold following the deregulation of the gold market in 1971 has effectively remonetized gold. In 1982, for example, gold accounted for only 9% of total foreign reserves held by all countries. However, this estimate values gold at the official rate of 35 SDR. If market price values are used (375 SDR) the percentage of gold to total reserves jumps to 51 per cent. Gold will no doubt continue to fulfil this function until a world government establishes a world paper currency. As there is no prospect for this happening for some time yet, gold is likely to be around for some time as a symbol of the anarchy and mistrust that characterizes the world economy.

The rise to dominance of paper money and coin tokens at the expense of metallic currencies is not difficult to understand. It was a technological advance in the sphere of exchange that was brought about by the technological changes in the sphere of production: the upsurge in the production of commodities required the development of an efficient medium for their exchange and distribution. What is difficult to explain, however, is why some 'archaic' currencies have not only continued to exist but have flourished under the impact of colonization. For example, the establishment of one of the world's largest copper mines on Bougainville Island, Papua New Guinea, has generated an enormous upsurge in demand for traditional shell currency. This has to be imported from Malaita Islands in the neighbouring Solomon Islands, some 550 kms away (Connell 1977). This is not an isolated case as similar evidence comes from other parts of the country (e.g. Chowning 1978).

At one level this can be seen as a minor problem of trying to understand the process by which a very small country of some three million people has been integrated into the world economy. At another level, however, it challenges us to reflect on the nature of our own money and society and to examine it within a comparative context. Early attempts to come to terms with the problem did so within the framework of a 'primitive money/modern money' dichotomy (Einzig 1948; Quiggin 1949). This formulation, which still has its adherents today (e.g. Melitz 1974), confuses the issue by labelling as 'primitive' what is obviously very much a 'modern' phenomenon. What is needed is a theoretical framework that gets beyond the terminological and conceptual inadequacies of the 'primitive/modern' dichotomy. Karl Polanyi and his followers have made important contributions in this regard (see Polanyi 1977). The 'gift/commodity' distinction (Gregory 1982), which has its origins in the

theories of Mauss (1925) and Marx (1867) respectively, is a recent attempt to come to terms with the problem from a somewhat different theoretical perspective. The issues here are complex and controversial and the debates surrounding this issue will no doubt continue for some time to come.

Currency Boards

Federico Sturzenegger

Abstract

Currency boards are exchange rate arrangements in which the exchange rate is fixed to an anchor currency and central banks just buy and sell domestic currency at this exchange rate. We review the advantages and disadvantages of currency boards. While some of the alleged benefits of currency boards have diminished hand in hand with a reduction in inflation rates in most countries since the mid-1990s, currency boards may remain an attractive option for certain countries.

A currency board is defined as an exchange rate arrangement in which the exchange rate is fixed to an anchor currency and the central bank operates with a simple rule that precludes the monetary authorities from issuing money unless they obtain an equivalent amount of international assets to back it. From a practical point of view this means that the central bank has no independent monetary policy and that it creates or contracts the money supply only as the result of its interventions in the foreign exchange market. If there is excess demand for domestic currency capital will flow in (probably in response to an increase in interest rates) and the central bank, by acquiring these flows, will expand the money supply. If there is excess supply of domestic currency, the central bank will take in this excess supply by giving away international assets, thus contracting the money supply. In some cases this rule is implemented by forcing the central bank to have full backing of domestic base money with international reserves. In some cases a currency board does not require a one-to-one backing of the monetary base, but it still precludes the conduct on an independent monetary policy beyond very strict

limits. In fact, a currency board also differs from a typical peg in its commitment to the system, which is usually enshrined in law and in the Central Bank charter.

As of July 2006 the exchange rate arrangement classification published by the International Monetary Fund (IMF) identifies 13 countries with currency boards. Of these, six correspond to countries in the Eastern Caribbean Currency Union (Antigua and Barbuda, Dominica, Grenada, St Kitts and Nevis, St Lucia and St Vincent and the Grenadines), plus seven others: Bosnia and Herzegovina, Brunei Darussalam, Bulgaria, China-Hong Kong SAR, Djibouti, Estonia and Lithuania. Because all these countries are relatively small, currency boards are placed in a relatively unpopular category amongst potential exchange rate regimes.

There are two main reasons why countries have typically used currency boards. In some cases the currency board is more attractive than a common currency. For example, for the Eastern Caribbean countries mentioned above it seems relatively obvious they should use the US dollar as currency to maximize the benefits from a stable exchange rate arrangement with their almost sole trading partner. However, the currency board allows them to keep the exchange rate credibly fixed without giving up the seigniorage revenue of domestic currency. In other cases countries have resorted to a currency board as a way out of monetary and inflation chaos. Argentina's currency board experience in the 1990s and Bulgaria's currency board are appropriate examples. Even though, as we will see below, the evidence points to large trade benefits of currency boards, it is typically assumed that the main benefit of currency boards is as a tool to fight inflation.

The interest in and excitement about currency boards reflects both the need that countries have faced to solve either of the two problems mentioned above – currency integration without seigniorage cost and exiting from a high inflation situation – and the assessment made at the time of whether a currency board is the most efficient way to reach those objectives. Recent years have been unkind to currency boards on both counts. While the use of a currency board as a replacement for a common currency remains a valid motive, its effect as an anti-inflation device has become less relevant as inflation rates fell throughout the 1990s. In 2007 most countries exhibit single-digit inflation rates, and only a handful of exotic cases appear to have a monetary policy that is out of control. The high-inflation history of yesteryear has been critical to this improvement by fostering much stronger fiscal policies and monetary policies that are much freer from political pressures (both when central banks are independent and when they are not) and increasingly within an inflation targeting framework. As inflation has decreased, so have the benefits of a currency board, thus making it a relatively less attractive proposition. Furthermore, while before the demise of Argentina's currency board in early 2002 no currency board had been forced to end, the fact that Argentina's currency board came to an end in the midst of a major crisis (after enduring a long period of high interest rates) raised some questions as to how much credibility the regime actually bought. As a result, many countries have opted to jump directly all the way to dollarization (for example, El Salvador and Ecuador) or to pursue integration into a currency union (Slovenia) thus making currency boards lose ground even to alternative 'harder' exchange-rate commitments.

In spite of the recent drop in interest in this specific regime, nothing precludes a rise in interest again in the future, so a discussion of the specifics of currency boards remains useful. The best way to organize the discussion is to present the advantages of a currency board, then move to the disadvantages, and then attempt a synthesis.

Advantages of a Currency Board

The main advantage that is ascribed to a currency board is the credibility gains that it allows, helping deliver lower inflation and better fiscal results. The argument is simple: a currency board represents a strong commitment that if broken can have a large and costly effect on expectations. Because politicians fear this loss of credibility, the currency board, while in place, lowers inflation

expectations and inflation itself and should provide the incentives for an improvement in fiscal behaviour.

These predictions have been broadly borne out. On the inflation front Ghosh et al. (1998), drawing on a data-set for all IMF countries between 1970 and 1996, found that countries with currency boards delivered an inflation rate that was about four per cent lower, a sizable effect. This result has held up in later work (see for example Levy-Yeyati and Sturzenegger 2001; Kuttner and Posen 2001).

The record on fiscal discipline is also relatively favourable. Ghosh et al. (1998) and Culp et al. (1999) find that countries on currency boards tend to run tighter fiscal policies. Fatas and Rose (2000) also find that currency boards are associated with fiscal restraint (though, somewhat surprisingly, this restraint does not carry on to dollarized economies or those operating within the context of a common currency). Anecdotal evidence also seems to point in the same direction. In 2001, as Argentina's currency board was under fire, fiscal authorities implemented large budget adjustments in an attempt to strengthen the system.

Currency boards may also have an effect on trade as a result of the stability it induces on the exchange rate, an effect similar to the one that has been identified for countries that adopt a common currency with other countries. This exercise is specifically undertaken in Frankel and Rose (2002), who find that the effect of a currency board is a more than tripling of trade (in fact they find that the trade effects for currency boards and common currencies are statistically indistinguishable). Thus the trade motive for a currency board seems to be important. Added to the benefits of saving on seigniorage, it explains why currency boards may remain an attractive option for some small countries.

Disadvantages of a Currency Board

Four main arguments have been advanced against currency boards. First, the fact that it precludes monetary authorities from running an independent monetary policy and that the exchange rate cannot adjust in response to real shocks; second, that it may 'hide' underlying problems, leading to larger crises down the road; third, that it stimulates large currency mismatches in the portfolio structures of government and the private sector; and fourth, that it limits the ability of the central bank to act as a lender of last resort, thus hindering the possibility of developing a locally based financial sector.

The debate has focused mostly on whether alternative mechanisms and policies within the context of the currency board are available to deal with these problems. Let us review each of them briefly.

On the loss of monetary/exchange rate policy, the question is how relevant a loss this it. It can be argued that the idea of a currency board is indeed to limit the scope for an independent monetary policy, which had otherwise proven unable to contain high inflation. To the extent that inflation and fiscal policy improve, not much may be lost relative to the situation in which monetary policy merely induced inflation without any particular benefit in terms of macroeconomic stabilization. Thus, assessing whether this is a cost requires us to evaluate what the counterfactual is. Proponents of currency boards could argue that only countries where monetary policy serves no purpose choose currency boards as a commitment device.

Of course, if monetary policy *were* possible, the costs of doing without it may turn out to be particularly costly for currency boards. The case of Argentina helps illustrate why this should be so. Argentina had established a currency board with the dollar to quell inflation expectations in the early 1990s. Like any other emerging country, it was hurt by the rush out of emerging markets following Russia's default in 1998. This rush strongly appreciated the dollar, making Argentina's currency stronger exactly when the country needed it to weaken. The fact that currency boards require a strong anchor currency and that capital flows may strengthen these currencies when there is turmoil in emerging countries – thus moving the exchange rate exactly in the opposite direction to the one the country would have otherwise chosen – poses a problem for currency

boards during periods of high turbulence in international financial markets. Of course, as much as in the optimal currency area debate, how costly the loss of the monetary instrument is depends on the availability of alternative adjustment mechanisms: fiscal transfers, remittances, labour market mobility, or internal price flexibility, which may all operate as substitutes for the loss of monetary policy (the effectiveness of these alternative mechanisms may explain the different fates of Hong Kong's and Argentina's currency boards). Fiscal policy can also be used as a stabilizer that may substitute for the lack of exchange or monetary policy, though the ability of countries to use it seems relatively limited, particularly for those countries that opted for a currency board as a result of their poor fiscal policies. Some evidence for the fact that the lack of monetary policy may hurt is provided by Levy-Yeyati and Sturzenegger (2001), who compare the growth performance of hard pegs generally (including currency boards) with other regimes. They find that hard pegs trail floating regimes in growth performance (though not by more than pegs or intermediate regimes). However, this allows us to conclude that, in the end, the lack of policy responses may have a detrimental effect on overall economic performance.

The fact that currency boards may delay an adjustment has also been a cause of concern. Aizenman and Glick (2005) and Kuttner and Posen (2001) have both found that the harder and longer the peg, the larger are the depreciations upon exiting. This is to be expected, because the stronger the commitment, the fixed exchange rate spell will be typically longer, and only under more unfavourable conditions will the peg be abandoned, suggesting that an earlier adjustment may have been beneficial. This conclusion, however, should be treated with care because it fails to take into account the fact that this stringency also helps avoid many exits that later on would have turned out to be unnecessary.

The same caution should be used when evaluating the tendency of currency boards to foster the evolution of mismatches in government and private sector debt structures. The basic idea is that as long as the currency board holds countries develop a tendency to 'dollarize' their financial sectors (see Catao and Terrones 2000), with banks piling foreign currency deposits on their liability side, firms borrowing in dollars abroad and governments issuing debt in dollars. This is a problem because the asset side of these borrowers is in most cases linked mostly to the local economy, and thus, whether denominated in foreign currency or not, subject to currency risk in the event of a devaluation. This mismatch, however, is a double-edged sword. On the one hand it increases the commitment of the authorities to the peg (and this is why sometimes it is encouraged by the authorities as an additional credibility booster), but on the other it may also trigger large capital outflows in anticipation of a crisis. In the presence of large mismatches, agents would correctly anticipate a devaluation to produce a costly crisis, thus accelerating the run and the likelihood that the currency will sink. How these two factors play out during a crisis depends on the specifics of each individual country.

Finally, a currency board limits the ability of the central bank to operate as lender of last resort, particularly in the event of a bank run. This has been suggested as an explanation of why countries with currency boards quickly develop an international based banking system (typically with local institutions bought by foreign banks) which is better insured against runs at any specific location. Proponents of currency boards have suggested several alternatives to replace the central bank's function as lender of last resort with other mechanisms. Among these are the possibility of the government operating as lender of last resort, potentially by borrowing in dollars in times of need; the setting up of insurance schemes by which financial institutions buy in advance the access to funds in the context of a systemic liquidity run (these schemes were implemented by Mexico and Argentina); tighter capital and liquidity requirements on the banking sector; and the piling up of 'extra reserves' as far as possible. The first of these mechanisms is doubtful, as the government may have limited access to financing when it faces a crisis, and the others entail a cost. However, it may be said that some of these schemes have been implemented and used successfully. Specifically,

Argentina used its contingent credit line with private banks during its 2001 crisis and banks honoured their pledge at the time.

Where Does This Leave Us?

The conclusion is then that, as much as with currency unions, there seems to be a strong trade motive to set up a currency board. In fact, for a fiscally sound small country with the ability to conduct fiscal policy with some flexibility a currency board may be superior to a common currency as it allows the country to retain the seigniorage on its money stock. For larger middle-income countries a currency board has been pursued more as a way of improving credibility than anything else. While currency boards seem to have delivered, the Argentina case also suggests that their role in improving credibility cannot be taken fully for granted. If a currency board is implemented in times of easy access to international financial markets, fiscal discipline may be sidestepped and a fiscal and currency crisis may still occur at the end of the day. Additionally, policymakers should ask themselves if it makes sense to buy the credibility through a peg, or to buy it the hard way, day by day, implementing reasonable fiscal policies while maintaining some degree of flexibility in monetary policy. The successful experience since the mid-1990s of many countries with managed floating regimes and inflation targeting seems to point to this direction. If this trend continues, currency boards may become even rarer in the future.

Currency Competition

Stacey L. Schreft

Abstract

'Currency competition' means the virtually free entry of private-sector firms into the issuance of a currency. Such competition no longer exists, but interest in it revived in the 1970s as high inflation was attributed by some to governments' incentives to overissue their currencies to generate additional seigniorage. Competition was advocated as a potential remedy because it was thought to give issuers an incentive to protect the value of their currencies by limiting issuance.

'Currency competition' refers to the free, or virtually free, entry of private-sector firms into the issuance of a circulating medium of exchange in lieu of a government monopoly on currency issue. Although there is little analytical basis for focusing on the private issuance of securities that circulate at the expense of those that do not, that is exactly the approach of the literature on currency competition and thus of this article.

The best real-world examples of currency competition come from periods, some lasting more than a century, in which countries allowed banks to operate relatively free from regulation. This freedom allowed, among other things, banks to issue paper notes. Shuler (1992) identified 66 countries as having free banking for some period in the 19th and 20th centuries, and all of them reportedly had multiple private-sector note issuers.

Today, there is no true private note issuance. Any privately issued notes are issued by banks that operate as agents of their respective central banks. Shuler (1992) attributed the demise of privately issued notes to several factors. One factor was a shift in attitudes about the need for and proper role of central banks. The view took hold that currency issuance could be destabilizing if left to the private sector, and governments nationalized currency issuance in their central banks. This was the case in England, for example, where the Currency School came to dominate and the Bank Act of 1844 eliminated private note issuance. Another major factor leading to government monopolies over currency issuance was the First World War and governments' need for additional sources of revenue. The ability to issue currency directly became very appealing.

By the 1970s, governments' monopoly on currency creation was raising its own concerns. These government issuers had an incentive to overissue to generate additional seigniorage revenue. When inflation began rising in the 1970s, some blamed this incentive to overproduce and called for denationalization of currency issuance. Friedrich Hayek (1990) was perhaps the most prominent proponent of a return to currency competition. Hayek argued, in the terms of today, that an equilibrium could exist with competitive issuance and that it would likely dominate the equilibrium arising when the government monopolizes currency issuance. The logic was that the demand for a privately issued currency depends in part on the currency's quality because such currencies are distinguishable. The more units of a currency supplied, the lower is the currency's value in exchange and thus its perceived quality and the public's demand for it. Competition would thus give issuers an incentive to protect the value of their currencies by not overissuing.

In considering what currency competition might look like, economists rediscovered the free banking periods, and a literature arose studying them. The first wave of that literature consisted of historical studies of free banking and private note issuance, although there were also a few theoretical models. Later, in the 1990s, the potential for new electronic means of payment, such as stored value and digital currencies for the Internet, led to another generation of research on currency competition, this time primarily theoretical.

Most discussions of currency competition, whether from a theoretical or an historical perspective, failed to distinguish inside money from outside money. Hellwig's work (1985) was an exception. Inside money is a claim that obligates its issuer to redeem or exchange the money for some specified monetary or nonmonetary object. Failure to do so, perhaps because of insufficient reserves held against the money, can result in a failure to fulfill that obligation and ultimately bankruptcy. The value of a privately issued inside money depends in part, then, on the likelihood of the issuer fulfilling its claim, and only in part on the value of using the money in exchange. Outside money is not a claim against the issuer or anyone else. The issuer makes no promise to redeem its currency at any time for anything of value. The value of a privately issued outside money derives solely from its value in exchange.

The experience in the US free banking era (1837–63) is an example of the importance of the claim that backs an inside money. Bank notes issued in the free banking era were supposed to be fully backed to guarantee the issuer's ability to redeem them, but often they were not. In some cases, no backing was held. Bank note reporters

kept track of the financial condition of issuers and of the prices at which notes were trading. Weber (2002) found that notes traded for one another at flexible exchange rates that often depended in part on the extent to which the notes were backed. When the public became aware that an issuer's notes lacked backing, the notes stopped circulating.

The distinction between inside and outside money is important for studying currency competition. Competition in outside note issuance is likely to divert fewer resources from consumption and production than competition in inside note issuance because there is no need to hold reserves against the outside notes. However, without reserves to back outside money, the money is likely to be overissued because of its near-zero marginal cost of production. Thus, the welfare gain from avoiding overissuing with an inside money must be balanced against the welfare loss from holding full or fractional reserves against such money.

Historical experience with outside money has almost always involved a single, government-issued fiat currency. The existing theoretical literature suggests why privately issued outside money is virtually never observed. In many different economic environments, economists have shown that there can be no equilibrium with competitive issuance of outside money if issuers cannot make binding commitments about the volume of notes they will issue. Taub (1985) and Bryant (1981) showed this in an overlapping-generations model. Ritter (1995) did so in a search model of money. In all cases, the argument is as follows, and similar to Hayek's. If issuing new money is costless, issuers cannot make binding commitments, and money has some positive value, then any private agent that issues notes will issue an unlimited quantity, driving the inflation rate to infinity and the real value of the money to zero. Rational agents would anticipate this ultimate outcome and be unwilling to hold the money at any earlier date. The inability to make binding commitments, coupled with a time inconsistency problem, is a key feature of this argument because issuers always want to believe they will constrain their note issuance, but when they need to they never have the incentive to do so.

A few models have gotten around this result. Klein (1974), for example, provided an early argument based on reputation formation for the existence of equilibria with free entry into private issuance. He argues that the monies of different issuers can be distinguishable by quality, so they can circulate at flexible exchange rates with one another. His discussion, however, blurs the distinction between inside and outside money.

In another example, Martin and Schreft (2006) showed that privately issued outside money can be valued if agents believe that all notes issued up to some threshold will be valued, but additional notes will be worthless. These beliefs create a discontinuity in the value of the marginal unit of currency. Because the value of a marginal unit of currency reaches zero for some finite supply, the limit argument no longer applies. Martin and Schreft derived their existence result in both an overlapping generations and a search-theoretic environment, though it should hold in any environment in which fiat currency could be valued. Interestingly, welfare is not necessarily greater with competitive issuance than with monopoly issuance and depends on the environment considered. In the search environment, neither competitive issuers nor a monopolist achieve the efficient quantity of money in the long run. In the overlapping-generations environment, the efficient allocation is achieved in finitely many periods if agents incur a cost of becoming money issuers. A monopoly issuer might achieve as desirable an allocation, but only if its actions are sufficiently constrained by agents' beliefs.

In contrast, the historical experience with inside money has involved multiple inside monies that are all convertible into some single dominant outside money. A modern literature on privately issued inside notes, largely attributable to Wallace and others, has considered this case. Cavalcanti and Wallace (1999a, b) studied a search-theoretic model with an exogenously given and indivisible outside money and inside money issued by private agents known as banks. To get the private money to be valued, they assumed that issuers who do not accept a note when presented with one face a stiff punishment: they lose the ability to issue notes and revert to autarky. This assumption is

reminiscent of the redemption requirements of successful systems for private inside currency issuance, like the Suffolk Banking System that operated in New England in the early 1800s. The authors found that, if the stock of outside money is sufficiently small, then the optimal mechanism has private notes issued and also redeemed on demand. Additionally, expected utility is greater in economies with inside money than only outside money because the set of implementable allocations is larger.

In the United States, at least, it is claimed that little currently prohibits private-sector issuance of outside currency in either paper or digital form. The laws prohibiting it have either expired or been repealed. It will be interesting to see if a resurgence of private issuance occurs.

Currency Crises

Graciela Laura Kaminsky

Abstract

This article describes models and empirical evidence on currency crises. The evidence from developed and developing countries indicates that crises are of different varieties. It also shows that crises do not occur in economies with sound fundamentals, with vulnerabilities far more widespread and profound in emerging economies. Vulnerabilities are associated with fiscal problems, loss of competitiveness and a deteriorating current account, external debt unsustainability, or problems in the financial sector – especially banks. Interestingly, those crises associated with bank fragility are the costliest in terms of output losses and loss of access to international capital markets.

A currency crisis occurs when investors flee from a currency en masse out of fear that it might be devalued. Currency crises are episodes characterized by sudden depreciations of the domestic currency, large losses of foreign exchange reserves of the central bank, and (or) sharp hikes in domestic interest rates.

There have been numerous currency crises since 1980. The so-called debt crisis erupted in 1982 following Mexico's default and devaluation in August. This crisis spread rapidly to all Latin American countries, and by the time it was over, most Latin American countries had devalued their currencies and defaulted on their foreign debts. The debt crisis was followed by a decade of negative growth and isolation from international capital markets. The output costs of this crisis were so large that the 1980s became known as the 'lost decade' for Latin America.

Crises are not just emerging-market phenomena. The 1990s opened with crises in industrial Europe – the European Monetary System (EMS) crises of 1992 and 1993. By the end of these crises, in the summer of 1993, the lira and the sterling had been driven from the Exchange Rate Mechanism (ERM); Finland, Norway, and Sweden had abandoned their unofficial peg to the European Currency Unit (ECU); the Spanish peseta, the Portuguese escudo and the Irish punt had devalued; and Europe's central bank governors and finance ministers had widened the ERM's intervention margins to ± 15 per cent from ± 2.25 per cent. Only then did the currency market stabilize.

Crises are hardy perennials. Within one year of the EMS crises, a currency crisis exploded in Mexico, with currency jitters spreading around the Latin American region. In 1997, it was Asia's turn. A new episode of currency turbulences started in July of that year with the depreciation of the Thai baht. Within a few days the crisis had spread to Indonesia, Korea, Malaysia and the Philippines. Turmoil in the foreign exchange market heightened in 1998 with the Russian default and devaluation in August. The Russian crisis spread around the world with speculative attacks in economies as far apart as South Africa, Brazil and Hong Kong. Currency crises have continued to erupt in the new millennium, with Argentina's crisis in December 2001 including the largest foreign-debt default in history.

The numerous financial crises that have ravaged emerging markets as well as mature economies have fuelled a continuous interest in developing models to explain why speculative attacks occur. Models are even catalogued into three generations. The first-generation models focus on the fiscal and monetary causes of crises. These models were mostly developed to explain the crises in Latin America in the 1960s and 1970s. In these models, unsustainable money-financed fiscal deficits lead to a persistent loss of international reserves and ultimately to a currency crash (see, for example, Krugman 1979).

The second-generation models aim at explaining the EMS crises of the early 1990s. These models focus on explaining why currency crises tend to happen in the midst of unemployment and loss of competitiveness. To explain these links, governments are modelled facing two targets: reducing inflation and keeping economic activity close to a given target. Fixed exchange rates may help in achieving the first goal but at the cost of a loss of competitiveness and a recession. With sticky prices, devaluations restore competitiveness and help in the elimination of unemployment, thus prompting the authorities to abandon the peg during recessions. Importantly, in this setting of counter-cyclical policies, the possibility of self-fulfilling crises becomes important, with even sustainable pegs being attacked and frequently broken (see, for example, Obstfeld 1994).

The next wave of currency crises, the Mexican crisis in 1994 and the Asian crisis in 1997, fuelled a new variety of models – also known as third-generation models – which focus on moral hazard and imperfect information. The emphasis here has been on 'excessive' booms and busts in international lending and asset price bubbles. These models also link currency and banking crises, sometimes known as the 'twin crises' (Kaminsky and Reinhart 1999). For example, Diaz-Alejandro (1985) and Velasco (1987) model difficulties in the banking sector as giving rise to a balance of payments crisis, arguing that, if central banks finance the bail-out of troubled financial

institutions by printing money, we have the classical story of a currency crash prompted by excessive money creation. Within the same theme, McKinnon and Pill (1995) examines the role of capital flows in an economy with an unregulated banking sector with deposit insurance and moral hazard problems of the banks. Capital inflows in such an environment can lead to over-lending cycles with consumption booms, real exchange rate appreciations, exaggerated current account deficits, and booms (and later busts) in stocks and property markets. Importantly, the excess lending during the boom makes banks more prone to a crisis when a recession unfolds. In turn, the fragile banking sector makes the task of defending the peg by hiking domestic interest rates more difficult and may lead to the eventual collapse of the domestic currency. Following the crisis in Argentina in 2001, the links between debt sustainability, sovereign defaults, and currency crises again attracted the attention of the economics profession. Finally, currency crises have also been linked to the erratic behaviour of international capital markets. For example, Calvo (1998) has brought to general attention the possibility of liquidity crises in emerging markets due to sudden reversals in capital flows, in large part triggered by developments in the world financial centres.

To summarize, all models suggest that currency crises erupt in fragile economies. Importantly, the three generations of models conclude that vulnerabilities come in different varieties. Still, the first attempts to study the vulnerabilities that precede crises have adopted 'the one size fits all' approach (see, for example, Frankel and Rose 1996; Kaminsky 1998). That is, the regressions estimated to predict crises include all possible indicators of vulnerability. These indicators include those related to sovereign defaults, such as high foreign debt levels, or indicators related to fiscal crises, such as government deficits, or even indicators related to crises of financial excesses, such as stock and real estate market booms and busts. In all cases, researchers impose the same functional form on all observations. When some indicators are not robustly linked to all crises, they tend to be discarded even when they may be of key importance for a subgroup of crises. Naturally, these methods leave many crises unpredicted and, furthermore, cannot capture the evolving nature of currency crises.

The next step in the empirical analysis of crises should be centred on whether crises are of different varieties. The first attempt in this direction is in Kaminsky (2006). In this article, a different methodology is used to allow for *ex ante* unknown varieties of currency crises. To identify the possible multiple varieties of crises, regression tree analysis is applied. This technique allows us to search for an unknown number of varieties of crises and of tranquil times using multiple indicators. This technique was also applied to growth by Durlauf and Johnson (1995).

Interestingly, this method catalogues crises into six classes:

1. *Crises with current account problems.* This variety is characterized by just one type of vulnerability, that of loss of competitiveness, that is, real exchange rate appreciations.
2. *Crises of financial excesses*. The fragilities are associated with booms in financial markets. In particular, they are identified as crises that are preceded by the acceleration in the growth rate of domestic credit and other monetary aggregates.
3. *Crises of sovereign debt problems.* These crises are characterized by fragilities associated with 'unsustainable' foreign debt.
4. *Crises with fiscal deficits.* This variety is just related to expansionary fiscal policy.
5. *Sudden-stop crises.* This type of crisis is only associated with reversals in capital flows triggered by sharp hikes in world interest rates, with no domestic vulnerabilities.
6. *Self-fulfilling crises*. This class of crises is not associated with any evident vulnerability, domestic or external.

These estimations allow us to answer four important questions about crises.

1. *Do crises occur in countries with sound fundamentals?* Even though this estimation allows for the identification of self-fulfilling crises (crises in economies with sound fundamentals), the results indicate that basically all

crises are preceded by domestic or external vulnerabilities. Only four per cent of the crises are unrelated to economic fragilities.

2. *How important are sudden reversals in capital flows in triggering crises?* While many have stressed that the erratic behaviour of international capital markets is the main culprit in emerging market currency crises, only two per cent of the crises in developing countries are just triggered by sudden-stop problems. While sudden-stop problems do occur, the reversals in capital flows mostly occur in the midst of multiple domestic vulnerabilities (see, Calvo et al. 2004).
3. *Are crises different in emerging economies?* Crises in emerging markets are preceded by far more domestic vulnerabilities than those in industrial countries. Overall, 86 per cent of the crises in emerging economies are crises with multiple domestic vulnerabilities, while economic fragility characterizes only 50 per cent of the crises in mature markets.
4. *Are some crises more costly than others?* It is a well-established fact that financial crises impose substantial costs on society. Many economists have emphasized the output losses associated with crises. But these are not the only costs of crises. In the aftermath of crises, most countries lose access to international capital markets, losing the ability to reduce the effect of adverse income shocks by borrowing in international capital markets. In most cases, countries have to run current account surpluses to pay back their debt. Finally, the magnitude of the speculative attack is itself important. For example, large depreciations may cause adverse balance sheet effects on firms and governments when their liabilities are denominated in foreign currencies. *Crises of financial excesses*, those also associated with banking crises – twin crisis episodes – are the costliest. Not only does the domestic currency depreciate the most, but also output losses are higher and the reversal of the current account deficit is attained via a dramatic fall in imports. In the aftermath of these crises, exports fail to grow even though the depreciations in this type of crises are massive. This evidence suggests that countries are even unable to attract trade credits to finance exports when their economies are mired in financial problems. In contrast, *self-fulfilling crises* and *sudden-stop crises* (but with no domestic vulnerabilities) have no adverse effects on the economies. Output (relative to trend) is unchanged or continues to grow in the aftermath of crises with no observed domestic fragility. In these crises, booming exports are at the heart of the recovery of the current account.

Currency Crises Models

Craig Burnside, Martin Eichenbaum and Sergio Rebelo

Abstract

Currency crises have occurred frequently in the post-war era. In this article we review the literature on the causes and consequences of currency crises. First- generation models attribute a central role to fiscal policy as a fundamental determinant of crises. Second-generation models emphasize the possibility of self-fulfilling speculative attacks and multiple equilibria. Third-generation models stress how financial fragility can lead to currency crises.

There have been many currency crises during the post-war era (see Kaminsky and Reinhart 1999). A currency crisis is an episode in which the exchange rate depreciates substantially during a short period of time. There is an extensive literature on the causes and consequences of a currency crisis in a country with a fixed or heavily managed exchange rate. The models in this literature are often categorized as first-, second- or third-generation.

In first-generation models the collapse of a fixed exchange rate regime is caused by unsustainable fiscal policy. The classic first-generation models are those of Krugman (1979) and Flood and Garber (1984). These models are related to earlier work by Henderson and Salant (1978) on speculative attacks in the gold market. Important extensions of these early models incorporate consumer optimization and the government's intertemporal budget constraint into the analysis (see Obstfeld 1986; Calvo 1987; Drazen and Helpman 1987; Wijnbergen 1991). Flood and Marion (1999) provide a detailed review of first-generation models.

In a fixed exchange rate regime a government must fix the money supply in accordance with the fixed exchange rate. This requirement severely limits the government's ability to raise seigniorage revenue. A hallmark of first-generation models is that the government runs a persistent primary deficit. This deficit implies that the government must either deplete assets, such as foreign reserves, or borrow to finance the deficit. It is infeasible for the government to borrow or deplete reserves indefinitely. Therefore, in the absence of fiscal reforms, the government must eventually finance the deficit by printing money to raise seigniorage revenue. Since printing money is inconsistent with keeping the exchange rate fixed, first-generation models predict that the regime must collapse. The precise timing of its collapse depends on the details of the model.

The key ingredients of a first-generation model are its assumptions regarding purchasing power parity (PPP), the government budget constraint, the timing of deficits, the money demand function, the government's rule for abandoning the fixed exchange rate, and the post-crisis monetary policy. In the simplest first-generation models there is a single good whose domestic currency price is P_t and whose foreign currency price is 1. Let S_t denote the nominal exchange rate. PPP implies $P_t = S_t$. Suppose for simplicity that the

government has a constant ongoing primary deficit, δ. It finances this deficit by reducing its stock of foreign reserves, f_t, which can either evolve as a smooth function of time or jump discontinuously. In the former case, f_t evolves according to $\dot{f}_t = rf_t - \delta + \dot{M}_t/S_t$, where r is the real interest rate, M_t is the monetary base, and a dot over a variable denotes its derivative with respect to time. When foreign reserves change discontinuously, $\Delta f_i = \Delta(M_t/S_t)$. When $\delta > rf_0$ interest income from foreign assets will not be sufficient to finance the deficit.

To illustrate the key properties of first-generation models, we make three simplifying assumptions. First, money demand takes the Cagan (1956) form, $M_t = \theta P_t \exp[-\eta(r + \pi_t)]$, where $\theta > 0$ and $\pi_t = \dot{P}_t/P_t$ is the inflation rate. Second, the government abandons the fixed exchange rate regime when its foreign reserves are exhausted. Third, as soon as foreign reserves are exhausted, the government prints money at a constant rate μ to fully finance its deficit.

These assumptions imply that after the crisis the level of real balances, $m_t = M_t / P_t$, is constant and equal to $\overline{m} = \theta \exp[-\eta(r + \mu)]$. The post-crisis government budget constraint reduces to δ $\delta = \mu \overline{m}$. This equation determines μ. Let t^* denote the date at which foreign reserves are exhausted and the government abandons the fixed exchange rate regime. PPP implies $S_{t^*} = P_{t^*} = \overline{M}/\overline{m}$, where $\overline{M}$ is the monetary base the instant after date t^*. Under perfect foresight the exchange rate cannot jump discontinuously at t^* since such a jump would imply the presence of arbitrage opportunities. Given that the exchange rate must be a continuous function of time at t^*, $S_{t^*} = S$ and $\overline{M} = \overline{m}S$.

Prior to the crisis real balances are given by $m = \theta \exp(-\eta r)$. Therefore, at date t^* there is a sudden drop in real money demand from m to $\overline{m}$ implying that reserves drop discontinuously to zero at time $t^* : \Delta f_{t^*} = \overline{m} - m$. This is why the literature refers to t^* as the date of the speculative attack. Prior to the crisis the government's reserves fall at the rate $\dot{f}_t = rf_t - \delta$. The budget constraint implies that $t^* = \ln\{[\delta - r(m - \overline{m})]/(\delta - rf_0)\}/r$. While the collapse of the fixed exchange rate regime is inevitable, it does not generally occur at time zero unless $m - \overline{m} > f_0$.

A shortcoming of this type of first-generation model is that the timing of the speculative attack is deterministic and the exchange rate does not depreciate at the time of the attack. These shortcomings can be remedied by introducing shocks into the model, as in Flood and Garber (1984).

Early first-generation models predict that ongoing fiscal deficits, rising debt levels, or falling reserves precede the collapse of a fixed exchange rate regime. This prediction is inconsistent with the 1997 Asian currency crisis. This inconsistency led many observers to dismiss fiscal explanations of this crisis. However, Corsetti et al. (1999), Burnside et al. (2001a), and Lahiri and Végh (2003) show that bad news about prospective deficits can trigger a currency crisis. Under these circumstances a currency crisis will not be preceded by persistent fiscal deficits, rising debt levels, or falling reserves. These models assume that agents receive news that the banking sector is failing and that banks will be bailed out by the government. The government plans to finance, at least in part, the bank bailout by printing money beginning at some time in future. Burnside et al. (2001a) show that a currency crisis will occur before the government actually starts to print money. Therefore, in their model, a currency crisis is not preceded by movements in standard macroeconomic fundamentals, such as fiscal deficits and money growth. Burnside, Eichenbaum and Rebelo argue that their model accounts for the main characteristics of the Asian currency crisis.

This explanation of the Asian currency crisis stresses the link between future deficits and current movements in the exchange rate. This link is also stressed by Corsetti and Mackowiak (2006), Daniel (2001), and Dupor (2000), who use the fiscal theory of the price level to argue that prices and exchange rates jump in response to news about future deficits.

In first-generation models the government follows an exogenous rule to decide when to abandon the fixed exchange rate regime. In second-generation models the government maximizes an explicit objective function (see, for example, Obstfeld 1994, 1996). This

maximization problem dictates if and when the government will abandon the fixed exchange rate regime. Second-generation models generally exhibit multiple equilibria so that speculative attacks can occur because of self-fulfilling expectations. In Obstfeld's models (1994; 1996) the central bank minimizes a quadratic loss function that depends on inflation and on the deviation of output from its natural rate (see Barro and Gordon 1983, for a discussion of this type of loss function). The level of output is determined by an expectations-augmented Phillips curve. The government decides whether to keep the exchange rate fixed or not. Suppose agents expect the currency to devalue and inflation to ensue. If the government does not devalue then inflation will be unexpectedly low. As a consequence output will be below its natural rate. Therefore the government pays a high price, in terms of lost output, in order to defend the currency. If the costs associated with devaluing (lost reputation or inflation volatility) are sufficiently low, the government will rationalize agents' expectations. In contrast, if agents expect the exchange rate to remain fixed, it can be optimal for the government to validate agents' expectations if the output gains from an unexpected devaluation are not too large. Depending on the costs and benefits of the government's actions, and on agents' expectations, there can be more than one equilibrium. See Jeanne (2000) for a detailed survey of second-generation models.

Morris and Shin (1998) provide an important critique of models with self-fulfilling speculative attacks. They emphasize that standard second-generation models assume that fundamentals are common knowledge. Morris and Shin demonstrate that introducing a small amount of noise into agents' signals about fundamentals will lead to a unique equilibrium.

Many currency crises coincide with crises in the financial sector (Diaz- Alejandro 1985; Kaminsky and Reinhart 1999). This observation has motivated a literature that emphasizes the role of the financial sector in causing currency crises and propagating their effects. These third-generation models emphasize the balance- sheet effects associated with devaluations. The basic idea is that banks and firms in emerging market countries have explicit currency mismatches on their balance sheets because they borrow in foreign currency and lend in local currency. Banks and firms face credit risk because their income is related to the production of non-traded goods whose price, evaluated in foreign currency, falls after devaluations. Banks and firms are also exposed to liquidity shocks because they finance long-term projects with short-term borrowing. Eichengreen and Hausmann (1999) argue that currency mismatches are an inherent feature of emerging markets. In contrast, authors such as McKinnon and Pill (1996) and Burnside et al. (2001b) argue that, in the presence of government guarantees, it is optimal for banks and firms to expose themselves to currency risk.

Different third-generation models explore various mechanisms through which balance-sheet exposures may lead to a currency and banking crisis. In Burnside et al. (2004) government guarantees lead to the possibility of self-fulfilling speculative attacks. In Chang and Velasco (2001) liquidity exposure leads to the possibility of a Diamond and Dybvig (1983) style bank run. In Caballero and Krishnamurthy (2001) firms face a liquidity problem because they finance risky long-term projects with foreign loans but have access to limited amounts of internationally accepted collateral.

An important policy question is: what is the optimal nature of interest rate policy during and after a currency crisis? There has been relatively little formal work on this topic. Christiano et al. (2006) take an important first step in this direction. They argue that it is optimal to raise interest rates during a currency crisis and to lower them immediately thereafter. Studying optimal monetary policy in different models of currency crises remains an important area for future research.

Currency Unions

Andrew K. Rose

Abstract

This article reviews currency unions, that is, groups of countries that use a common money. There are a large number of such monetary unions in both the industrial and the developing worlds. I review both the theoretical reasons why countries choose to belong to currency unions and the empirical performance of these unions.

I thank Steven Durlauf for helpful comments.

Currency unions (also known as monetary unions) are groups of countries that share a single money. Currency unions are unusual, since most countries have their own currency. For instance, the United States, Japan and the United Kingdom all have their own monies. But a reasonable number of countries participate in currency unions, and their importance is growing. In May 2005, 52 of the 184 IMF members participated in currency unions.

Currency Unions Present and Past

Currency unions commonly come about when a small or poor country unilaterally adopts the money of a larger, richer 'anchor' country. For instance, a number of countries currently use the US dollar, including Panama, El Salvador, Ecuador, and a number of smaller countries and dependencies in the Caribbean and Pacific. Swaziland, Lesotho and Namibia all use the South African rand. Both the Australian and New Zealand dollars are used by a number of countries in the Pacific; Liechtenstein uses the Swiss franc; and so forth. In the past, a number of countries have used the currency of their colonizer; over 50 countries and dependencies have used the British pound sterling at one time or another. Cases like this are known as official dollarization (unofficial dollarization occurs when the currency of a foreign country circulates widely but is not formally the national currency). In such cases, the small country essentially relinquishes its right to sovereign monetary policy. It loses its ability to independently influence its exchange and interest rates; these are determined by the anchor country, typically on the basis of the interests of the anchor.

There are also a number of multilateral currency unions between countries of more or less equal size and wealth. For instance, the East Caribbean dollar circulates in Anguilla, Antigua and Barbuda, Dominica, Grenada, Montserrat, Saint Kitts and Nevis, Saint Lucia, and Saint Vincent and the Grenadines. The Central Bank of the West African States circulates the Communautéfrançaise d'Afrique (CFA) franc in Benin, Burkina Faso, Côte d'Ivoire, Guinea-Bissau, Mali, Niger, Senegal, and Togo. The Bank of the Central African States circulates a slightly different CFA franc in Cameroon, the Central African Republic, Chad, Republic of Congo, Equatorial Guinea, and Gabon.

The largest and most important currency union is the Economic and Monetary Union of the European Union (EMU). EMU technically began on 1 January 1999, although the euro was physically introduced only three years later. Twelve countries are formally members of EMU: Austria, Belgium, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, the Netherlands, Portugal, and Spain. (A number of smaller European territories and French dependencies also use the euro.) These countries jointly determine monetary policy for EMU through the international European Central Bank. The number of members in EMU is expected to grow with time, especially as countries that acceded to the European Union in 2004 become eligible for EMU entry. However, both Sweden and Denmark have rejected membership in referenda, and the euro remains unpopular in the UK.

While a number of currency unions currently exist, many have not survived. The Latin Monetary Union began in 1865 when France, Belgium, Italy and Switzerland (later joined by Greece, Romania, and others) adopted common regulations for their individual currencies to encourage the free international flow of money. This essentially amounted to a commitment to mint silver

and gold coins to uniform specifications, but without other restrictions on monetary policy. The union effectively ended with the onset of the First World War. The war also ended the Scandinavian Monetary Union which Denmark, Norway, and Sweden began in 1873. The economic union between Belgium and Luxembourg that began in 1921 has been absorbed into EMU. Multilateral currency unions in East Africa, Central Africa, West Africa, South Asia, South-East Asia, and the Caribbean have also disappeared.

Theory: Why Should Countries Enter Currency Union?

Historically, most countries have had their own moneys. There seems to be a tight connection between national identity and national money; a country's money is a potent symbol of sovereignty. Still, some countries have entered into currency union. Why? Economists have theorized about the potential economic benefits of currency union which can, in certain circumstances, overwhelm the perceived political costs.

Like all other monetary regimes, currency unions are fully compatible with Robert Mundell's (1968) celebrated 'Trilemma' or 'Incompatible Trinity'. A country would like its monetary regime to deliver three desirable goals that turn out to be mutually exclusive: domestic monetary sovereignty, capital mobility, and exchange rate stability. Currently, large rich countries like the United States, Japan and the UK have domestic monetary sovereignty and open capital markets but have floating exchange rates. By way of contrast, members of a currency union essentially relinquish the first objective (monetary independence) in exchange for the latter benefits (capital mobility and stable exchange rates). Indeed, some economists think of currency unions as simply extreme forms of fixed exchange rates, with all the associated pros and cons. Countries inside currency union receive more microeconomic benefits than they would from a fixed exchange rate, since sharing a single money leads to deeper integration of real and financial markets. On the other hand, a country can devalue or float the exchange rate more easily than it can leave a currency union. Still, this is an unsatisfying theoretical approach the issue of currency unions. It does not address to the vital question: what is the optimal size of a currency union? If the right size for a currency union is not necessarily the country, how should we tackle the problem?

The theoretical analysis of currency unions began with a seminal paper by Mundell (1961). Mundell's analysis answered the question: what is the appropriate domain for a currency? Mundell briefly argued there are advantages to regions that use a common money. In particular, currency union facilitates international trade; a single medium of exchange reduces transactions costs, as does a common unit of account. However, a common currency can also cause problems in the dual presence of asymmetric shocks and nominal rigidities (in prices and wages). Suppose demand shifts from Western to Eastern goods. The increase in demand for Western output results in inflationary pressures there, while East goes into recession. Mundell argued that, if unemployed labour could move freely from East to relieve inflationary pressures in West, the two problems could be resolved simultaneously. However, in the absence of labour mobility, the asymmetric shock could be better handled by allowing the Western currency to appreciate. But in order for this to happen, both East and West must have their own monies! Mundell concluded that the optimal currency area was the area within which labour is mobile; regions of labour mobility should have their own currencies.

Two other classic contributions to the theory of optimal currency areas are worthy of note. McKinnon (1963) examined the effects of country size on currency unions; he concluded that smaller countries tend to be more open and have fewer nominal rigidities, making them better candidates for currency union. Kenen (1969) considered the effects of the economy's degree of diversification, and argued that more diversification resulted in fewer asymmetric shocks, and accordingly fewer benefits from national monetary policy.

The key focus of Mundell's theoretical optimum currency area framework – the adjustment to

asymmetric shocks – has stood the test of time well. The ability of a region to respond to such shocks is viewed as a critical part of a sustainable and desirable currency union. Still, hardly anyone now takes the narrow specifics of Mundell's original article seriously. In particular, Mundell's conclusion that the optimum currency area is a region of labour mobility is no longer widely believed. The problem of asymmetric business cycles that Mundell described is intrinsically a problem of. . . business cycles. The costs of shifting labour are high almost everywhere in the world, which is why labour moves only slowly, even within countries with relatively flexible labour markets like the United States. Accordingly, most economists are uncomfortable thinking that labour could or should shift in response to the shocks and propagation mechanisms that cause business cycles. After all, the nominal rigidities that are responsible for business cycles do not last for ever. Thus, Mundell's idea of labour mobility is no longer viewed as a viable adjustment mechanism. (This conclusion is tempered if one believes that real shocks cause business cycles without nominal rigidities.)

Still, there are other ways to share the risks of, or adjust to, asymmetric shocks, and much of the relevant work has incorporated these other mechanisms. Mundell originally ignored capital mobility. But private capital markets can, in principle, spread shocks internationally if investors diversify across regions or sectors. However, more attention has been paid to the public sector, since a federal system of taxes and transfers may be an efficient way to spread risks across regions. To continue with the East and West example, a progressive federal tax structure reduces inflationary Western pressures, and allows benefits to be paid to the unemployed in the East. Both regions suffer less macroeconomic volatility with such automatic stabilizers in place. The most controversial adjustment mechanism is counter-cyclical fiscal policy. In response to an asymmetric shock, regions that are free and capable of deploying discretionary fiscal policy can uses changes in taxes and government spending to respond to asymmetric shocks, even within the monetary confines of a currency union. More generally, mechanisms to handle asymmetric shocks are still an integral part of the theory of currency unions.

Mundell originally thought the great benefit of currency union was the facilitation of trade since money is a convenience that lowers transactions costs. But suppose that countries produce moneys of different qualities. Argentina has gone through five currencies since 1970; high Argentine inflation results in a low convenience value for Argentine money. Suppose Argentina decides to give up on a national money altogether and enter into a currency union with a foreign producer of higher-quality money: the United States, say. Argentina will surely experience different shocks from the United States, and these shocks have to be handled. Perhaps then Argentina should enter a currency union with a country with more similar shocks? The problem is that the most obvious contender, Brazil, also has a history of monetary incompetence. The larger point is that a low-quality domestic monetary authority increases a country's willingness to enter currency union, as does the availability of high-quality foreign money. Alesina and Barro (2002) provide an elegant model that incorporates such features. In their model, countries enter currency unions with neighbours in order to facilitate trade, so long as the neighbours possess monetary institutions of quality. Lower inflation and reduced transactions costs of trade provide gains, while the inability to respond to idiosyncratic asymmetric shocks generates losses.

Empirics: What Do We Know in Practice About Currency Unions?

During the run-up to EMU, a considerable empirical literature developed that quantified different aspects of optimal currency areas. Much attention was paid to estimating the synchronization of business cycles for potential EMU candidates; Bayoumi and Eichengreen (1992) was the first important paper. The tradition has since been generalized to more countries by Alesina et al. (2002), who characterized co-movements in prices as well as output. Frankel and Rose (1998) showed that the intensity of trade had a strong positive effect

on business cycle synchronization; that is, the optimum currency area criteria are jointly endogenous. If currency union lowers the transactions costs of trade and thus leads to an increase in trade, it may also thereby reduce the asymmetries in business cycles; areas that do not look like currency unions ex *ante* may do so *ex post.* Bayoumi and Eichengreen (1998) successfully link optimum currency area criteria (principally the asymmetry of business cycle shocks) to exchange rate volatility and intervention, and show that a number of features of the optimum currency area theory appear in practice, even for countries not in currency unions.

Somewhat curiously, little work was done to analyse actual currency unions until around 2000. This is probably because the currency unions that preceded EMU consisted mostly of small or poor countries, which were viewed as irrelevant for EMU. But this gap in the literature implicitly allowed economists to focus their attention on the costs of currency union, which tend to be macroeconomic in nature (resulting from the absence of national monetary policy as a tool to stabilize business cycles). As Mundell clearly pointed out, there are also benefits from a currency union, mostly microeconomic in nature. Fewer monies mean lower transactions costs for trade, and thus higher welfare. An unresolved issue of importance is the size of the benefits that stem from currency union. There is evidence that currency unions have been associated with increased trade in goods, though its size is much disputed. Using data on pre-EMU currency unions (such as the CFA franc zone), Rose (2000) first estimated the effect of currency union on trade, and found it to result in an implausibly high tripling of trade. This finding and the intrinsic interest of EMU have resulted in a literature that has almost universally found smaller estimates, which are yet of considerable economic size. Rose and Stanley (2005) provide a quantitative survey that concludes that currency union increases trade by between 30 and 90 per cent. Engel and Rose (2002) examine other macroeconomic aspects of pre-EMU currency unions, and find that currency union members are more integrated than countries with their own monies, but less integrated than regions within a single country. Edwards and Magendzo (2003) compare inflation, output growth and output volatility in countries inside currency unions and those outside them, and find that currency unions have lower inflation and higher output volatility than countries with their own currencies.

Areas of Ignorance

The impact of currency union on financial markets is not something that is currently well understood. Yet this is an area of great interest, since currency union might result in deeper financial integration – or it might not. It is clearly of concern to the British government, which has made the financial effects one of its five tests for EMU entry (see HM Treasury 2003).

More generally, Europe's experiment with currency union is still young. It is simply too early to know whether EMU has resulted in substantial changes in the real economy, financial or labour markets, or political economy. As the data trickles in, most expect a continuing reassessment of currency unions in theory and especially practice.

Currie, Lauchlin (1902–1993)

Roger Sandilands

Abstract

At Harvard in the early 1930s Currie pioneered a monetary diagnosis of the 1929–32 collapse and placed blame on the Federal Reserve Board. As a prominent New Dealer at the Fed during 1934–9 he urged contra-cyclical monetary and fiscal activism. During 1939–45 he worked in Washington as President Roosevelt's economic adviser. After heading a World Bank mission to Colombia in 1949 he spent 40 years advising on national development there. He emphasized urban housing as a leading sector, based on an innovative housing finance system, and extended Allyn Young's ideas on macroeconomic increasing returns and endogenous growth.

Lauchlin Currie was born on 8 October 1902 in West Dublin, Nova Scotia, and died in Bogotá, Colombia, on 23 December 1993 after an unusually long and varied career as an academic economist and top-level policy adviser. After two years at St Francis Xavier University, Nova Scotia, 1920–2, he moved to the London School of Economics (LSE), where his teachers included Edwin Cannan, Hugh Dalton, A. L. Bowley, R. H. Tawney and Harold Laski. In 1925 he obtained his BsC and moved to Harvard, where the chief inspiration for his Ph.D. thesis, 'Bank Assets and Banking Theory' (January 1931), was Allyn Abbott Young. However, when Young moved to the LSE in 1927 his formal supervisor was John H. Williams.

He remained at Harvard until 1934 as teaching assistant to Williams, Ralph Hawtrey and Joseph Schumpeter. His Ph.D. thesis attacked the 'commercial loan' or 'needs of trade' theory of banking by showing that it was not only unsound in theory but had been more honoured in the breach than the observance – until its disastrous influence on monetary policy in the late 1920s and early 1930s.

In a January 1932 memorandum, Currie, Harry Dexter White and Paul Theodore Ellsworth presented a radical anti-depression programme (see Laidler and Sandilands 2002). In keeping with their explanation of the contraction as due to a collapsing money supply, they urged vigorous open-market operations and deficit spending

financed by money creation. This memorandum was part of an early Harvard influence (through Young, Hawtrey, Williams and Currie; see Laidler 1999) on what had been claimed as a unique Chicago monetary tradition.

In Currie (1933a) he showed the hopeless confusion that resulted from the ambiguity of the word 'credit'. He stressed control over the quantity of money (defined as cash plus demand deposits, for which there had been no estimates until Currie published a series in 1934) rather than the quantity or quality of credit or loans. He also computed the first estimate of the income velocity of money in the United States (Currie 1933b), with an explanation of its cyclical variations.

His 'The Failure of Monetary Policy to Prevent the Depression of 1929–32' (1934a) fully anticipated Milton Friedman and Anna Schwartz's (1963) diagnosis of this period. He argued that apart from the stock market there were none of the traditional signs of a boom in the 1920s. Tight monetary policies had been ineffectual in checking the rise in stock prices but only too effective in contributing to the decline in building activity and the pressure on foreign countries that preceded the Depression.

He also demonstrated the perverse elasticity of money in the business cycle due to differences in reserve requirements for different classes of bank and bank deposit (1934b). In the face of the banks' reserve losses in 1929–32 and their abhorrence of heavy indebtedness to the reserve banks, the administration's policy was 'one of almost complete passivity and quiescence', so the self-generating forces of the Depression continued unchecked.

In 1934 Jacob Viner recruited him to the 'freshman brain trust' at the US Treasury where he developed a blueprint for a system of 100 per cent reserves against demand deposits, to break the link between the lending and the creation of money and to strengthen central bank control (see Phillips 1995). Later that year Marriner Eccles, the new governor of the Federal Reserve Board, hired Currie as his top adviser, from 1934 to 1939. (Many of his memoranda to Eccles are published in Sandilands 2004.)

At the Fed Currie drafted what became the 1935 Banking Act that gave the Fed increased powers to raise reserve requirements. In 1936–7 these powers were used, 'as a precautionary measure', to reduce the huge build-up of banks' excess reserves. This has been widely blamed for the sharp recession of 1937–8, a view Currie consistently rejected (1938). Instead, he invoked his newly constructed 'net federal income-creating expenditure series' (1935; and see Sweezy 1972) to show the strategic role of fiscal policy in complementing monetary policy to revive an acutely depressed economy. In November 1937 he had a four-hour meeting with President Roosevelt to explain that the recession was due to sharp fiscal contraction and that balancing the budget was not the way to restore business confidence. He insisted on the need for better coordination of monetary and fiscal policy. In May 1939 the rationale for this was explained in theoretical and statistical detail by Currie and Alvin Hansen (respectively 'Mr Inside' and 'Mr Outside', according to Tobin 1976), in joint testimony before the Temporary National Economic Committee.

From 1939 to 1945, Currie was President Roosevelt's special adviser on economic affairs in the White House. He was also in charge of lend-lease to China, 1941–3, and ran the Foreign Economic Administration, 1943–4. In early 1945 he headed a tripartite (United States, British and French) mission to Bern to persuade the Swiss to freeze Nazi bank balances and stop shipments of German supplies through Switzerland to the Italian front. He was also closely involved in loan negotiations with British and Soviet allies and in preparations for the 1944 Bretton Woods conference (staged primarily by his friend Harry White).

After the war it was alleged by Elizabeth Bentley, an ex-Soviet agent, that Currie and White had participated in Soviet espionage. Though she had never met them herself, she claimed they had passed information to other Washington economists who were abetting her own espionage, and that they probably knew this. White and Currie were heavily involved in official wartime cooperation with the Soviets, but Bentley put a sinister interpretation on these activities. They appeared

together before the House Committee on Un-American Activities in August 1948 to rebut Bentley's charges. Their testimony satisfied the Committee at that time, though the strain contributed to the fatal heart attack that White suffered three days after the hearing.

No charges were laid against Currie, and in 1949 he headed a major World Bank survey of Colombia. In 1950 the Colombians invited him to return to Bogotá, where he remained for most of the next 40 years as a top presidential adviser. He has been falsely accused of fleeing the United States to avoid charges of disloyalty. In fact in December 1952 he was a witness before a grand jury in New York investigating Owen Lattimore's role in the famous *Amerasia* case that involved the publication of secret State Department documents by that magazine, though his next visit to the United States was not until 1961 when he had a meeting in the White House with Walt Rostow, then President Kennedy's National Security Adviser, to discuss a development plan for Colombia.

By that time Currie had assumed Colombian citizenship (personally conferred on him by President Alberto Lleras in 1958), partly because in 1954 the US government had refused to renew his passport, ostensibly because he was only a naturalized US citizen and was now residing abroad. However, the reality was probably connected with the then secret 'Venona' project that had deciphered wartime Soviet cables that mentioned Currie. The related cases of Currie and White are discussed in Sandilands (2000) and Boughton and Sandilands (2003), where it is shown that the evidence against them is far from conclusive. After reading the latter paper, Major-General Julius Kobyakov, deputy director of the KGB's American desk in the late 1980s, wrote to the present writer on 22 December 2003 to confirm our conclusions. After extensive archival research on Soviet intelligence in the 1930s and 1940s he found that

> there was nothing in [Currie's] file to suggest that he had ever wittingly collaborated with the Soviet intelligence. . . However, in the spirit of machismo, many people claimed that we had an 'agent' in the White House. Among the members of my profession there is a sacramental question: 'Does he know that he is our agent?' There is very strong indication that neither Currie nor White knew that.

There were two breaks to Currie's advisory and academic work in Colombia: during a military dictatorship, 1953–8, he retired to develop a prize-winning herd of Holstein cattle; and from 1966 to 1971 he was a professor at Michigan State (1966), Simon Fraser (1967–8 and 1969–71), Glasgow (1968–9), and Oxford (1969) universities. He returned permanently to Colombia in 1971 at the behest of President Misael Pastrana to prepare a national plan of development known as the Plan of the Four Strategies, with a focus on urban housing and export diversification. The plan was implemented and the institutions that were established in support of the plan played a major role in accelerating Colombia's urbanization.

He remained as chief economist at the National Planning Department for ten years, 1971–81, followed by 12 years at the Colombian Institute of Savings and Housing until his death in 1993. There he defended the unique index-linked housing finance system (based on 'units of constant purchasing power' for both savers and borrowers) that he had established in 1972. The system thus continued to boost Colombia's growth rate and urban employment opportunities year by year. Currie was also a top adviser on urban planning, and played a major part in the first United Nations Habitat conference in Vancouver in 1976. His 'cities-within-the-city' urban design and financing proposals (including the public recapture of land's socially created 'valorización', or 'unearned land value increments', as cities grow) were elaborated in *Taming the Megalopolis* (1976). To the time of his death he was a regular teacher at the National University of Colombia, Javeriana University, and the University of the Andes, and continued to publish widely (a comprehensive bibliography is in Sandilands 1990, reviewed by Charles Kindleberger 1991). His writings and policy advice were heavily influenced by his old Harvard mentor, Allyn Young. Notable is his posthumous (1997) paper that offers a unique macroeconomic interpretation of Youngian increasing returns and the endogenous nature of self-sustaining growth.

Customs Unions

Arthur Hazlewood

A customs union consists of two or more countries which have no tariff barriers between themselves and a common tariff against the rest of the world. There are variants which involve a greater or lesser degree of economic integration. A free trade area has no common external tariff; a union with free movement of production factors, particularly of labour, is often called a common market.

Theorizing about customs unions goes back to the classical economists, but contemporary

theory, which has been mainly concerned with the welfare effects of union, is founded on the work of Jacob Viner (1950). He introduced the concepts of trade creation and trade diversion. Trade creation occurs when the removal of the tariff on intra-union trade shifts members' demand from domestic production to lower-cost output from a union partner, diversion when the tariff preference for union members shifts demand from a non-union source to a higher-cost union supplier. The establishment of the union, according to the theory, improves welfare if trade creation predominates and worsens it if trade diversion predominates.

The removal of tariffs between union members might appear to be a move towards free trade, and presumed to be beneficial. The possibility that trade diversion will predominate shows the inadequacy of that presumption. Viner's analysis exemplifies the 'theory of the second best', showing that an incomplete move towards the optimum – the removal of some, but not all tariffs – may, in fact, make matters either better or worse.

The definition of trade creation and diversion was usefully widened by Johnson (1962) to include consumption effects. Changes in the pattern of consumption following union may either increase or decrease consumers' surplus, depending on whether there is a shift to a lower or a higher cost source of satisfying demand. The distinction between this consumption effect and the production effect of the tariff-induced price changes can be expressed as that between inter-commodity and inter-country substitutions.

Discussion stimulated by Viner's analysis was particularly concerned with establishing general conditions determining whether a union was trade creating or diverting, and the consequent welfare effects. Various assumptions were relaxed – such as that of constant costs or of fixed proportions in consumption – and various results obtained. However, no universal law of customs unions, and few conclusions of practical importance, emerged (Krauss 1972).

Meade (1955) and Johnson (1962), consistent with Viner's view that confident judgements cannot be made for customs unions in general and in the abstract, produced tentative and practically-oriented analyses of the conditions which favour a union's being on balance trade-creating, and there would be wide agreement on the following list:

1. Many union members.
2. Trade a small proportion of members' production, a high proportion giving more opportunity for a trade-diverting switch from non-union to union supply.
3. A high proportion of what trade there is being with members, and a low proportion with the outside world, again reducing trade diversion possibilities.
4. A low common external tariff as compared with the members' pre-union average tariff, further reducing the likelihood of diversion.
5. A wide overlap in the activities protected by the tariff in the different member countries, since with no overlap, there can be no trade-creating production effect through a shift in demand from a domestic to a union supplier, and a trade-diverting switch from a non-union supplier is probable.
6. Wide differences between union members in the cost of producing particular commodities.

These last two conditions provide for the countries forming the union to be actually competitive but potentially complementary.

In the light of these conditions, less-developed countries appear as most unlikely candidates for membership of a beneficial customs union. The theory deals with production and consumption shifts towards a more or a less efficient use of resources and satisfaction of consumer preferences. In developed, diversified economies such shifts can take place in response to price changes. The theory is much less adequate as an explanatory device for export-oriented, less-developed economies which produce a narrow range of commodities, and in which increased welfare requires primarily the growth and diversification of output. Yet there has been much activity in the formation of unions of such countries. Extension of the theory was required to explain this paradox, and to determine whether or not the formation of a union was economically rational: Johnson (1965);

Cooper and Massell (1965). There has, however, been little development of a theory of customs unions in the context of economic growth (see Robson 1983, ch. 2).

The basic theory acknowledges the existence of economies of scale. These may have cost-reduction effects with increased sales to union partners bringing domestic producers to a lower point on their supply curves. They may also have 'trade suppression' effects, with a switch to domestic products (in contrast with the standard trade diversion switch to products of union partners) from lower-cost (ex-tariff) non-union imports. These two effects may be thought of as parts of trade creation and trade diversion, respectively.

In a union of less-developed countries, economies of scale may have a much more central role. They may allow the development of competition between enterprises which would have monopolistic powers within the small domestic markets. Within the domestic markets many goods can be produced, if at all, only with extremely high protection. Access to the larger market allows a more efficient level of production. It also provides, above all, a stimulus to investment and economic growth. Many industries, operating with economies of scale, will be established only if they have access to the protected union market. These new industries, established to supply a demand previously satisfied entirely by imports, are by definition import-substituting and trade diverting. From this viewpoint, trade diversion becomes beneficial. In fact, it has become a major purpose of the union.

Other aspects of a customs union must be embraced by an extended theory if it is to be of particular relevance to less-developed economies. There is the existence of non-tariff barriers, which are often more serious restraints on trade than tariffs. There is the role of transport, because in many less-developed countries transport routes do not satisfactorily link potential union members, so that the removal of tariffs between them would be largely a formality, without any great effect on their trade. And there is the question of the distribution of the effects of union. For example, the location of new industries may be very unequal between members, so that some control of location or other equalizing procedures may be required. The basic theory says little or nothing about these matters, but in practice measures to deal with them are of fundamental importance to the viability of any customs union.

There is a further difficulty with the basic theory. It shows the circumstances in which the establishment of a customs union brings an improvement over protection on a national basis. However, precisely the same arguments about the efficient distribution of resources also show that free trade is better than a customs union. So why should customs unions be formed when, at their trade-creating best, they are inferior to the non-discriminatory removal of tariffs? Are customs unions simply irrational?

An explanation of why countries form customs unions, and why it can be rational for them to do so, requires the theory to be extended beyond the confines of the conventional assumption that welfare depends on private consumption alone. The inclusion of public goods, or public preferences, in the welfare function allows for policies to be counted as beneficial that would otherwise be irrational.

This approach provides a rationale for the policy commonly found in less-developed countries of attempting to secure a level of industrialization higher than would result from the operation of a free market. The preference for industry may have a non-economic basis, but it may also have economic rationality. It may be based on a belief in the importance of external economies created by industry and their beneficial effects on economic growth. In other words, the preference may have a long-run, growth-oriented basis, rather than a short-run allocation-oriented basis. The preference results in a policy of industrial protection as against free trade. Given economies of scale, this public preference for industry can be satisfied more efficiently within a customs union than within the smaller markets provided by protection on a national basis.

The device of counting as beneficial what would otherwise be seen as the opposite may be applied to a range of policies. The difficulty is that it can too easily be misinterpreted to justify any

policy; a preference that cannot be questioned may be what the governments of less-developed countries want, but not what the people need.

Customs unions were sometimes a feature of colonial arrangements, as in East Africa and Southern Africa. Many schemes have been formulated and some put into effect in the era of independence. They have not been across-the-board preferential systems, relying on the response of the market to the resulting price signals, as in the theoretical model. They have recognized the need for complex regulations if an acceptable distribution of the gains is to be achieved. There has been planned industrial specialization and location, partial protection for particular industries within the union, and fiscal redistribution. Despite these arrangements, success has been less than assured. The East African union was dissolved. In Central America the customs union, though not formally dissolved, is effectively moribund. In general, schemes failed to progress once the force of the original initiative faded.

Cycles in Socialist Economies

D.M. Nuti

In the Marxist–Leninist project of socialist economy the elimination of cycles in economic activity is the expected result of central planning replacing the ‘anarchy’ of capitalist markets. *Ex-ante* coordination of the activities of government, households and firms according to a consistent, feasible and efficient plan should, in principle, ensure the continued full employment of labour and other resources along smooth growth paths instead of the recurring bouts of booms and recessions and persistent unemployment characteristic of capitalism.

The experience of those capitalist countries which, especially since World War II, have tried to implement a social-democratic version of this project while maintaining free enterprise does not differ significantly, at least qualitatively, from that of more conventional capitalist economies. Built-in stabilizers and anticyclical management of demand may have reduced the amplitude of fluctuations and the depth of unemployment (though some government intervention has been deemed cyclical because of leads and lags); the individual cost of fluctuations and unemployment has been partly collectivized by the welfare state; but the undesired phenomena have persisted. The same is true for Yugoslavia, a country which has implemented an associationist form of socialism introducing self-management on a large scale but has retained enterprise initiative and markets.

Other countries attempted to implement the marxist-leninist project – state ownership, central

planning, equalitarianism, 'democratic centralism' under the leadership (and practical monopoly of power) of the communist party, such as the Soviet Union, the East European Six, Mongolia, China, Cuba and the other countries loosely classed as centrally planned economies or CPEs. These countries have been successful in eliminating fluctuations in the degree of labour employment. Full employment of labour was reached in the Soviet Union at the inception of the First Five-Year Plan (1928) as a result of full-scale mobilization of labour and in the other countries in the course of reconstruction after the wars that brought about the new system. Ambitious accumulation policies maintained full employment; the wage pressure generated by labour shortage itself, combined with government commitment to price stability, added sustained excess demand for consumption which contributed further to full employment stability, without any need for specific policies to support it. Full employment has been the by-product of growthmanship. In view of the persistent microeconomic inefficiency of central planning and the underfulfilment of labour productivity targets it can also be said, in a sense, that full employment of labour has been achieved 'by default'. If, however, the decentralization process currently undertaken in most centrally planned economies were to reproduce unemployment tendencies no doubt specific policies would be adopted to restore and stabilize full employment.

Outside labour employment the performance of socialist planning has been less satisfactory than originally expected. In the Soviet Union, since the completion of reconstruction and the launching of accelerated industrialization in 1928, and in the other socialist countries since the corresponding dates in their economic history, fast growth of all performance indicators in peacetime until *circa* 1960 has smoothed small-scale cyclical phenomena, reducing them to fluctuations of positive growth rates rather than of levels of income and consumption. Since then, partly because of the gradual exhaustion of labour reserves and of easily accessible natural resources, partly because of the systemic microeconomic inefficiency exacerbated by the lack of such reserves, a discernible slowdown of growth trends has been accompanied by the appearance of negative rates, i.e. fluctuations of levels as in capitalist countries. Instances range from the early minor case of Czechoslovakia in 1963 to the large-scale income drop of one third in three years in Poland 1980–82.

These phenomena are only partly attributable to exogenous shocks and their echoes, whose persistence in the socialist economy was recognized by Oskar Lange (1969), or to adjustment processes such as accelerator-type movements, whose persistence in the socialist economy had been anticipated by Aftalion already in 1909 and recognized by Notkin (1961) and Coblijc– Stojanovic (1969). Partly – indeed mostly – these phenomena are caused by systemic factors which could be classed under three groups: (i) the lack, or at any rate the slowness, of automatic adjustment feedbacks in the economic life of centrally planned economies; (ii) the acceleration of economic activity towards the end of the planning period – be it a month, a year or five years– to avoid the formal and informal penalties of underfulfilment of targets and to obtain the rewards associated with fulfilment and overfulfilment, followed by slackening at the beginning of the next period; (iii) the presence of political feedbacks, such as popular discontent and unrest resulting from deteriorating economic performance, the changes in political centralization induced by manifestations of unrest, the economic management changes associated with political changes; these phenomena adding up to a systemic mechanism of economic/political cycles.

Markets, like all servomechanisms or homeostatic (self-regulating) devices, are neither costless nor instantaneous but are automatic in their operation; at the cost of unemployment and possibly with a considerable lag, for example, an unexpected contraction in world trade can be gradually accommodated through lower wages and prices than would otherwise have prevailed, lower exchange rate and higher interest rates regardless of government intervention, capital flows etc. Central planning, like manual control, may or may not be faster and cheaper, or more

accurate, than automatic servomechanisms, depending on the relative quality of alternative controls and the actual circumstances, but is never automatic. The experience of centrally planned economies has shown repeated and sometimes glaring instances of inertia and sluggish response to exogenous change, such as persistent accelerated accumulation in the face of rising labour shortages, wage and price stability administratively enforced in spite of rising excess demand for labour and goods, systematic underpricing of imported materials and of exportables in spite of sharpening external imbalance. Reliance on monetary budget constraints and the continued presence of consumers' discretion (if not sovereignty) and some managerial room for manoeuvre make these forms of inertia and delayed response an important handicap for central planners trying to outperform market adjustments. It is precisely inadequate central response to a changing environment (including inadequate ability to innovate institutions and technology) that has given impetus to repeated attempts at reform in the last two decades.

The incentive system typical of central planning, strongly and discontinuously geared to the degree of fulfilment of physical targets, leads to frantic speeding-up of activity (*shturmovshchina* in Russian, literally 'storming') towards the end of the planning period. For monthly plans this haste leads to frequent quality deterioration; for yearly plans 'storming' leads to output being overestimated, or 'borrowed' from the subsequent period (i.e., made up through subsequent unrecorded additional output); so much so that the ratio of December output to that of the following January can be regarded as an index of economic centralization (Rostowski and Auerbach 1984). For five-year plans, 'storming' implies a concentration of investment project completions towards the end of the period and a spate of new starts at the beginning, with corresponding fluctuations. Moreover, the generalized growthmanship and emphasis on capital accumulation typical of the centrally planned economy leads usually to the inclusion in investment plans of more projects than can be completed on schedule, through 'investors' (local authorities, ministries, enterprises) underestimating true requirements in order to get a place in the plan and later escalating their demands, and through central planners systematically overestimating capacity and especially labour productivity prospects. Sometimes investment ambition leads to additional investment projects being added after or outside the plan balance (as in Gierek's Poland). As they say in East European literature, 'the investment front widens'. Sooner or later specific or generalized bottlenecks of productive or import capacity slow down implementation and reduce or block new starts. Efficiency falls due to investment resources being frozen for periods longer than economically and technically justified, and possibly because of disruption elsewhere in the economy due to resources being sucked in by investment projects given priority over current operations (a 'supply-multiplier' effect). Capital – i.e. in Marxian terminology 'dead labour' – is made unemployed instead of live labour. The cyclical pattern of starts and completions of projects, mostly within the plan period but sometimes overstepping it, leads to cyclical patterns of capacity and output endogenously generated by the system and not justified by exogenous factors. These processes have been investigated theoretically and empirically by Olivera (1960), Goldman (1964 and 1965), Baijt (1971), Bauer (1978), Dahlstedt (1981), Dallago (1982) and above all by Bauer (1982, in Hungarian, forthcoming in English).

Political factors induce cycles in socialist economy directly, through successive leaders trying to reinforce the legitimacy of their rule by appeasing their subjects with short-lived but significant spurts of consumption before the standard growth and accumulation oriented policy typical of socialist governments is resumed and comes up against the constraints discussed in the previous paragraph (Mieczkowski 1978; Hanson 1978; Bunce 1980; Lafay 1981). The association of economic and socio-political factors is investigated by Eysymontt and Maciejewski (1984), who apply discriminant analysis to a large number of indicators of such factors over time in order to identify – and anticipate – periods of crisis; they do not, however, have a model of the actual interaction of political and economic factors. An attempt at constructing such a model is made by

Nuti (1979, 1985): a critical relationship is assumed between political centralization and popular unrest, inverse up to a threshold level and direct beyond it; economic centralization is directly related to political centralization and affects – through its impact on investment policy – the level of shortages and inefficiency which in turn fuel political unrest. A recursive model with lagged variables is shown to simulate the kind of recurring rounds of reform attempts and accumulation drives observable in actual socialist economies. Screpanti (1985) has modified such a model applying catastrophe theory and obtaining a political/economic accumulation cycle similar to that of capitalist economies.

The further progress of economic reform in centrally planned economies towards market socialism is bound to attenuate and ultimately eliminate the systemic types of economic cycles discussed above. However, as Maurice Dobb had already anticipated in 1939, the diffusion of markets instead of solving the instability problems of the centrally planned economy transforms them into those typical of capitalist economies.

Cyclical Markups

Julio J. Rotemberg

Abstract

This article first shows that countercyclical variations in the ratios of prices to marginal cost (markups) can cause pro-cyclical fluctuations in the demand for labour at a given real wage and thus induce fluctuations in economic

activity that look like business cycles. It then discusses methods for measuring cyclical movements in markups and shows that several types of evidence suggest that these are counter-cyclical. Lastly, it discusses economic mechanisms that can explain these counter-cyclical markup movements.

Firms that have increasing returns to scale, that produce differentiated products, or that are part of a small oligopoly can generally be expected to set a price above marginal cost. In so far as a firm's ratio of price to marginal cost is larger than one, there is no particular reason to suppose that this ratio, or markup, will stay constant when overall economic conditions change. Indeed, different models of imperfect competition have different predictions concerning how this markup should vary as aggregate income and activity expands and contracts. Thus, an analysis of whether markups rise when aggregate activity rises or whether they rise when aggregate activity declines provides a useful lens for determining which theories of firm behaviour have more validity.

Markup variations are also of central importance for macroeconomics. One of the central questions for macroeconomics is why the economy expands and contracts at cyclical frequencies in the first place, and cyclical movements in markups are potentially an important nexus that allows such fluctuations to occur. When a single firm (or industry) raises the ratio of its price to its marginal cost, one expects its relative price to rise so that the quantity it sells falls. However, when every firm in the economy tries to raise its price relative to its marginal cost, relative prices need not be affected.

When every firm raises its markup two important consequences follow. The first is that real marginal cost, which can be defined as nominal marginal cost divided by the typical price charged by firms, must fall. Thus, the question of whether markups are countercyclical is the same as the question of whether real marginal costs are pro-cyclical. The second consequence of all firms varying their markups at the same time is that the aggregate demand for labour changes. To see this, notice that nominal marginal cost is equal to the nominal wage divided by the marginal product of labour. Thus, a generalized increase in markups means that prices must rise relative to nominal wages if employment is to remain at a level that keeps the marginal product of labour constant. Alternatively, firm are willing to pay the same real wage only if the marginal product of labour rises, and this requires that employment fall if labour is subject to diminishing returns. In either way of seeing this change, the demand for labour at any given wage falls.

The Role of Markup Changes in Economic Fluctuations

The capacity of markup changes to generate changes in aggregate labour demand is important because several pieces of evidence suggest that short-run business fluctuations are the result of changes in the demand for labour. That the willingness of firms to hire labour at any given real wage increases in economic expansions is suggested first of all by the tendency of real wages to increase when the economy expands. As shown by Bils (1985), this tendency is particularly strong when one looks at the wages of individuals (as opposed to looking at average wages paid to all workers). Moreover, as emphasized by Bils (1987), firms tend to use more overtime hours in economic booms, and firms are legally obliged to pay higher hourly wages for these overtime hours. When combined with the pro-cyclicality of real wages, other pieces of

evidence also suggest that labour demand is higher in booms. In booms, both the unemployment rate and the fraction of the unemployed who have been unemployed for longer than 5 weeks tend to be lower (both of which suggest that finding jobs is easier) and that the number of help-wanted advertisements is larger (suggesting that it is more difficult for firms to find workers even as they pay them higher wages).

The real business cycle literature stresses a different source of labour demand movements: namely, exogenous changes in the productivity of the typical firm. This hypothesis has the advantage that it explains in a straightforward fashion why labour productivity is somewhat pro-cyclical. However, as discussed below, movements in markups lead to pro-cyclical productivity under a variety of plausible assumptions. In this regard, a clear advantage of the view that markup movements are responsible for important labour demand movements is that labour productivity and real wages rise together with output also when output increases appear to be due to non-technological factors such as increases in military spending, expansionary monetary policy or reductions in the price of oil. (Evidence of these conditional correlations of productivity and output can be found in Hall 1988.)

Relative to markup variations, exogenous short-run changes in technical progress have another disadvantage as sources of cyclical fluctuations. This is that technical progress not only increases the willingness of firms to hire workers but also reduces the willingness of workers to work at any given wage. These contractionary movements in labour supply are the result of 'wealth effects': technical progress makes people richer and thus induces them to consume both more goods and more leisure. These effects are particularly large if technical progress is somewhat permanent, as tends to be true with actual examples of such progress. These reductions in labour supply imply that shocks to technical progress have only small expansionary effects on employment. By contrast, reductions in markups induce only modest wealth effects, so employment responds more strongly to the resulting increases in labour demand.

These conceptual benefits of countercyclical markups raise the question of whether markups do indeed rise in economic contractions and fall in booms. To discuss this, it is worth starting with the case where the value added production function takes the Cobb–Douglas form. With capital essentially fixed in the short run, this implies that aggregate value added Y is equal to the labour input H to the power α. The marginal product of labour is then equal to α times the average product of labor Y/H The ratio of marginal cost to price is then the wage divided by both the marginal product of labour and the price, so that it is proportional to the labour share in value added (or unit labour cost) WH/PY.

Measuring Markup Variations

If aggregate data are used, the labour share in value added is not a very cyclical variable. Labour productivity Y/H tends to rise mildly in expansions, as does the average real wage – though the size of these effects depends on how one measures economic expansions. Because cyclical productivity changes are slightly larger than the corresponding average changes in real wages, the labour share has a modest tendency to fall in expansions. If the labour share were seen as equal to the inverse of the markup (as implied by the Cobb–Douglas assumptions), markups would be pro-cyclical and actually dampen cyclical fluctuations.

As suggested in the survey by Rotemberg and Woodford (1999), this Cobb–Douglas case is a good baseline, but a number of corrections to the resulting measure of the markup immediately suggest themselves, and these tend to make measured markups more counter-cyclical. The first of these is that, as already alluded to above, what matters for marginal cost is not the average wage but the marginal wage for an additional hour of work. The average wage is dragged down in booms by the absorption into employment of many relatively low-wage workers who are not employed in recessions. If these workers are less productive, their wage per effective unit of labour input may actually be relatively large. Whatever the case, individual workers who remain employed do see their

wages rise more substantially, as emphasized by Bils (1987). Admittedly, these wage increases are concentrated among workers who change jobs, and the increases in the 'straight-time' wages of people who stay in the same job are more modest. The marginal hour of work, on the other hand, is more likely to be an overtime hour in booms, and this is probably the most important reason for believing that the marginal hour of labour is more expensive then.

It also seems important to correct the way the Cobb–Douglas approach measures the marginal product of labour. According to this functional form. the marginal product of labour is simply proportional to the average product of labour. Given that the average product of labour actually rises slightly in booms, this functional form essentially requires that the economy become 'more productive' in booms, perhaps as a result of increased technical progress.

The tendency of labour productivity to be pro-cyclical can be interpreted in two rather different ways, both of which have a direct bearing on calculations of the cyclical properties of the marginal product of labour. The first is that firms are subject to increasing returns to scale. The simplest functional form that captures this supposes that there are fixed costs, that is, that some of their inputs are 'overhead' inputs that are required to produce even a minuscule positive quantity of output for sale. Suppose for example, that $\overline{H}$ units of labour are overhead units so that output continues to be given by the Cobb–Douglas form but is now proportional to $(H-\overline{H})$ to the power α. The marginal product of labour is then proportional to the ratio $Y/(H-\overline{H})$. In booms, the percentage increase in $H-\overline{H}$ obviously exceeds the percentage by which H rises so that $Y/(H-\overline{H})$ falls by more than Y/H. This means that for $\overline{H}$ sufficiently large, the marginal product of labour falls, marginal costs rise and measured markups fall. Assuming that some of the labour input takes this overhead form can thus easily lead to the inference that markups are indeed counter-cyclical.

A second possible reason for the observation that the average product of labour is pro-cyclical is that firms do not fully utilize all their labour in recessions. They 'hoard' labour to avoid having to incur hiring and training costs when economic activity recovers. This raises two important questions. The first is whether workers produce something else other than measured output when they are being hoarded. The second is whether the firm needs to pay them less when their GDP-producing effort is lower. Given that real wages are only slightly pro-cyclical, it is probably more realistic to suppose that the cost of an hour of labour services to the firm is the same whether the worker incurs effort (and produces) or not. Particularly if the workers are not producing much unmeasured output in recessions, this implies that marginal cost in recessions is considerable smaller than is implied by H/Y. Real marginal cost is more pro-cyclical than WH/PY and markups are more counter-cyclical. One attractive feature of this explanation for pro-cyclical labour productivity is that it is very compatible with the idea that markups are counter-cyclical. Firms are willing to keep workers idle in recessions even though marginal cost is extremely low precisely because they are keeping their prices high relative to marginal cost.

There are two additional types of evidence suggesting that markups are relatively low in booms and high in recessions. The first comes from the behaviour of intermediate inputs relative to final goods. A crude view of materials is that these are used in fixed proportions relative to the gross output of final goods. However, Basu (1995) shows that the ratio of materials to final goods tends to rise when the economy expands. If the material intensity of output is a choice variable, the ratio of marginal cost to price must also equal the real price of materials divided by the marginal product of materials. It is reasonable to suppose with Basu (1995) that the marginal product of materials diminishes as the level of materials inputs rises. With constant returns, the increase in the ratio of materials to output in booms thus implies that real marginal cost is pro-cyclical even if the price of materials relative to final output were constant. In fact, Murphy et al. (1989) show that that prices of more processed goods tend to fall relative to prices of less

processed goods in economic expansions, and this too indicates a tendency of price to fall relative to marginal cost during booms.

The second additional source of evidence comes from the behaviour of inventories. Inventories rise in booms but, as stressed by Bils and Kahn (2000), they rise by less in percentage terms than sales. At the same time, long-run growth in sales does tend to be associated with equiproportonate increases in inventories in the industries they consider. In addition, they discuss cross-sectional evidence that shows that, within industries, the inventory–sales ratios of products with large sales are not smaller than the inventory-sales ratios for products with low sales. This suggests that there is something special about the decline in inventory–sales ratios that is observed in booms. It suggests, in particular, that conditions in booms lead firms to economize on inventory holding. As Bils and Kahn (2000) argue, the evidence seems most consistent with the idea that firms keep their inventories relatively low in booms because real marginal cost is relatively high.

Theories of Cyclical Markup Variations

A considerable body of evidence, then, seems consistent with counter-cyclical markups, and suggests that countercyclical markups might be central to aggregate fluctuations because they rationalize the changes in employment that characterize such fluctuations. The question that remains is why markups should vary cyclically. There are basically five types of models that explain these movements in markups. These are: models of variable demand elasticity, models of variable entry, models of sticky prices, models of investment in market share and models of implicit collusion.

In a monopolistically competitive setting, markups are equal to the elasticity of demand over the the elasticity of demand minus 1. Increases in the elasticity of demand thus lower markups (towards the competitive level of 1) and could thus be a source of business expansions. This still leaves the question of why the elasticity of demand facing the typical firm should vary over time. One possibility is that the proportion of demand that comes from highly elastic customers rises in booms. Gali (1994) obtains such composition effects under the supposition that investment is more price sensitive than consumption. Ravn et al. (2004) obtain a related effect by supposing that people have formed a 'habit' for at least a fraction of past purchases, and the elasticity of demand for these habitual purchases is negligible relative to the elasticity of demand for non-habitual ones. As consumption rises in economic expansions, more of the purchases are non-habitual so that the elasticity of demand is higher and markups have to be correspondingly lower.

Devereux et al. (1996) show that changes in demand induced, for example, by changes in government purchases lead new firms to enter existing industries. Entry of new firms is indeed quite pro-cyclical. Such entry can, in turn, make each firm's perceived elasticity of demand higher (because they fear more competitors). Thus variable entry can be seen as a reason for changes in elasticities that lead to counter-cyclical markups. Even if the expansion in the number of firms that takes place in booms is seen as too small for this effect to be large, the potential for increases in entry may lead incumbents to keep their prices low to avert the creation of an even larger number of new firms. This limit pricing might also be able to rationalize counter-cyclical markups.

Sticky prices, which are widely assumed in new Keynesian macroeconomics, probably provide the most straightforward model of counter-cyclical markups. Firms that keep their prices constant when demand increases (as a result of expansionary government policy, for example) will generally see their marginal costs rise both because of diminishing returns and because of increases in the costs of factor inputs. Thus, keeping their prices relatively constant will lead them to have lower markups. The argument that sticky prices derive their influence on the economy from their consequences for variable markups is presented in more detail in Kimball (1995).

If customers who have already purchased a good have relatively inelastic demand, keeping price low is like an investment activity for the firm. It encourages new customers (those whose demand is elastic) to become addicted. Changes in

economic conditions can lead firms to desire to either increase or decrease these investments. Increases in interest rates in particular might lead firms to wish to reduce these investments, at least temporarily. Chevalier and Scharfstein (1996) provide evidence that the cash condition of firms plays a large role in these investments as well. They show that recessions have a disproportionate effect on the pricing of cash-strapped firms, who turn out to be more eager to raise prices and thereby reduce their investment in market share.

Lastly, Rotemberg and Saloner (1986) have emphasized that high prices may be more difficult to sustain for implicitly collusive oligopolists in economic expansions. When current sales are high, each firm perceives a greater benefit from undercutting the implicit agreement because it can thereby secure even higher sales. To prevent this, the oligopolists must lower their markups of price relative to marginal cost. Some cross-sectional evidence suggests that markups are indeed more counter-cyclical in more concentrated sectors, as a theory that applies only to implicitly collusive oligopolists suggests. As shown by Rotemberg and Woodford (1992), the model can be embedded in a general equilibrium structure so that increases in government purchases raise output together with real wages. The increased rate of interest induced by additional government purchases lowers the present value of the future benefits from cooperation. It thus forces oligopolies to be less ambitious in the profits that they seek from current prices, so that markups fall and labour demand rises.
