M

Macfie, Alec Lawrence (1898–1980)

Andrew Skinner

Alec Macfie was born in Partick on 29 May 1898. He went first to school at Hillhead but later joined his brother at the High School of Glasgow where he had a distinguished career.

When he left school, Macfie, too young to enlist, worked in a munitions factory for a few months. But in 1916 he joined the Second Battalion, the Gordon Highlanders, and was commissioned as a lieutenant. He saw action at Passchendaele, and was badly wounded during an action on the Asiego Plateau in the early summer of 1918. After recovering to some extent from his wounds, Macfie entered Glasgow University where he graduated with first class honours in philosophy and English literature in 1922. Thereafter he entered a law office and took his LL.B. But having opted for an academic career, he returned to the university and took a first in economics and politics in 1927.

In the years that followed Macfie held temporary teaching posts in Nottingham and St Andrews (where he deputized for the professor of moral philosophy) before returning to Glasgow in 1932 as lecturer in the Department of Political Economy under W.R. Scott. Scott (the 'chief') died in 1940 and Macfie was invited to take the Adam Smith Chair in 1945.

Side by side with his teaching, Macfie produced three books in the period up to 1945, all of which reflect his interest in philosophy and psychology as well as in economics: *Theories of the Trade Cycle* (1934), *An Essay on Economy and Value* (1936) and *Economic Efficiency and Social Welfare* (1943). It was not until the mid-1950s, only a few years before retiring, that he embarked on a serious study of Adam Smith with special reference to the *Theory of Moral Sentiments*. Following the acquisition of the manuscripts, discovered by J.M. Lothian in 1958, Macfie became one of the driving forces behind the Glasgow edition of the Works and Correspondence of Adam Smith, and acted as co-editor (with D.D. Raphael) of the *Theory of Moral Sentiments* (1976). He also produced a little book which has exerted an enormous influence in this field, *The Individual in Society: Papers on Adam Smith* (1967).

Few modern scholars have been better equipped for the study of Smith. Macfie was a qualified lawyer, with degrees in philosophy, literature, and economics, while Smith was writing at a time when it was possible to think in terms of a global system of thought which might embrace these separate disciplines.

That machinery is of benefit to the manufacturer who introduces it has never been a point of discussion in the history of economics and the machinery question is solely a dispute over whether society benefits from the introduction of machinery, the most pressing social issue being the displacement of labour by machinery and the consequent threat of widespread unemployment. In general terms, the social benefits of machinery were well appreciated by the middle of the 18th century. However, the greatly increased use of machinery at the end of the 18th century gave a new intensity to the debate at the beginning of the 19th century. The analytical tools used by classical economists to tackle this general equilibrium problem were however quite inadequate and it is doubtful whether a deeper understanding of the issue was achieved by the heroic abstractions of the 19th century.

The earliest explicit discussions of machinery appear to be in the pamphlets of John Cary (1695), *A Discourse on Trade.* It was a time when the competitiveness of English industry was being much discussed and John Cary pointed out that England retained her business advantage because of the ability of English manufacturers to invent.

> Tobacco is cut by Engines: Books are printed; Deal Boards are sawn with Mills; Lead is smelted by Wind-Furnaces; all which save the Labour of many Hands, so the Wages of those employed need not be fallen. . . .New Projections are every Day set on Foot to render the making our Woollen Manufactures easy, which should be rendered cheaper by the Contrivance of the Manufacturers, not by falling the Price of Labour: Cheapness creates Expence, and gives fresh Employments, whereby the Poor will be still kept at Work. (Cary 1695, pp. 99–100)

A few years later, in his *Considerations of the East-India Trade* (1701), Henry Martin advocated the import of cheaper cloth from the East Indies by comparing it with the effects of machinery:

> Arts, and Mills, and Engines, which save the labour of Hands, are ways of doing things with less labour, and consequently with labour of less price, tho' the Wages of Men imploy'd to do them shou'd not be abated. The *East-India* Trade procures things with less and cheaper labour than would be necessary to make the like in *England*; it is therefore very likely to be the cause of the invention of Arts, and Mills, and Engines, to save the labour of Hands in other Manufactures. Such things are successively invented to do a great deal of work with little labour of Hands; they are the effects of Necessity and Emulation; every Man must be still inventing himself, or be still advancing to farther perfection upon the invention of other Men . . . (Martin 1701, pp. 589–90)

At this stage the effect of machinery in preserving competitiveness receives primary emphasis. There is as yet no link drawn between high wages and the incentive to create machinery. In the years that followed only the prolific Daniel Defoe paid serious attention to the role of

machinery without making any substantive analytical contribution. Indeed, Defoe even wondered whether machinery were not sometimes an evil because it displaced labour. In parliamentary debates in 1738 on the making of buttons by loom instead of by hand, Henry Archer implicitly subscribed to the full employment and sustainability thesis in a speech of considerable eloquence:

> As to the honourable gentleman's other arguments, drawn from the number of hands employed in the needle-work manufacture . . . it is, in my humble opinion, a very good argument for dismissing this Bill; because, as the manufacture may be carried on by a much fewer number of hands, with equal advantage to our trade in general, those who are employed in the needle-work way, are so many hands taken from other arts and other manufactures, in which they might be employed to much better purpose.

Archer goes on to use an example that was repeated often by classical economists:

> There was a time, Sir, when all the learning of this kingdom, and the rest of Europe, was contained in manuscripts, the writing of which employed great numbers of hands, and took up a vast deal of time in re-copying. But, Sir, how ridiculous would it have been, if on the discovery of the art of printing, the transcribers and copyers of those manuscripts had joined in a petition to the legislature, that it would be pleased to prohibit the art of printing, for the same reason which the honourable gentleman now uses, because great numbers would thereby be deprived of bread! (Archer 1742)

The next advance was stimulated by Montesquieu's claim in *The Spirit of the Laws* that the introduction of machinery was not necessarily beneficial. This provoked Josiah Tucker to provide one of the best statements on the effects of machinery:

> What is the Consequence of this Abridgment of Labour, both regarding the Price of the Goods, and the Number of Persons employed? The Answer is very short and full, *viz*. That the Price of Goods is thereby prodigiously lowered from what otherwise it must have been; and that a much greater Number of Hands are employed. . . .
>
> And the first Step is, that Cheapness, *ceteris paribus* is an Inducement to buy, – and that many Buyers cause a great Demand, – and that a great Demand brings on a great Consumption; – which great Consumption must necessarily employ a vast Variety of Hands, whether the original Material isconsidered, or the Number and Repair of Machines, or the Materials out of which those Machines are made, or the Persons necessarily employed in tending upon and conducting them: Not to mention those Branches of the Manufacture, Package, Porterage, Stationary Articles, and Book-keeping, &c. &c. which must inevitably be performed by human Labour. . . .
>
> That System of Machines, which so greatly reduces the Price of Labour, as to enable the Generality of a People to become Purchasers of the Goods, will in the End, though not immediately, employ more Hands in the Manufacture, than could possibly have found Employment, had no such machines been invented. And every manufacturing Place, when duly considered, is an Evidence in this Point. (Tucker 1757, pp. 241–2)

The subject received little further impetus in the half-century that followed. The tangential discussion of machinery by Adam Smith in the *Wealth of Nations* perhaps contributed to this state of affairs. The only notable treatment is in the lectures of Dugald Stewart at Edinburgh (1858–78), which were very influential as part of an oral tradition, but which were not available in print till the 1860s. Stewart's contribution lay in seeing the machinery question as part of a much larger and more fundamental policy issue – the trade-off between individual losses and social gains. He therefore links together three issues that had hitherto been separately discussed – the creation of large farms, the benefits of enclosures and the use of machinery. In each case Stewart grants that the hardships imposed on individuals were undeniable. He then continues;

> In judging of the policy of such innovations. . . it is absolutely necessary to abstract from the individual hardships that may fall under our notice, and to fix our attention on those general principles which influence the national prosperity. (Stewart 1856, vol. 8, p. 131)

In deciding upon the benefits of introducing machinery, Stewart observes that the material improvement of mankind and the use of machinery are practically inseparable. The policy recommendation was thus unequivocal.

> It is hardly possible to introduce suddenly the smallest innovation into the Political Economy of a State, let it be ever so reasonable, nay, ever so profitable, without incurring some inconveniences. But temporary inconveniences furnish no objection

> to solid improvements. Those which may arise from the sudden introduction of a machine cannot possibly be of long continuance. The workmen will, in all probability, be soon able to turn their industry into some other channel; and they are certainly entitled to every assistance the public can give them, when they are thus forced to change their professional habits. (1856, vol. 8, p. 193)

The severe post-Napoleonic depression contributed greatly to a reconsideration of the effects of machinery and John Barton should perhaps be given most credit for the new interest with his pamphlet, *Observations on the Circumstances which Influence the Condition of the Labouring Classes of Society* (1817). Commenting on the distinction, inherited from Adam Smith, between circulating and fixed capital, Barton pointed out that only the former serves to employ labour – the latter is embodied in machinery. Since it appeared empirically undeniable that progress involved a greater proportionate use of fixed capital Barton argued that the funds for employing labour, or circulating capital, must be subject to proportionate decrease and lead to greater unemployment. Barton was very clear about the role of high wages in inducing the adoption of machinery.

> It is the proportion which the wages of labour at any particular time bear to the whole produce of that labour, which appears to me to determine the appropriation of capital in one way or the other. For if at any time the rate of wages should decline, while the price of goods remained the same, or if goods should rise, while wages remained the same, the profit of the employer would increase, and he would be induced to hire more hands. If, on the other hand, wages should rise, in proportion to commodities, the labour's share in the produce of his own industry would be increased at the expense of his master, who would of course keep as few hands at possible. – He would aim at performing every thing by machinery, rather than by manual labour. (Barton 1817, pp. 17–18)

How far David Ricardo was directly influenced by Barton in reversing his initial optimistic position on the benefits of machinery is unclear, but in the third edition of his *Principles of Political Economy and Taxation* (1821, pp. 388–95) Ricardo tried to justify some of the pessimistic attitudes to machinery by means of a numerical example. To begin with, we have a farmer whose yearly activities can be summarized as follows:

Fixed Capital	7,000
Wages (Circulating)	13,000
	20,000
Profits (10 per cent)	2,000 (used for consumption)
Total	22,000

The circulating capital is said to 'replace the value of 15,000', that is, to provide the required profit of 2,000. In year 1, the capitalist sets half his workers to construct machines. As surplus value arises from circulating capital, the profits of 2,000 arises in equal parts from the workers in farming and the workers in machines:

Fixed Capital (Old)	7,000
Wages (Farming)	6,500
Profits (Farming)	1,000
Wages (Machines)	6,500 (Embodied in machines)
Profits (Machines)	1,000
Total	22,000

If the farmer still spends 2,000 for his own consumption, he is left with 5,500 to spend on wages the next year. In other words, the wage bill falls from 13,000 to 5,500 because of the construction of machines. The gross produce consists of profits, rent and wages, while the net produce consists of profits and rent only. In our case, there is no rent, so the gross produce falls from 15,000 to 7,500 while the net produce stays at 2,000. Ricardo concludes as follows:

> In this case, then, although the net produce will not be diminished in value, although its power of purchasing commodities may be greatly increased, the gross produce will have fallen from a value of 15,000 *l* to a value of 7,500 *l*, and as the power of supporting a population, and employing labour, depends always on the gross produce of a nation, and not on its net produce, there will necessarily be a diminution in the demand for labour, population will become redundant, and the situation of the labouring classes will be that of distress and poverty.

Subsequently, Ricardo concedes that more workers can be employed in producing goods that the capitalist may wish to consume with his increased real power of consumption, but this may not be strong enough to compensate for the initial loss of employment.

> All I wish to prove, is, that the discovery and use of machinery may be attended with a diminution of gross produce; and whenever that is the case, it will be injurious to the labouring class, as some of their number will be thrown out of employment, and population will become redundant, compared with the funds which are to employ it.

There are a number of curious features about Ricardo's analysis which, though based on a simple numerical example, is claimed to have some relevance. First, it is not at all clear whether Say's Law, which Ricardo adhered to so vehemently on other occasions, also operates when labour is displaced by machinery. Secondly, Ricardo simply presents the initial disruption of new machinery without saying anything about the nature of the new equilibrium or the adjustment process leading to it. This contrasts sharply with his usual emphasis upon permanent effects –indeed, in assuming that the new machines made will be able to realize 1,000 units of profit Ricardo is implicitly assuming some sort of pervasive equilibrium. Thirdly, Ricardo appears to deny the practical importance of his example at the end of the chapter when he emphasizes that his argument holds only when the new machinery is introduced suddenly.

> The statements which I have made will not, I hope, lead to the inference that machinery should not be encouraged. To elucidate the principle, I have been supposing, that improved machinery is *suddenly* discovered, and extensively used; but the truth is, that these discoveries are gradual, and rather operate in determining the employment of the capital which is saved and accumulated, than in diverting capital from its actual employment.

This point gains additional force from Ricardo's insistence that the state take no action to discourage technological progress. Most subsequent economists, from Malthus onwards, took exception to the collection of assumptions necessary to produce Ricardo's result.

Of the classical economists who followed, only Nassau Senior and John Stuart Mill tried to justify Ricardo's reasoning, sometimes with the same surprising pattern of argument that characterized Ricardo. For example, John Stuart Mill (1848) begins by asserting that workers suffer temporarily when circulating capital is converted to fixed capital; almost immediately however he adds that this is a case which scarcely ever occurs in practice. An attempt by J.E. Tozer to provide a mathematical formulation of the question does not go beyond the framework set of by Ricardo. Tozer (1838) grants that there is an initial deduction from the wages fund but points out that the fund is replenished over time as the additional output from the machinery is produced. There does not appear to be a serious effort at going beyond Ricardo's analytical schema until the writings of Knut Wicksell.

With his usual clarity, Wicksell begins his section on production and distribution by setting forth the technical conditions necessary for the validity of the marginal productivity theory of distribution. He recognizes that the distributive impact of machinery depends upon the manner in which machinery alters the marginal productivities of labour and capital and that simple answers to such a question are unlikely. One issue which he analyses with considerable acumen is the position of Ricardo that machinery may actually diminish the gross product. Wicksell takes issue with Ricardo's conclusion and claims that Ricardo did not follow his premises to their logical conclusion – under free competition, changes in technique cannot lead to a diminution of gross product. This is proved as follows:

> Let x and y denote the number of labourers per acre using the old and new methods of cultivation, and let $f(x)$ and $\varphi(y)$ denote the production functions of these lands. If m acres are cultivated by the old method and n acres by the new method, then the problem of maximizing total product is Maximize
>
> $$mf(x) + n\varphi(y)$$
>
> subject to
>
> $$m + n = B \quad mx + ny = A$$
>
> where B is the total number of acres and A is the total amount of labour available. The first order conditions for a maximum are,
>
> $$f'(x) = \varphi'(y) \text{ and } f(x) - xf'(x) = \varphi(y) - y\varphi'(y)$$

where the prime denotes differentiation. The first condition states that total product is maximized

when the marginal product of labour is equal, under both methods and the second condition states the equality of rents per acre. Wicksell now observes that these are precisely the conditions achieved by pure competition and hence that Ricardo was wrong to claim that a diminution of gross product was possible. Modern readers will note that Wicksell assumes throughout the validity of interior maxima. Subject to this qualification, Wicksell's analysis is a considerable improvement on anything produced before him. The problem just discussed considered labour and land as the only explicit factors of production. Even here, Wicksell feels that 'It is scarcely possible to discover a simple and intelligible criterion which will indicate whether a change in the technique of production is in itself likely to raise or lower wages'. When Wicksell goes on to add capital as a factor of production, he has to concede that inventions may reduce the marginal product and share of labour. This leads him to say that 'The capitalist saver is . . . fundamentally, the friend of labour, though the technical inventor is not infrequently its enemy'. (Wicksell 1911, pp. 140, 143, 164)

A satisfactory treatment of the machinery question depends upon modelling the general equilibrium of an economy and of following its transition from an initial equilibrium to the new equilibrium after the introduction of machinery. Even today, such a treatment is by no means easily achieved. Perhaps the classical economists would have done best to accept the general benefits of machinery, subject to transitional difficulties, as expounded by economists such as Tucker and Stewart, and wait until the proper analytical tools to discuss the issue satisfactorily had been developed.

Fritz Machlup was born in Wiener Neustadt, south of Vienna, on 15 December 1902, and died in New York on 30 January 1983. He studied economics at the University of Vienna in the 1920s under Friedrich von Wieser and Ludwig von

Mises, and wrote his doctoral dissertation on the gold-exchange standard (Machlup 1925) under the latter. In the years 1922–1932 he pursued a business career in the family cardboard-manufacturing partnership while continuing his intellectual interests in economics and philosophy of science in association with von Mises, Hayek, Haberler, Morgenstern, Felix Kaufmann and Alfred Schütz. During this period he wrote two more books including one (Machlup 1931) dealing with the role of stock-market speculation in capital formation. As business conditions deteriorated in the 1930s he took leave from his partners to accept a Rockefeller fellowship, and spent 1933–1935 in the United States. Upon receiving an appointment at the University of Buffalo in 1935 he liquidated his Austrian business interests, and following a brief stay in England began an academic career in the United States. He moved to Johns Hopkins in 1947, and to Princeton in 1960 to succeed Jacob Viner. At Hopkins he had a profound influence as a graduate teacher and in building up a first-rate graduate programme that achieved national prominence; a list of his students is contained in Machlup (1963), and tributes and testimonials from many of them will be found in Dreyer (1978). At Princeton he was extremely active in his direction of the International Finance Section. Upon his retirement in 1971 he resumed his active career at New York University until his death shortly after his 80th birthday. He was president of the Southern Economic Association (1959), the American Association of University Professors (1962–1964), the American Economic Association (1966), and the International Economic Association (1971–1974).

Machlup's two great areas of research were international monetary economics and industrial organization, the latter with special emphasis on the 'knowledge industry', an activity which began with a study of the patent system (Machlup and Penrose 1950; Machlup 1958), continued with the development of a formal theory of invention, innovation, and the optimal lag of imitation behind innovation (see Bitros 1976, pp. 439–502), and culminated in a monograph on the subject (1962), the multi-volumed second edition of which remained unfinished at the time of his death (Machlup 1980b, 1982b, 1983). What was especially original in his contributions was his peculiar talent, resulting from his business background and study of philosophy of science, of being able to formulate a theory that took into account – in addition to the usual economic facts – the theories or rationalizations put forward by economic agents to justify their own actions. This was used to support his contention that economic agents engage in maximizing behaviour even though they may deny this. Such perceptions permeate his works on industrial organization (Machlup 1949, 1952a, b) and were developed in numerous articles collected in Machlup (1963).

Machlup's contributions to international economics were likewise characterized by a combination of clear logical thinking and intimate knowledge of the workings of economic institutions. His two-country extension of the theory of the multiplier (1943) was especially illuminating in bringing out the implicit financial assumptions of Keynesian theory. His work on the theory and policy of foreign-exchange markets and international economic adjustment (collected in Machlup 1964) was very influential. His classic (1939–1940) article developing Haberler's concepts of demand and supply of foreign exchange was required reading for a generation of graduate students. In his famous controversy with Sidney Alexander, while stressing the importance of relative prices he proved himself to be always the eclectic, never espousing one narrow 'approach' to the exclusion of all others. At first countering 'elasticity pessimism' and championing flexible exchange rates in his academic writings, he later became the prime architect of plans to reform the international monetary system in his organization of the 'Bellagio group' (Machlup and Malkiel 1964). These activities have been recounted by Robert Triffin and John Williamson in Dreyer (1978). Machlup's last contributions to international economics included a series of penetrating analyses of the Eurodollar market (starting with Machlup 1970) and his one foray into 'real' international trade, a work on the theory of economic integration (Machlup 1977).

Machlup had a remarkable and unforgettable personality. He was brilliant and as sharp as a whistle in his keen analysis and grasp of economic

issues; he was lucid and patient as a teacher, yet tough; he was charming and witty; he was a great music-lover and an avid sportsman to the end of his days. Above all he was a man of extraordinary energy and passion.

Most of Machlup's important articles have been reprinted in Machlup (1963, 1964) and Bitros (1976); the first and third of these contain bibliographies of his work. Further information concerning his life and work will be found in Dreyer (1978), Chipman (1979), Machlup (1980a, 1982a), and Haberler (1983). The latter concludes with an apt poetic tribute by Kenneth Boulding.

Macleod warrants special mention in this *Dictionary* if only because in the late 1850s and early 1860s he undertook to produce single-handedly a dictionary of economics on a grand scale – and, what is more, one to which he was to be the sole contributor. In the event the task proved to be beyond him, as it would for any mortal, and all that appeared was the first volume covering the letters A–C. Macleod never held an academic appointment, though he applied unsuccessfully for chairs at Cambridge (1863), Edinburgh (1871), and Oxford (1888).

Macleod, the son of a Scottish landholder, was born in Edinburgh. After graduation from Cambridge (BA, Trinity, 1843) and admission to the Bar (1849), he wrote a report on the administration of poor relief in the nine local parishes of the district of Easter Ross in Scotland (1851). This report led directly to the establishment of a poor-house under Scotland's first Poor Law Union. In 1854, he joined the Royal British Bank and wrote a memorandum and opinion on that bank's legal position under the Joint Stock Banking Act of 1845. This first excursion into financial matters stimulated him to study the literature of economics on the subject, but he found that

> for the purpose of describing the actual principles and mechanisms of commerce they [Smith, Ricardo and Mill] were absolutely worthless. . . . I saw that the greatest opportunity that had come to any man since Galileo had come to me, and I then determined to devote myself to the construction of a real science of Economics on the model of the already established physical sciences. (1896b, pp. 142–3)

To his credit he stuck fast to his task. His detractors, however, have passed harsh judgement on its results (see, for example, the assessment of him in Higgs's edition of *Palgrave's Dictionary*); his sympathetic readers have been more generous (see, for example, Hayek 1933). Given the sheer magnitude of his project, there would seem to be more to be said for the position of the critics.

Macleod's employment in the banking system led to what is perhaps his most important book on that subject: *The Theory and Practice of Banking* (1855–6). Its two most interesting features for the modern reader are, perhaps, the discussion of discount policy and the insistence on the proposition that 'the distinction between capital and currency . . . is of the most profound delusions that ever existed' (1855, vol. 2, p. lxxii; see also the entry on 'Credit' in his *Dictionary).* Not surprisingly, for one who kept fast to the basic position of the Bullion Report, this latter notion introduced a number of ambiguities into the argument. However, not withstanding these peculiarities, the book was apparently quite successful, going through five editions by the 1890s and being reprinted soon after his death. Charles Rist referred to it as Macleod's 'great book' (1940, p. 261).

There followed many publications on monetary matters of which two may be singled out. In *Bimetallism* (1894), he criticized the proponents of a dual standard for advocating 'an impossibility'; a position which put him at odds with many of his contemporaries. This polemic was continued in two short tracts issued by the Gold Standard Defence Association in 1895 under the titles 'Gresham's Law' and 'Bimetallism in France'. Secondly, in 1898, he published two contributions to the debate surrounding the Fowler Commission on Indian currency arrangements: *Indian Currency* and *A Tentative Scheme for Restoring a Gold Currency to India.*

Macleod's project of reconstructing economic science continued on more general matters with *Elements of Political Economy* (1858). The book is interesting as an example of Macleod's advocacy of a definition of economics as the 'science of exchanges', or catallactics, which Marshall claimed 'anticipated much both of the form and substance of recent criticisms on the classical doctrine of value in relation to cost, by Profs. Walras and Carl Menger' (1920, p. 821), and for the fact that in it he introduces into the vocabulary of economics the phrase 'Gresham's Law'.

One of Macleod's interesting habits was that of publishing the same material in different forms and under different titles. In this he reminds one of McCulloch. Thus, *Bimetallism* was itself an expanded version of the seventh chapter of his *Theory of Credit* (1889–91), his *Elements of Political Economy* (1858) appeared in successive editions under the titles *The Principles of Economic*

Philosophy (1872–5) and *The Elements of Economics* (1881–6), and his *History of Economics* (1896b) seems to be made up of material from his unfinished dictionary.

Macleod died at Norwood on 16 July 1902.

Macroeconometric Models

Ray C. Fair

The topic 'macroeconometric models' is very broad. Conceivably it could include any study in which at least one equation was estimated using macroeconomic data. I will limit my discussion to structural models that try to explain the overall economy, although I will also have a few things to say about vector autoregressive models.

One might have thought at the beginning of large-scale model construction in the early 1950s that there would be a gradual and fairly systematic improvement in the accuracy of the specification of the equations, so that by the late 1980s there would exist a generally agreed upon model. This is not the case. Macroeconomics has now been in a state of flux for more than a decade. There is currently much disagreement among macroeconomists about the structure of the economy, and there is certainly no generally agreed upon model. This lack of agreement manifests itself in quite different monetary and fiscal policy recommendations that are made at any one time by different economists.

The unsettled nature of macroeconomics makes it an exciting research area, but also a difficult one to review in a short essay. Any current review of macroeconometric models must be selective and somewhat idiosyncratic, and this is certainly true of the present review. I have chosen some topics that I think are important in the area, but the list is by no means exhaustive.

A Brief History

A comprehensive discussion of the history of macroeconometric model-building is in Bodkin et al. (1986). The following discussion is very brief. The beginning of the construction of macroeconometric models is usually traced back to Tinbergen's (1939) work on business cycles in the late 1930s, although there were earlier efforts

by Tinbergen and others that could be classified as macroeconometric models. Tinbergen's model was an annual model and consisted of 31 behavioural equations and 17 identities. It was estimated by ordinary least squares for the period 1919–32. There are few exogenous variables in the model; Bodkin et al. (1986) have identified only five. Tinbergen never 'solved' his model in the modern sense. He did, however, spend considerable time analysing the dynamic properties of the model analytically after reducing the model to a linear difference equation in corporate profits.

Work on macroeconometric models began in earnest after World War II. The leading figure in the postwar period has been Lawrence Klein, who built his first models while at the Cowles Commission in the mid-1940s. The results of this work were published in Klein (1950). This monograph contained three models. Model I contains three behavioural equations and three identities, and it was estimated by full-information maximum likelihood, limited-information maximum likelihood and ordinary least squares. This model has been an important pedagogical tool for many decades. Model II contains a consumption function and two identities. Model III contains 12 behavioural equations and 4 identities. It is best known today as the precursor of the Klein–Goldberger model.

The Klein–Goldberger model (1955) began as a project of the Research Seminar in Quantitative Economics at the University of Michigan. It was an annual model, estimated for the split-sample period 1929–41, 1946–52. It consisted of 15 behavioural equations and 5 identities and was estimated by limited-information maximum likelihood. It was the first model to be used for regular *ex ante* forecasting purposes. The first forecast was for the year 1953.

The 1960s was an active time for model-builders. One of the major efforts of the decade was the Brookings model, a quarterly model which at its peak contained nearly 400 equations. This model was a joint effort of many individuals, and although it never achieved the success that was initially expected, much was learned during the effort. The model was laid to rest around 1972.

The 1970s was a time in which many models became commercially successful, the most successful being DRI (Data Resources, Inc.), Wharton, and Chase. The commercialization of the models changed the focus of research somewhat. Less time was spent on what one might call basic research on the models, such as experimenting with alternative estimation techniques and statistical testing. More time was spent on the month-to-month needs of keeping the models up to date. The 1970s was also a time in which macroeconometric models came under attack on academic grounds. The key attack was the Lucas (1976) critique, which argued that the models are not likely to be useful for policy purposes. More will be said about this later. These attacks had the effect of moving academics away from research on large-scale models to other things, and very little academic research was done on models in the 1970s. This has continued to be true to some extent in the first half of the 1980s.

Methodology

Economic theory is used to guide the specification of macroeconometric models. The 'traditional' procedure is to use theory to guide the choice of explanatory variables in the equations to be estimated. Consider, for example, the multi-period utility-maximization theory of household behaviour. This theory tells us that a household's consumption and labour-supply decisions are a function of the prices of the goods, the wage rate, non-labour income, interest rates and the initial value of wealth. The traditional procedure is thus to use these as explanatory variables in the equations explaining consumption and labour supply. In many cases theory indicates the signs of the coefficients of the explanatory variables. Theory is generally not used to decide the functional forms of the estimated equations and the lengths of the lag distributions. Functional forms and lag lengths are generally chosen empirically, by trying alternative forms and lengths to see which produces the best results.

The transition from theoretical models to empirical models is a difficult problem

in macroeconomics. One is usually severely constrained by the quantity and quality of the available data, and many restrictive assumptions are generally needed in the transition from the theory to the data. In other words, extra 'theorizing' occurs during the transition, and it is usually theory that is less appealing than that of the purely theoretical model.

The place where extra theorizing occurs most is the treatment of expectations. Expected future values play an important role in most theoretical models. In the multi-period utility-maximization model, for example, expected future values of prices, the wage rate, non-labour income and interest rates affect current consumption and labour-supply decisions. Since expected values are generally not observed, one needs to make some assumption about how expectations are formed when specifying the empirical equations to estimate. A common approach is to assume that expectations of a particular variable are a function of current and lagged values of the variable. Under this assumption one simply replaces the expected future values with current and lagged values. This assumption is fairly ad hoc, and much of the research in macroeconomics in the last decade is on the question of how expectations are formed. More will be said about expectations later.

Once enough assumptions have been made so that only observed variables appear in the equations, the equations are ready to be estimated. The estimation techniques range from ordinary least squares and two-stage least squares to three-stage least squares and full information maximum likelihood. Many equations in macroeconometric models have serially correlated error terms, and a common procedure is to estimate the equations under the assumption that the error terms are first-order autoregressive. If the model is simultaneous, which almost all models are, ordinary least squares produces inconsistent estimates.

Much experimentation takes place at the estimation stage. Different functional forms and lag lengths are tried, and explanatory variables are dropped if they have coefficient estimates of the wrong expected sign. Variables with coefficient estimates of the right sign may also be dropped if the estimates have t-statistics that are less than about two in absolute value, although practice varies on this. If things are not working out very well in the sense that very few significant estimates of the correct sign are being obtained, one may go back and rethink the theory or the transition from the theory to the estimated equations. This process may lead to new equations to try and perhaps to better results. This back-and-forth movement between theory and results can be an important part of the construction of the model.

The estimation technique that is used in experimenting with alternative specification is usually a limited-information technique, such as two-stage least squares. These techniques have the advantage that one can experiment with a particular equation without worrying very much about the other equations in the model. Knowledge of the general features of the other equations is used in the choice of the first-stage regressors for the two-stages least squares technique, for example, but one does not need to know the exact features of each equation when making this choice. If a full-information technique is used, it is usually used at the end of the search process to estimate the final version of the model. If the full-information estimates are quite different from the limited-information ones, it may again be necessary to go back and rethink the theory and transition. In particular, this may indicate that the version of the model that has been chosen by the limited-information searching is seriously misspecified. Sometimes ordinary least squares is used in the searching process even though the model is simultaneous. This, however, has little to recommend it since the ordinary least squares estimates are inconsistent, and consistent alternatives like two-stage least squares are not expensive to use.

The next step after the model has been estimated is to test and analyse it. One way in which models are tested is to compute predicted values from solving the overall model and compare the predicted values to the actual values. The accuracy of the predictions is usually examined by calculating room mean-squared errors. The properties of models are analysed by performing 'multiplier' experiments. These experiments involve

changing one or more exogeneous variables and observing how the predicted values of the endogenous variables change. Models can also be analysed by performing optimal-control experiments. Given a particular objective function and given a set of policy variables, one can find the values of the policy variables that maximize the objective function subject to the constraints imposed by the model.

It may also be the case that things are not working out well at the testing and analysis stage. Poor fits may be obtained; multipliers that seem (according to one's *a priori* views) too large or too small may be obtained; and optimal control experiments may yield optimal values that do not seem sensible. This may also lead one to rethink the theory, the transition to the estimated equations, or both, and perhaps to try alternative specifications. The back-and-forth movement between theory and results may thus occur at both the estimation and analysis steps.

It is important to note that the back-and-forth movement between theory and results may yield a model that fits the data well and seems on other grounds to be quite good, when it is in fact a poor approximation of the structure of the economy. If one searches hard enough, it is usually possible with macro time-series data to come up with what seems to be a good model. The searching for models in this way is sometimes called 'data mining' and sometimes called 'specification searches', depending on one's mood. Fortunately, there is a way of testing whether one has mined the data in an inappropriate way, which is to do outside sample tests. If a model is poorly specified, it should not fit well outside the sample period for which it was estimated, even though it looks good within sample. It is thus possible to test for misspecification by examining outside sample results. A method for doing this is discussed in the next section.

Because of the dropping of variables with wrong signs and (possibly) the back-and-forth movement from multiplier results to theory, an econometric model is likely to have multiplier properties that are similar to what one expects from the theory. Therefore, the fact that an econometric model has properties that are consistent with the theory is in no way a confirmation of the model, at least in my view. Models must be tested by using methods like the one discussed in the next section, not by examining the 'reasonableness' of their multiplier properties.

There are two main alternatives to the traditional procedure just outlined. One, which is discussed in section "The Lucas Critique and the Estimation of Deep Structural Parameters", is to take more seriously the theoretical restrictions that are implied by the assumption that decisions are made by maximizing objective functions. The other alternative is to estimate vector autoregressive models, where very few theoretical restrictions are imposed. This alternative has been stressed by Sims (1980). A vector autoregressive (VAR) model is one in which each variable is regressed on lagged values of itself and lagged values of all the other variables in the model. This approach imposes some restrictions on the data – in particular, the number of variables to use, the lengths of the lags and (sometimes) cross-equation restrictions on the coefficients – but the restrictions are in general less restrictive than the exclusionary ones used by the traditional approach. As discussed in the next section, VAR models are useful for comparison purposes even if one otherwise does not agree with the VAR methodology.

Macroeconometric models are also used to make forecasts. Given a set of coefficient estimates, a set of values of the future-error terms, and a set of guesses of the future values of the exogenous variables, one can use a model to make predictions of the future values of the endogenous variables. A forecast beyond the data, where guessed values of the exogenous variables must be used, is called an *ex ante* forecast. A forecast within the data, where actual values of the exogenous variables are used, is called an *ex post* forecast. The values chosen for the error terms are usually the expected values, which are almost always zero. If an equation has been estimated under the assumption of a first-order autoregressive error, the estimate of the autoregressive coefficient and last period's estimated-error term are used in estimating the current period's error term.

In practice, *ex ante* forecasts are often 'subjectively adjusted'. If, when unadjusted, the model is not forecasting what the model-builder thinks is

going to happen, the equations are changed by adding or subtracting values from the constant terms. In many cases a constant term in an equation is changed more than once over the forecast horizon. Adjusting the values of constant terms is equivalent to adjusting the values of the error terms, given that a different value of the constant term can be used each period. This procedure can thus be looked on as the model-builder guessing the future values of the error terms. Instead of setting the future-error terms equal to their expected values, the model-builder overrides this aspect of the model and sets values based on his or her own feelings about what is going to happen. With enough adjustments it is possible to have the forecasts be whatever the user wants, subject to the restriction that the identities must be satisfied. This means, of course, that in practice one can never be sure how much of the forecast is due to the model and how much is due to the model-builder. It also means that *ex ante* forecasts are of little use for testing and comparing models *qua* models.

Testing

The testing of macroeconometric models is extremely difficult, and this is undoubtedly one of the reasons that there is so little agreement in the area. There are two main problems in comparing different models. First, models may differ in the number and types of variables that are taken to be exogenous. If, for example, one model takes prices as exogenous whereas a second model does not, the first model has an obvious advantage over the second in predictive tests. Second, data mining may make a model look good within sample when it is in fact a poor approximation of the structure.

I have developed a method for comparing models that helps account for these problems (Fair 1980). The method is briefly as follows. There are four main sources of uncertainty of a forecast from a model: uncertainty due to (1) the error terms, (2) the coefficient estimates, (3) the exogenous variables and (4) the possible misspecification of the model. Uncertainty from the error terms and coefficient estimates can be estimated using stochastic simulation. From the estimation of the model one has estimates of the covariance matrix of the error terms and the covariance matrix of the coefficient estimates. Given these estimates and given an assumption about the functional form of the distributions, such as normality, one can draw error terms and coefficients. For a given set of draws the model can be solved and the predicted values of the endogenous variables recorded. This is one trial. Many trials can be performed, and after, say, J trials, one has J predicted values of each endogenous variable for each period of the forecast. From the J values one can compute the mean of the forecast and the variance of the forecast error.

In order to account for exogenous-variable uncertainty, one needs some assumption about the uncertainty itself. One polar assumption is that the exogenous variables are in some sense as uncertain as the endogenous variables. One might, for example, estimate autoregressive equations for each exogenous variable and add these equations to the model. This would produce a model with no exogenous variables, which could then be tested. The other polar assumption is that there is no uncertainty attached to the exogenous variables. This might be true of some policy variables. I have generally worked with an in-between case, where I estimate an autoregressive equation for each exogenous variable and use the estimated variance from this equation as an estimate of the variance of the exogenous-variable forecast error. I the use these estimated variances and the normality assumption to draw values for the exogenous variables. Each trial of the stochastic simulation thus consists of draws of the error terms, coefficients and exogenous variables.

Estimating the degree of misspecification of the model is based on a comparison of two estimated forecast-error variances. One is the stochastic simulation estimate; the other is the square of the outside-sample forecast error. If the model is correctly specified, the expected value of the difference between the two estimates is zero (ignoring simulation error). If one has data mined in an inappropriate way and the model is misspecified, one would expect the stochastic simulation estimate to be smaller than the estimate

from the outside-sample error. The expected value of the different is thus likely to be positive for a misspecified model. By repeated re-estimation and stochastic simulation of the model, where one observation is added at the end of the sample period for each estimation, the expected value of the difference between the estimated variances can be estimated. The differences are then estimates of the degree of misspecification of the model.

The final estimated forecast-error variance for each variable for each period is obtained by adding the estimated difference to the stochastic-simulation estimate that is based on draws of the error terms, coefficients and exogenous variables. This estimated variance has accounted for the four main sources of uncertainty of a forecast, and it can be compared across models. Speaking loosely, each model is on an equal footing for comparison purposes. If one model has smaller estimated variances than another, this is evidence in favour of the model. Autoregressive and vector autoregressive models are useful for comparison purposes. Estimated variances of a structural model can be compared to those of an autoregressive or vector autoregressive model. If the estimated variances of the structural model are in general larger after taking all the sources of uncertainty into account, this is a cause of some concern.

The Lucas Critique and the Estimation of Deep Structural Parameters

The theory that is used to guide the specification of econometric equations in what I am calling the traditional approach is generally based on some implicit objective function that is being maximized. The parameters of the objective function are not, however, directly estimated. The parameters of the derived-decision equations are estimated instead, where the estimated parameters are combinations of the parameters of the objective function, the parameters of expectation-formation mechanisms, and other things. A problem with estimating combinations is that if, say, one wants to examine the effects of changing an exogenous variable or a policy rule on the decision variables, there is always the possibility that this change will change something in the combinations. If so, then it is inappropriate to use the estimated-decision equations, which are based on fixed estimates of the combinations, to examine the effects of the change. This is the point emphasized by Lucas (1976) in his critique of macroeconometric models.

Lucas's critique has led to a line of research concerned with estimating parameters of objective functions, which are sometimes called 'deep' structural parameters. These parameters, which are primarily taste and technology parameters, are assumed not to change when policy rules and exogenous variables change, and so one can use them and the associated model to examine the effects of policy changes. The approach is appealing in this sense, although many restrictive assumptions are involved in setting up the estimation problem, such as the specification of a particular form for the objective function. It is too early to know how useful this approach will be in practice.

If the approach of estimating deep structural parameters turns out not to lead to econometric models that are good approximations, this does not invalidate Lucas's critique. The critique is a logical one. If parameters that are taken to be constant change when policy changes, the estimated effects of the change are clearly in error. The key question for any experiment with a model is the likely size of the error. There are many potential sources of error, and even the best econometric model is only an approximation. One of the most important sources of error in my view is the use of aggregate data. As the age and income distributions of the population change, the coefficients in aggregate equations are likely to change, and this is a source of error in the estimated equations. This problem may be quantitatively much more important than the problem raised by Lucas.

One encouraging feature regarding the Lucas critique is the following. Assume that for an equation or set of equations the parameters change considerably when a given policy variable changes. Assume also that the policy variable changes frequently. In this case the method discussed in section "Testing" is likely to reject a

model that includes this equation or set of equations. The model is obviously misspecified, and the method should be able to pick up this misspecification if there have been frequent changes in the policy variable. One may, or course, still be misled regarding the Lucas critique if the policy variable has changed not at all or very little in the past. In this case the model will still be misspecified, but the misspecification has not been given a change to be picked up in the data. One should thus be wary of drawing conclusions about the effects of seldom-changed policy variables unless one has strong reasons for believing that the Lucas critique is not quantitatively important for the particular policy variable in question.

Models with Rational Expectations

In the past few years research has begun on macroeconometric models with rational expectations. Consider a model in which some of the explanatory variables are expected future values. In particular, assume that y^e_{t+1} appears as an explanatory variable in the first equation, where y^e_{t+1} is the expected value of y for period $t + 1$ based on information through period $t - 1$. In the utility-maximization model in section "A Brief History", the equation being estimated might be a consumption equation and y might be the wage rate. If expectations are assumed to be rational in the sense of Muth (1961), then the value of y^e_{t+1} is equal to the model's prediction of y for period $t + 1$. In other words, the expectation of a variable is equal to the model's prediction of it. Under the assumption of rational expectations, agents know the model and use it to generate their expectations. Agents are obviously assumed to be much more sophisticated in this case than they are in the case in which expectations of a variable are simply a function of current and lagged values of the variable.

Models with rational expectations are more difficult to estimate and solve than are standard models. Two types of estimation methods have been proposed for these models. One is full-information maximum likelihood, FIML (Fair and Taylor 1983). This method accounts for all the restrictions that are implied by the rational-expectations hypothesis, including all cross-equation restrictions. Unfortunately, the method is expensive to use, and it is not currently computationally feasible for large non-linear models.

There are limited information alternatives to FIML. The main alternative is Hansen's (1982) method of moments estimator. Limited-information methods like Hansen's estimator are based on the assumption that agents form expectations rationally and that there is an observed vector of variables (observed by the econometrician), denoted Z_t that is used in part by agents in forming their (rational) expectations. The methods do not require for consistent estimates that Z_t include all the variables used by agents in forming their expectations. Limited-information techniques are not very expensive to compute, and they have been widely used in practice.

The solution of rational expectations models is more difficult than the solution of standard models because future predicted values affect present predicted values. In other words, one cannot solve for the present without knowing the future. The solution method that has come to be used (Fair and Taylor 1983) iterates on solution *paths*. One guesses paths for the future values of the expectations and then solves the model period by period, treating the paths as predetermined. This solution yields new paths for the future values of the expectations, and so the model can be solved again period by period, treating the new paths as predetermined. This then yields new solution paths, which can be used for a new period-by-period solution, and so on. Convergence is achieved when the solution paths on one iteration are within some prescribed tolerance level of the solution paths on the next iteration. This method turns out to work quite well in practice and is not that expensive.

Work is essentially just beginning on macroeconometric models with rational expectations, and no strong conclusions can as yet be drawn. Results are presented in Fair (1985) that provide only mild support for the use of more sophisticated expectational hypotheses than are traditionally used in model-building. More work, however, is clearly needed. It should be noted

finally that macroeconometric models with rational expectations in the sense described here do not necessarily satisfy the Lucas critique. Depending on the set up, the coefficients that are estimated in the stochastic equations are not necessarily deep structural parameters even if there are expected future variables among the explanatory variables.

Conclusion

Work in macroeconometrics has the advantage that new observations are continually being generated. The current range of disagreement in macroeconomics may be narrowed in the future as more data are generated and more tests performed. Whether this will happen and whether there will be a return to more academic research on macroeconometric models is hard to say. Academic research on models clearly peaked in the 1960s, and it may have reached a trough in the late 1970s or early 1980s. But trying to predict research cycles is probably more hazardous than trying to predict business cycles.

Macroeconomic Effects of International Trade

Reuven Glick

M

Abstract

International trade can affect the macroeconomy by helping to transmit disturbances from one economy to another and by muting or amplifying the impact of fiscal and monetary policies on economic activity. Representative open economy macro models are discussed, highlighting the role different theoretical features play in influencing the channels through which trade flows can have macro effects.

The field of open economy macroeconomics deals with the macroeconomic behaviour of economies that trade with each other. International trade can have macroeconomic effects by helping the transmission of disturbances from one economy to another as well as by affecting the impact of macroeconomic policies on economic activity. This article discusses several representative open economy macro models, highlighting the role different theoretical features play in influencing the channels through which trade flows can have macro effects.

Keynesian Framework

At its simplest level, international trade is linked to macroeconomic activity through the national income relation. Consider the Keynesian income–expenditure model of a small open economy, in which prices and the interest rate are given, foreign demand for exports is exogenous, and domestic output is determined by demand. With these assumptions, an exogenous increase in domestic expenditures raises domestic income and worsens the current account balance; however, income rises less than in a closed economy because of leakages from the income stream through imports and through saving. In contrast, an exogenous increase in foreign demand for domestic goods leads to an increase in both exports and domestic income. Because the increased direct demand for exports is only partially offset by the expansion of imports induced by higher income, the current account improves overall. The resulting rise in domestic output implies positive cross-country transmission of the foreign disturbance.

Income multiplier effects through changes in trade also characterize open economy extensions of the Keynesian framework, such as the classic Mundell–Fleming model. This model also takes prices as given, but allows the income effects of monetary stimulus and exogenous expenditure changes to take account of interest rate changes depending on the degree of international capital mobility and of exchange rate changes, which in turn depend on the exchange rate regime. With a flexible exchange rate regime, exchange rate changes affect the relative demand for domestic and foreign goods. Thus, for example, domestic monetary stimulus that reduces the interest rate, raises income, and creates an excess demand for foreign exchange also depreciates the domestic currency. If the Marshall–Lerner–Robinson condition is satisfied, that is, the sum of price elasticities of domestic and foreign demands for imports exceeds unity, then the lower relative price of domestic goods switches demand from foreign to domestic goods and raises the current account balance, causing domestic income to increase and foreign income to decrease. Accordingly, the domestic income multiplier effect of the monetary stimulus is augmented by the expenditure-switching effect of the exchange rate; in addition, the trade transmission effect of domestic monetary shocks to foreign income is negative.

In these models crucial parameters affecting transmission effects include the marginal propensity to import and the elasticity of trade with respect to the exchange rate. Thus, for example, an increase in the marginal propensity to import out of income lessens the multiplier effects of domestic policy stimulus.

New Open Economy Macro Models

New open-economy macroeconomic models (NOEM) integrate older fixed-price Keynesian

models of macroeconomic fluctuations with dynamic intertemporal analysis based on microeconomic foundations and optimizing agents. These models embed imperfect competition and short-run nominal rigidities in a general equilibrium framework and provide clear welfare criteria in the form of the utility of the representative consumer. They also assume that bond (but not equity) markets are integrated, providing a consumption-smoothing role for net trade flows via the current account. Thus, for example, a temporary productivity shock that raises domestic output induces higher saving and a temporary current account surplus (though with investment dynamics a current account deficit may result if the increase in investment exceeds the increase in saving).

In a seminal paper, Obstfeld and Rogoff (1995) use a two-country framework in which each country specializes in producing a subset of tradable goods, and domestic and foreign consumers have identical preferences over a basket of both domestic and foreign goods. They show that monetary shocks have a positive effect on domestic output and a negative transmission effect on foreign output, as in the Mundell–Fleming model. Because monetary stimulus depreciates the domestic currency, it lowers the domestic country's terms of trade, reduces the purchasing power of domestic residents and raises the purchasing power of foreign residents. This terms-of-trade effect makes foreign residents better off and domestic residents worse off, but not by enough to offset the domestic gains from greater output. A temporary current account surplus is generated as well via the intertemporal consumption-smoothing channel.

A key parameter in NOEM models is the elasticity of substitution between goods embedded in consumer preferences. Obstfeld and Rogoff assume that the elasticity of substitution between goods produced in the same country is the same as the elasticity of substitution between goods produced in different countries. Several papers show how the international transmission of shocks is affected by relaxing this assumption. Tille (2001) shows that, if the elasticity of substitution of domestic and foreign goods exceeds unity, the Marshall–Lerner–Robinson condition holds. In this case, a currency depreciation and decline in the terms of trade results in a large demand switch towards domestic goods and a rise in export revenue. Tille also shows that, if there is less substitutability between domestic and foreign goods across countries than within countries (the empirically more relevant case), the terms-oftrade effect of domestic monetary expansion may be large enough to lower domestic welfare (termed a 'beggar-thyself' effect), while raising foreign welfare. In contrast, greater fiscal expenditures on domestic output raise the domestic terms of trade and domestic welfare, while reducing relative demand for foreign goods and foreign welfare (a 'beggar-thy-neighbour' effect), particularly when domestic and foreign goods are poor substitutes.

Corsetti and Pesenti (2001) deal with the special case in which the elasticity of substitution between domestic and foreign goods is unity, implying constant expenditure shares on domestic and foreign goods. This specification implies that the current account is always in balance. The reason is that, with unit elasticity between domestic and foreign goods, an increase in the foreign price of foreign goods results in a proportionate decrease in the quantity of foreign demand for domestic goods, leaving expenditures on exports constant and the current account unaffected.

Other extensions to NOEM models that affect the transmission of policy include consumption bias for domestic over foreign goods (Warnock 2003), pricing-tomarket behaviour (Betts and Devereux 1998), and non-traded distribution services (Burstein et al. 2006).

International Real Business Cycle Models

The tendency of macro aggregates, such as output, to move together in different countries is well documented (Backus et al. 1992; Baxter 1995). Cross-country business cycle correlations depend on the interaction of common international shocks, country-specific shocks, and the transmission of these shocks between countries. An important question in international macroeconomics is how much these comovements reflect the transmission of shocks across borders through

international trade linkages. International real business cycle (IRBC) models analyse this issue within a dynamic general equilibrium framework based on microfoundations. Unlike NOEM models, these models typically assume flexible prices and complete markets, though more recent work has introduced price rigidity and incomplete asset markets.

On theoretical grounds, the effect of international trade links on the comovement of national business cycles is ambiguous. On the one hand, greater integration can increase intra-industry specialization and production-sharing because of low elasticity of substitution between intermediate inputs produced in different countries; in addition, it may allow demand shocks to propagate more easily across national borders, which may lead to a higher correlation of business cycles when countries trade more. On the other hand, greater trade integration can increase interindustry specialization if countries specialize more in the goods in which they have a comparative advantage in order to achieve gains from trade; this case, if industryspecific shocks are a dominant source of business cycle movements, may lead to a lower correlation of business cycles when countries trade more.

On balance, the empirical evidence suggests that the former effect dominates, and that countries with a lot of bilateral trade tend to have more synchronized business cycles (for example, Frankel and Rose 1998; Baxter and Kouparitsas 2005). However, since the early 1980s business cycle synchronization has not in fact increased among industrial countries despite increasing trade integration. Stock and Watson (2005) provide a partial explanation by showing that common international shocks experienced by G-7 countries have been smaller in the 1980s and 1990s than they were in the 1960s and 1970s. But they also show that cyclical comovements have increased for subgroups of countries, notably within Europe and North America. Burstein et al. (2005) construct a model that is consistent with this development in which trade between core countries and their periphery (for example, the United States and Canada) involves more production sharing than does trade between core regions (for example, the United States and Europe). Consequently, one should observe higher output correlations between core and peripheral countries than between core regions. IRBC models have been less successful in explaining the quantitative magnitude of the relation between trade intensity and the cross-country correlation of business cycles; that is, a given change in bilateral trade intensity generates a much smaller change in output correlations than is apparent in the data; this is referred to as the 'trade comovement gap puzzle' (Kose and Yi 2006).

The finding that greater trade intensity is associated with greater cross-country comovements in business cycles suggests that these comovements depend on policies that enhance international trade, such as lowering of trade barriers or reductions in exchange rate costs due to membership in currency unions. Frankel and Rose (2002) find that the positive effect of currency unions on trade in turn has a large effect on output in member countries. Since the main cost of joining a currency area is the cost of giving up monetary independence, this has the implication that a pair of countries with business cycles that are dissimilar *ex ante* (making the act of joining a currency union appear costly) might have more correlated business cycles *ex post* because the increase in trade stimulated by the currency union tends to synchronize business cycles.

Trade Frictions and Macro Models

The international tradability of goods depends not just on the degree of substitutability in consumption, but also on transport costs and other trade frictions. In fact, Obstfeld and Rogoff (2000) argue that introducing real trade costs helps explain a variety of puzzles in international economics, including the low crosscountry correlation of consumption (consumption correlations puzzle), the limited magnitude of current account imbalances (Feldstein–Horioka puzzle), international price discrepancies (purchasing power parity puzzle), and home bias in trade and asset holdings.

Taken to the extreme, trade frictions play a role in explaining why some goods may not be traded at all. While open economy macroeconomics by

definition analyses trade across national borders, the field has long found it useful to assume that a given exogenous set of goods is non-traded. This traded/non-traded distinction is essential to many well-known results in the field, such as the Balassa–Samuelson effect, which says that, as the productivity of traded goods rises relative to that of non-traded goods, there will be tendency for the real exchange rate to appreciate.

The international trade literature has explained non-tradedness as an outcome of trade frictions. For example, Dornbusch et al. (1977) show how a range of non-traded goods can arise in the presence of cross-country trade costs within a model in which differences in labour productivity across a continuum of goods determine the range of goods a country produces as well as the pattern of trade.

A growing field of international economics research tries to integrate models of trade and macroeconomics and treats the set of tradable goods not as exogenously given but rather as an endogenously determined characteristic of the analysis. Several authors (Ghironi and Melitz 2005; Bergin et al. 2006) formulate open economy macro models with monopolistic competition and heterogeneously productive firms, in which firms face fixed costs of selling in domestic and export markets, to explain phenomena such as the Balassa–Samuelson effect. Since only relatively more productive firms are profitable enough to engage in trade, they endogenously satisfy the precondition of the Balassa–Samuelson story that productivity gains are concentrated in the traded goods sector.

Loose Ends

International trade can influence macroeconomic activity through other channels. For example, as highlighted in endogenous growth models, technological progress may depend on incentives to undertake R&D and innovate, which, in turn, may depend on externalities or spillover effects from greater markets provided by international trade (Grossman and Helpman 1991). Greater openness to trade can also complicate the optimal conduct of monetary policy because of the impact of the exchange rate on real activity and inflation. Clarida et al. (2001) show how more openness to international trade can influence a central bank following an optimal policy feedback rule to raise the domestic interest rate more aggressively in response to inflation pressures. Lastly, trade may serve as a transmission channel through which financial crises may spread contagiously across countries (Glick and Rose 1999).

Macroeconomic forecasts are 'guesses' of the future values of important macroeconomic aggregates such as GDP, inflation, or the unemployment rate. These forecasts inform the decisions of business, policymakers, investors, and consumers. Macroeconomic forecasts are regularly constructed by government agencies and private companies. For example, every quarter the Bank of England publishes its *Inflation Report*, which contains forecasts of inflation over the next three years. Federal Reserve policymakers also rely on forecasts from the Green Book; however, unlike the Bank of England, the Fed does not release its forecasts to the public. The Federal Reserve Bank of Philadelphia summarizes private sector macroeconomic forecasts for the United States in its quarterly *Survey of Professional Forecasters*.

Macroeconomic forecasts are constructed using a variety of methods. These methods can be grouped into four categories: (1) leading indicator indexes; (2) structural econometric models; (3) time series models; and (4) judgement.

The origin of leading indicator indexes can be traced to the 1930s when, at the request of the US Secretary of the Treasury, Wesley Mitchell proposed a set of variables that historically had moved in anticipation of the business cycle. Averages of these leading indicators are an index of leading indicators. Such an index was constructed in the United States for several years by the Department of Commerce and is now maintained and published monthly by the Conference Board, which also publishes leading indicator indexes for several other countries.

Structural econometric models construct forecasts using dynamic relationships suggested by economic theory and estimated by statistical methods. Work on these models by Tinbergen, Klein and Haavelmo resulted in Nobel prizes for these researchers in 1969, 1980 and 1989

respectively. Large-scale structural models with hundreds of equations were developed in the 1960s and early 1970s, but forecast failures in the 1970s led researchers to question both the economic theory used in the models and the statistical procedures used to fit the models' equations. Refinements in theory (notably the importance of expectations and dynamic adjustment) and statistical methods (notably time series methods) are incorporated in the current generation of large-scale structural models. Currently, there is a significant research effort aimed at constructing small-scale structural models ('dynamic stochastic general equilibrium' models) for policy evaluation and forecasting.

Time series models use serial correlation (or persistence) in variables to construct forecasts. For example, a simple autoregressive model (AR) has the form $y_t = \alpha + \varphi y_{t-1} + \varepsilon_t$, where y_t is an economic variable of interest and ε_t is a zero-mean serially uncorrelated random shock. When φ is positive (negative), larger than average values of y_{t-1} tend to be associated with larger (smaller) than average values of y_t. Thus, an autoregressive forecast of y_{T+1} using data through time T is $y_{T+1|T} = \alpha + \varphi y_T$. Many macroeconomic variables display short-run dependence, and time series models typically produce more accurate short-run forecasts than other forecasting methods. Time series models have been developed to construct forecasts based on linear and nonlinear dependence properties in macroeconomic variables, and multivariate time series models, such as vector autoregressions (VARs), are widely used for short-horizon macroeconomic forecasting.

Professional forecasters also rely on judgement when constructing their forecasts. That is, while the macroeconomic forecasts published by the Bank of England or the Fed's Green Book forecasts rely on econometric models, the forecasts are not identical to model-based forecasts. Professional forecasters typically use judgement to adjust model-based forecasts. These adjustments – sometimes called 'add-factors' – allow forecasters (so they argue) to incorporate information that is not captured in the economic model. As an empirical matter, good judgement appears to improve the accuracy of model-based forecasts.

Much of the theory of forecasting can be derived from elementary concepts in probability theory. Let y_{T+1} denote the variable to be forecast and X_T denote a set of variables to be used for constructing the forecast. In general, X_T will include y_T, y_{T-1}, and longer lags, as well as current and lagged values of other series. Let $g(X_T)$ denote the forecast or 'guess' of y_{T+1} constructed from X_T, where good choices of $g(.)$ lead to more accurate forecasts. The forecast error is $e_{T+1} = y_{T+1} - g(X_T)$, and accuracy can be measured by mean squared forecast error (MSFE), where the conditional $\text{MSFE} = E\left(e_{T+1}^2 | X_T\right)$. A fundamental result from probability theory is that $E\left(e_{T+1}^2 | X_T\right)$ is minimized using $g(X_T) = E(y_{T+1}|X_T)$; that is, the regression (conditional expectation) produces the minimum mean squared forecast error.

A key implication of this theoretical result is that more information is always better – that is, it never hurts to include more variables in X_T, and the information in these additional variables will often reduce the MSFE. But, this result assumes that the regression function $E(y_{T+1}|X_T)$ is known, and in practice this function must be estimated using sample data. Including many variables in X_T means that many parameters must be estimated to characterize the regression function, and estimating a large number of parameters leads to statistical estimation error that increases the MSFE. This trade-off between including more variables in X_T to capture more information about y_{T+1} and the increased statistical error associated with estimating additional parameters for the forecasting model is one of the major practical problems in forecasting.

Another major problem is the temporal stability of the forecasting model. That is, the regression $E(y_{T+1}|X_T)$ might change over time, so that a regression estimated using past data might provide poor forecasts for future values of y_T. These two problems – developing methods for forecasting using many past variables and problems associated with instability – are active areas of current research. The relevant chapters in Elliott et al. (2006) summarize current research on these and other important topics in economic forecasting.

Macroeconomics, Origins and History of

Robert W. Dimand

Abstract

Macroeconomics, the analysis of economic aggregates, became a recognized field with Keynes's *General Theory* (1936) and its mathematical and diagrammatic reformulations, and the macroeconometric modelling pioneered by Tinbergen and Frisch. Macroeconomics grew out of two long-standing traditions: business cycle analysis from Jevons and Juglar to Mitchell, and monetary theory, building on the work of Hume, Thornton, Ricardo, Wicksell, and Fisher, supplemented by the circular flow analysis of Quesnay and Marx.

Macroeconomics analyses a whole economy or economies, dealing with aggregate output and employment, the price level and interest rate, rather than with the prices or quantities of particular commodities. It became a recognized field as textbooks and course offerings responded to John Maynard Keynes's *General Theory of Employment, Interest and Money* (1936; 1971–89, vol. 7), to the mathematical and diagrammatic reformulations of Keynes by David Champernowne, Brian Reddaway, Roy Harrod, J. R. Hicks, James Meade, Oskar Lange, Mabel Timlin and Franco Modigliani (Hicks 1937; Young 1987), and to the first aggregate econometric models such as Tinbergen (1939). Ragnar Frisch (1933) introduced the terms 'macrodynamics' and 'macroanalysis', and his distinction between macroanalysis and microanalysis is the same as the subsequent distinction between macroeconomics and microeconomics. Michal Kalecki (1935) first used 'macrodynamic' in a title, and by the time that Lawrence Klein (1946) used 'macroeconomics' in the title of a journal article, he presumed that its meaning would be clear to his readers. But just as Molière's *bourgeois gentilhomme* spoke prose long before he knew he was doing so, economists wrote macroeconomics long before they called it by that name. Macroeconomics grew out of two long-standing traditions within economics: business cycle analysis and the theory of money.

Macroeconomic Themes in Pre-classical and Classical Political Economy

The quantity theory of money is the oldest surviving theory in economics, yet remained, in David Laidler's (1991a) phrase, 'always and everywhere controversial' (primarily over whether changes in the quantity of money are exogenous or endogenous). Holding that a change in the money supply will ultimately change prices in the same proportion, the quantity theory was first used in the 16th century by Martin Navarro de Azpilcueta (writing in Latin as Navarrus) and other scholastics at the University of Salamanca (Grice–Hutchinson 1952), and then by Jean Bodin in France, to explain the 'Price Revolution', the inflation following the inflow of silver from the Spanish colonies in the New World. John Locke, Richard Cantillon and Isaac Gervaise contributed to understanding the velocity of circulation and the adjustment of international payments (Vickers 1959). The economic essays in David Hume's *Political Discourses* (see Hume 1752) mark a high-point of pre-classical monetary economics (see Humphrey 1993). Hume's analysis of the specie-flow mechanism of adjustment under the gold standard showed that an increase in the quantity of gold in one country would increase prices and spending in that country, causing a trade deficit and gold inflow until balance of payments of equilibrium was restored with the world's gold distributed among countries in proportion to their demand for real money balances. Hume's specie-flow mechanism provided a crushing rejoinder to mercantilist schemes for increasing the amount of gold in a country by promoting exports and restricting imports. Such tariffs, quotas and subsidies would distort resource allocation without producing a lasting trade surplus, and would raise prices rather than the real wealth of a nation. Hume recognized that an increased money supply would provide a temporary stimulus to real output, which would fade as prices and wages adjusted. While Hume linked each country's price level to that country's money stock and emphasized relative price effects on trade balances, his younger contemporary and friend

Adam Smith anticipated the monetary approach to the balance of payments by assuming purchasing power parity (with the world price level set by the world gold stock and world demand for real money balances) with adjustment taking place, not through relative price changes, but through the direct effect of a nation's excess demand for or supply of money on spending, hence on the balance of payments and on the country's stock of gold.

Keynes's *General Theory* revived interest in the debate in the years after the Napoleonic Wars about the possibility of a general glut of commodities. Keynes deplored the victory of David Ricardo's sharper analysis and endorsement of Say's (or James Mill's) Law of Markets over what Keynes regarded as Thomas Robert Malthus's deeper (but fuzzier) insight that insufficient effective demand could result in an excess supply of labour without an excess demand for any good (other than money). Malthus's insight was obscured by his failure to distinguish between a decision to save and a decision to invest, and hence to see the significance of hoarding. Statements of the Law of Markets by classical economists were more varied and complex, often subtler, and sometimes confused and contradictory than Keynes suggested in short quotations from the classics, which sometimes misled when taken out of context (see Link 1959; Corry 1962, on the macroeconomics of English classical economists and their critics, and Sowell 1972, on Say's Law). John Stuart Mill and others searched for a statement of the Law of Markets that would be the stronger truism that Oskar Lange later labelled as Say's Equality (if each and every commodity market is in equilibrium, then the sum of excess demand over all commodity markets much add to zero) but weaker than what Lange called Say's Identity, that excess demand for all commodity markets (that is, all markets except money) always sums to zero for any set of prices, regardless of whether any individual market is in equilibrium. Say's Identity, taken together with the adding up of budget constraints that Lange termed Walras's Law, implies that the money market always clears for any prices, leaving the absolute level of prices indeterminate. The policy implications that classical economists drew from their analysis are also more varied and pragmatic than the later textbook caricature: Jean-Baptiste Say recommended public works as a temporary response to unemployment during periods of adjustment, and criticized Ricardo for ignoring the possibility that savings might be hoarded if investment opportunities were inadequate. Ricardo, whose economic writings had begun with a pamphlet arguing that the premium on bullion demonstrated the wartime overissue and depreciation of inconvertible banknotes, was willing after the end of the war to support restoration of gold convertibility at the depreciated parity, rather than deflation to restore the pre-war parity. Henry Thornton (1802) introduced the concept of the central bank as the lender of last resort to support solvent but illiquid banks against bank runs. The proper role, if any, of the Bank of England generated prolonged controversy among the Banking, Currency, and Free Banking Schools in the first three quarters of the 19th century, producing analyses of lasting significance for monetary economics (Smith 1936; Fetter 1965).

François Quesnay's *Tableau Economique,* the crowning achievement of Physiocratic economics in France at the time of Hume and Smith, represented the circular flow of income and spending. It was not taken up by the mainstream of British and French classical political economy, but, a century after Quesnay, the *Tableau Economique* inspired Karl Marx's schemes of simple and expanded reproduction in the second volume of *Capital* (published posthumously in 1885), relating output and reinvestment rates in Department I (capital goods) and Department II (wage goods). For decades, this pioneering two-sector growth model was used only by Marxist economists such as Rosa Luxemburg and Otto Bauer constructing models of the supposed inevitable breakdown of capitalism, and then in 1928 by G. A. Fel'dman, proposing a growth theory for a planned economy. Fel'dman's articles were part of a false dawn of modern growth theory, appearing in the same year as the December 1928 issue of the *Economic Journal* that contained Allyn Young on increasing returns and

economic progress (inspired by Adam Smith) and Frank Ramsey's application of calculus of variations to optimal capital accumulation by a representative agent, but by 1930 Young and Ramsey were dead and Fel'dman had vanished in Stalin's purges (see Fel'dman, Ramsey and Young in Dimand 2002, vol. 3, and Bauer in vol. 5). Neoclassical hostility to Marx's theory of value and exploitation led to neglect of his contribution to growth theory, just as classical rejection of the Physiocratic doctrine of the exclusive net productivity of agriculture diverted attention from the circular flow. Marx also analysed the cyclical fluctuation of the profit rate around a downward trend, with cyclical troughs in the profit rate causing layoffs that force down wages by swelling the reserve army of the unemployed and cyclical peaks in the profit rate leading to realization crises as redistribution away from wages reduces demand for output (since Marx rejected Say's Law). However, his analysis of the increasing severity of crisis (as of the downward trend of the profit rate) was conducted within the special terminology and assumptions of his labour theory of value, which limited its influence on the mainstream of economics.

Business Cycles

Recognition of the more or less periodic recurrence of crises and prosperity goes back at least to Thomas Tooke's discussion in 1823 of 'waves' in prices (Arnon 1991), the beginning of the vast literature on cyclical fluctuations most conveniently sampled in the multi-volume anthologies of O'Brien (1997), Hagemann (2001), and Boianovsky (2005) and in the encyclopedia of Glasner (1997). Clément Juglar (1862) and W. Stanley Jevons (1884, collecting essays written from 1862 to 1882) advanced the analysis of economic fluctuations as periodic oscillations to a higher level, surpassing earlier descriptive and classificatory works (such as Max Wirth's *Geschichte der Handelskrisen* in 1858) and displacing the perception of crises as the result of occasional events. Jevons built upon Hyde Clarke's 1847 suggestion of a meteorological cause for the recurrence of crises every ten years or so (Hyde Clarke also perceived multiple, overlapping cycles, including a longer period of 54 years, anticipating Kondratiev). Jevons's sunspot theory of the trade cycle has so fallen out of favour that the term 'sunspots' in now used in the field of business cycles to refer to any intrinsically irrelevant variables (and even the term 'business cycles' is no longer taken to imply that fluctuations are in fact periodic cycles). This is unfair to Jevons, who was following the accepted meteorology of his era, which held that the cycle in solar activity affected weather. Cycles in weather would affect harvests, which, in a still largely agricultural world economy, would affect all economic sectors. Jevons's sunspot theory, together with his warnings about the impending exhaustion of coal, did much more than his marginal utility analysis of relative prices to persuaded the British Association for the Advancement of Science that economics was sufficiently scientific for Section F to remain in the Association. Nonetheless, as Wesley Mitchell (1927, p. 384) remarked,

> Jevons had an admirably candid mind; yet in 1875, when the sun-spot cycle was supposed to last 11.1 years, he was able to get from Thorold Rogers' *History of Agriculture and Prices in England* a period of 11 years in price fluctuations, and when the sun-spot cycle was revised to 10.45 years he was able to make the average interval between English crises 10.466 years.

Jevons was misled by the belief that an economic cycle must have a cause that is itself cyclical, but, as Knut Wicksell put it, the motion of a rocking horse does not resemble the motion of the stick that started it rocking (cited by Frisch 1933). Jevons's sunspot theory has distracted attention from such lasting contributions as the seasonal cycle (in his essay on the annual autumnal pressure on the Bank of England) and his use of index numbers to trace the effects of the Australian and California gold discoveries.

Wesley Mitchell (1913, 1927) was the leading figure in the statistical approach to business cycle analysis. In 1920, Mitchell founded the National Bureau of Economic Research (NBER), which was the model for institutes of business cycle or conjuncture research in Berlin, Vienna (directed

first by Friedrich Hayek and then by Oskar Morgenstern), Belgium, Sofia, Moscow (directed by Nikolai D. Kondratiev, the theorist of long waves), and Warsaw (where Kalecki worked), Britain's National Institute of Economic and Social Research, and the Institute of World Economics in Kiel. Although his Columbia lectures on types of economic theory were famous, Mitchell was sceptical about taking any single explicit economic theory, such as the quantity theory of money or utility maximization, as a starting point, as he felt that many of the theories surveyed in Mitchell (1927) captured something of the truth, but none the whole truth. Mitchell was influenced by his teacher at the University of Chicago, the institutionalist Thorstein Veblen (1904), who coined the term 'neoclassical' to describe the sort of Marshallian economics of which he disapproved. Mitchell and Arthur F. Burns (his successor directing the NBER) concentrated on investigating the statistical properties of time series, looking for patterns of leads and lags and for superimposed cycles of different periods and amplitudes. The widely reported index of leading indicators continues the original NBER approach.

Sir William Beveridge, director of the London School of Economics, used the periodogram, an early version of spectral analysis, to decompose wheat prices into 19 cycles with periods varying from 2.735 years to 68 years (Beveridge 1921, 1922). Finding so many cycles led sceptics, such as Harvard statistician E.B. Wilson, to wonder whether there were any truly periodic oscillations in economic time series (apart from seasonality), since with enough cycles any series could be represented as a summation of cycles. Eugen Slutsky (1937, originally published in Russian in 1927), used a moving average of the last three digits of the winning Moscow lottery numbers to show that summation of random series could produce apparent cycles. Slutsky (1937) and Frisch (1933) influenced economists to consider fluctuations as oscillatory responses to random shocks (real or monetary), turning away from the emphasis of Jevons, Juglar, Mitchell, Beveridge and Kondratiev on underlying cycles. Cowles Commission director Tjalling Koopmans (1947) denounced Burns and Mitchell's *Measuring Business Cycles* (1946) as 'Measurement without Theory', and argued instead for simultaneous equation macroeconometric models, with the equations identified by exclusionary restrictions derived from a priori economic theory. Koopmans's Chicago colleague Milton Friedman (whose Columbia dissertation had been supervised by Burns) responded by writing down a formal model representing Mitchell's business cycle analysis (Friedman 1952, Section III and Appendix, pp. 257–82). The vector autoregressions (VAR) of Christopher Sims (1980) marks a return (with more modern statistical techniques) to the NBER approach of investigating the statistical properties of macroeconomic time series with only limited reliance on a priori restrictions drawn from theory.

1886 and All That: The Dawn of Modern Monetary Macroeconomics, 1886–1914

Around 1886, during a period of depression, analysis of cycles and crises acquired a new emphasis on fluctuation of employment as the problem and variations in the general price level as a preventable cause. Carroll Wright (1886) devoted his first annual report as US Commissioner of Labor to a statistical study, *Industrial Depressions*, finding such depressions to be largely contemporaneous across manufacturing nations and advocating profit-sharing to mitigate the severity of fluctuations (a proposal independently rediscovered nearly a century later by Martin Weitzman). In the same year, Britain had a Royal Commission on the Depression of Trade and Industry, chaired by Lord Iddesleigh (Stafford Northcote) and including Professor Bonamy Price of Oxford but most notable for the evidence of Professor Alfred Marshall of Cambridge. In his evidence to that inquiry and to the Gold and Silver Commission of 1887–8 (both reprinted in Marshall 1926, edited by Keynes), and in a paper to the Industrial Remuneration Conference of 1885, Marshall considered how far remediable causes adversely affect continuity of employment. This led him to suggest 'Remedies for Fluctuations of General Prices' in the *Contemporary Review* in March 1887 (reprinted in Pigou

1925), revising Ricardo's ingot plan to make the monetary unit a claim on a fixed weight of gold plus a fixed weight of silver, a step toward pegging the monetary unit to a basket of commodities (Irving Fisher's compensated dollar). This symmetallism proved incomprehensible to bimetallists, who persisted in plans that would require pegging the relative price of gold and silver. Also in 1886 (two years after writing the introduction to the posthumous collections of Jevons's *Investigations in Currency and Finance),* Herbert Foxwell published a lecture on *Irregularity of Employment and Fluctuations of Prices* (in Dimand 2002, vol. 1). Like his colleague Marshall (both were fellows of St John's College, Cambridge), Foxwell emphasized fluctuations in employment as the crucial challenge posed by economic instability, and argued that the problem 'How to secure greater industrial stability' could be reformulated as 'How to diminish price fluctuations'. A young Swedish student named Knut Wicksell attended Foxwell's lectures at University College London in 1886. As Wesley Mitchell (1927, p. 7) observed, 'Before the end of the nineteenth century there had accumulated a body of observations and speculations sufficient to justify the writing of histories of the theories of crises': Eugen von Bergmann's *Die Wirtschaftskrisen: Geschichte der nationalökonomischen Krisentheorien,* published in Stuttgart in 1895, and E. D. Jones's *Economic Crises,* published in New York in 1900 (see also Barnett 1941). In 1909, the year of Beatrice and Sidney Webb's Minority Report of the Poor Law Commission and of the first edition of Beveridge's *Unemployment,* the London School of Economics published a 71-page bibliography of unemployment and the unemployed by F. Isabel Taylor.

The cover of David Laidler's *The Golden Age of the Quantity Theory* (1991b) shows the three economists who dominated monetary economics before the First World War, making the case for monetary shocks and imbalances as the avoidable source of fluctuations: Alfred Marshall, Knut Wicksell and Irving Fisher.

In *Interest and Prices* in 1898 and then in his *Lectures on Political Economy* (1915), Wicksell distinguished the market rate of interest, set by the banking system, from the natural rate, the interest rate at which desired saving and investment would balance and the price level would not change. If a technical innovation raises the natural rate, or the banking system lowers the market rate, it will be profitable for entrepreneurs to borrow for new investment projects as long as the natural rate exceeds the market rate, causing (in a pure credit economy with no cash drain) a cumulative inflation. If the market rate exceeded the natural rate, a cumulative deflation would ensue. Although he considered himself a quantity theorist following in the footsteps of Ricardo, Wicksell was a pioneer in analysing a pure credit economy, not anchored by gold or other base money, which is why Michael Woodford deliberately chose Wicksell's title *Interest and Prices* for his 2003 treatise analysing a world in which financial innovation has greatly reduced the role of cash and bank reserves. Wicksell's economic contributions (which included using what came to be called the Cobb–Douglas production function four years before Cobb and Douglas) were continued by a Stockholm School including Dag Hammarskjold, Karin Kock (1929), Erik Lindahl (1939), Erik Lundberg (1937), Gunnar Myrdal (1939) and Bertil Ohlin – a list including three Nobel laureates (two in economics, one in peace) and four Swedish cabinet ministers. The Stockholm economists later expressed confidence that, even if Keynes had never written *The General Theory*, they would have discovered it themselves, but Don Patinkin (1982) expressed doubt, because the focus of Wicksell's heirs was on price dynamics, not the equilibrium level of employment and national income. Keynes's earlier *Treatise on Money* in 1930 (1971–89, vols. 5 and 6) was much more Wicksellian than *The General Theory* in its emphasis on cumulative inflation or deflation when the interest rate does not equate planned investment to planned saving.

J. Bradford De Long (2000) writes:

> The story of 20th century macroeconomics begins with Irving Fisher. In his books *Appreciations and Interest* (1896), *The Rate of Interest* (1907), and *The Purchasing Power of Money* (1911) [Fisher 1997, vols. 1, 3, and 4], Fisher fueled the intellectual fire that much later became monetarism. To understand the determination of prices and interest rates and the course of the business cycle, monetarism holds,

M

> look first (and often last) at the stock of money – at the quantities in the economy of those assets that constitute readily spendable purchasing power. . . . It is true that the ideas that we see as necessarily producing the quantity theory of money go back to David Hume, if not before. But the equation-of-exchange and the transformation of the quantity theory of money into a tool for making quantitative analyses and predictions of the price level, inflation, and interest rates was the creation of Irving Fisher.

In *Appreciation and Interest,* Fisher argued that the difference between interest rates expressed in two standards (money and commodities, gold and silver, dollars and francs) is the expected rate of appreciation of one standard in terms of the other, deriving from this uncovered interest parity between two countries, the expectations theory of the term structure of interest rates, and the Fisher relation that nominal interest is the sum of real interest and expected inflation (plus a cross-product term). In *The Rate of Interest,* Fisher introduced the Fisher diagram, showing the optimal smoothing of consumption over two periods (assuming perfect credit markets) and an individual's saving or dissaving in each period. In *The Purchasing Power of Money*, Fisher (with his former student Harry G. Brown) upheld the quantity theory both against bimetallists who predicted permanent real benefits from expanding the money supply and against hard-money opponents of bimetallism (notably J. Laurence Laughlin of the University of Chicago), who denied the path of US prices could be explained by changes in the money supply. Fisher and Brown explained economic fluctuations by the slow adjustment of nominal interest to monetary shocks during 'transition periods' (lasting perhaps ten years), so that fluctuations could be avoided either by educating the public against what Fisher later termed 'the money illusion' (so that expected inflation and hence nominal interest would adjust to monetary shocks, leaving real interest unaltered) or by a monetary policy rule of varying the exchange rate (the dollar price of gold) to hold constant a price index (for which Fisher later proposed the Fisher ideal index, the geometric mean of the Paasche and Laspeyres indexes). Fisher's 1926 article, 'A statistical relation between unemployment and price changes' (in Fisher 1997, vol. 8), correlated unemployment with a distributed lag of past price level changes (as a proxy for expected inflation), and was reprinted in the *Journal of Political Economy* in 1973 under the heading 'Lost and Found: I Discovered the Phillips Curve – Irving Fisher'. Unlike Marshall in Cambridge and Wicksell in Stockholm, Fisher did not attract a school of disciples at Yale. Through his role in establishing the Econometric Society and the Cowles Commission, Fisher advanced his preferred economic methodology of formal theorizing using mathematical and statistical techniques, but his contributions to monetary economics and economic fluctuations (like those of Hayek, Hawtrey, and many others) were long overshadowed by Keynes's *General Theory,* notwithstanding Keynes's acknowledgement of Fisher as his intellectual great-grandparent in appreciating the real effects of monetary changes.

Although Alfred Marshall's *Money, Credit and Commerce* was not published until 1923, the year before his death, parts of it were drafted as early as the 1870s, and his ideas had long circulated through his lectures, his evidence to official inquiries (gathered by Keynes in Marshall 1926), and the 'Cambridge oral tradition' of monetary theory (Eshag 1963; Bridel 1987; Laidler 1999). Marshall, his professorial successor A. C. Pigou, Pigou's successor D.H. Robertson (1926), the young J.M. Keynes, and Cambridge economics lecturers Frederick Lavington and J.R. Bellerby used a cash balance version of the quantity theory, relating the number of units of purchasing power the public wished to hold as cash to the level of income (in contrast to Fisher's logically equivalent version, which expressed the quantity theory in terms of the velocity of circulation of money).

Departure from the gold standard during the First World War and the post-war central European hyperinflations provided the occasion for the highest achievement of Marshallian monetary economics, Keynes's *Tract on Monetary Reform* in 1923 (Keynes 1971–89, vol. 4), an innovative work but one that innovated within the tradition established by Marshall. Keynes analysed inflation as a form of taxation of real money balances, identified as a social cost the consequent reduction in desired holdings of real money balances (M/P),

and introduced covered interest parity (the spread between forward and spot exchange rates equals the difference between interest rates in the two currencies). Keynes calculated that real money balances had fallen by 92 per cent during the German hyperinflation, as a result of the soaring opportunity cost of holding money. Others had mistakenly argued that since the price level (P) was rising faster than the money supply (M), monetary expansion could not be the cause of the price inflation, and the Reichsbank president Rudolf Havenstein promised that, with 38 new high-speed printing presses, the Reichsbank would be able to print enough money to catch up with the prices. Robertson (1926), then collaborating closely with Keynes, examined forced saving ('induced lacking' in Robertson's terminology) caused by inflation. Turning from inflation to deflation, Keynes wrote *The Economic Consequences of Mr. Churchill* (in Keynes 1971–89, vol. 9) to oppose Britain's return to the gold standard at the pre-war parity in 1925, arguing that restoration of the pre-war parity would require a reduction of prices and money wages that could be achieved only through prolonged unemployment (see June Flanders 1989, on the development of international monetary economics).

Keynesian Revolution and Monetarist Counter-Revolution

The Great Depression of the 1930s helped provide a receptive audience for John Maynard Keynes's *General Theory of Employment, Interest and Money* (1936; 1971–89, vol. 7), which argued that involuntary unemployment could persist unless the government intervened with appropriate management of aggregate demand (Clarke 1988; Dimand 1988; Backhouse 1995). *The General Theory* challenged Lionel Robbins and Friedrich Hayek of the London School of Economics, who argued against expansionary fiscal and monetary policy and for letting the depression take its course, and William Beveridge, who held (until his conversion to Keynesianism) that the existing level of British unemployment could be fully accounted for by structural, frictional, and seasonal unemployment without invoking any deficiency of aggregate demand. To the rising generation of new economists, from Harvard students Paul Samuelson and James Tobin to LSE economists Abba Lerner and Nicholas Kaldor, Keynes offered a message of hope that depressions were curable and preventable without adopting a Soviet-style centrally planned economy. Attempts to dismiss or ignore Keynes (Burns and Mitchell 1946, mentioned Keynes in one sentence, in a footnote) were futile. Keynes provided an agenda for economists providing public policy advice and a framework for empirical, policy-oriented modelling, at a time when depression and war greatly expanded the role of governments.

Keynes's success in winning over the next generation of economists obscured the extent to which his contemporaries in economics shared his policy views rather than those of Robbins and Hayek: although Keynes used Pigou (1933) as the target of his attack on classical theory, he recognized how close they stood on practical policy. Even Ralph Hawtrey, the Treasury economist associated with the 'Treasury view' about crowding out and the ineffectiveness of fiscal policy, was convinced of the effectiveness of (and need for) stabilizing monetary policy (and contributed intriguing numerical examples to the development of the Kahn–Keynes spending multiplier; see Hawtrey 1932). Keynes's caricature in *The General Theory* of 'classical economists' from Ricardo to Pigou as upholders of a rigid version of Say's Law, denying any role to aggregate demand in explaining unemployment (in contrast to the superior insight but fuzzier analytics of mercantilists, Malthus, and the underconsumptionists Hobson and Mummery), was more widely noted than his subsequent clarification that he did not consider Fisher or Hawtrey or Robertson or Wicksell as classical. However, support for expansionary fiscal or monetary policy during the Depression did not necessarily imply anticipation of Keynesian economics: proposals circulated for emergency public works financed by cutting other government spending and for domestic monetary expansion while keeping the exchange rate fixed, and in the United

States the New Deal's National Recovery Administration was an attempt to raise price toward pre-Depression levels by restricting supply, rather than by stimulating demand. Keynes provided a framework within which the implications of such policies could be analysed. Independently of Keynes, starting from Marx and Rosa Luxemburg, Michal Kalecki in Poland developed a theory very close to Keynes's income–expenditure analysis, and in 1934 published in Polish a three-equation model of goods market equilibrium, money market equilibrium and aggregate supply. Patinkin (1982) argued that Kalecki was concerned with the dynamics of cyclical fluctuations, Keynes with determining the equilibrium level of income that equates saving to desired investment, and that Kalecki's 1934 essay (which Kalecki did not choose to be translated among his selected articles in 1966 and 1971, or refer to in other works) was not part of his central message.

The analytical framework that dominated macroeconomics for at least a quarter century after the Second World War was based on Keynes's aggregate supply and aggregate demand functions (generally with more attention to aggregate demand than to aggregate supply) and the small system of simultaneous equations behind the Hicks–Hansen IS/LM diagram, which included Keynes's money demand function (liquidity preference) and later substitutes for his consumption function (De Vroey and Hoover 2004). The system of equations representing Keynes's message in a form equivalent to IS/LM was a four-equation model in Keynes's Cambridge lectures in December 1933, attended by David Champernowne and Brian Reddaway, the first economists to use such a model in print, but Keynes did not include it in *The General Theory,* perhaps following Marshall's advice to use mathematics as a tool of inquiry but to then translate the analysis into English and burn the mathematics (Rymes 1989; Dimand 1988). The resulting framework (extended to open economies by Robert Mundell and J. Marcus Fleming in the 1960s) did not capture all of Keynes's message (or messages), notably his distinction between fundamental uncertainty and insurable risk. Econometric estimation of macroeconomic models was pioneered, independently of Keynes, by Ragnar Frisch, Jan Tinbergen and Trygve Haavelmo (and Keynes's review of the first volume of Tinbergen 1939, expressed severe scepticism), but it was taken up with enthusiasm by such Keynesians as Lawrence Klein. The claim in Chapter 2 of *The General Theory* that real and money wages move in opposite directions over the course of the cycle (and by implication, that real wages vary countercyclically) was challenged empirically by John Dunlop and Lorie Tarshis and on theoretical grounds by Michal Kalecki, leading Keynes in 1939 to acknowledge the cyclical pattern of real wages as an open question, which it remains to this day.

Milton Friedman and his students (Friedman 1956) offered a renewed quantity theory of money as a challenge to Keynesianism, claiming to follow a Chicago oral tradition of monetary theory. Certainly it drew on such Chicago landmarks as Henry Simons's 1936 argument for rules rather than authorities in monetary policy (reprinted in Simons 1948), but the intellectual inheritance from non-Chicago quantity theorists such as Irving Fisher and Clark Warburton (and even the young Keynes of *A Tract on Monetary Reform)* gradually came to be recognized. As Patinkin (1981) noted, a key element of Friedman's approach, the demand for money as a function of a small number of variables, originated in Keynes's *General Theory.* Although others had come close (in 1930, Fisher stated the marginal opportunity cost of holding cash balances), Keynes was the first to write the demand for money as a function of income and the interest rate. A further irony was that, though the spread of Keynesianism stemmed largely from its apparent ability to explain the Great Depression, the monetary interpretation of the Great Depression by Friedman and Schwartz (1963), as the consequence of mistaken Federal Reserve policy that permitted the US money supply to contract by a third, was crucial in persuading many economists of the explanatory power of monetarism, the revived form of the quantity theory. For an overview of the development of macroeconomics from Keynes through Friedman to the New

Classical and New Keynesian research programs (and the non-mainstream Post Keynesian and Austrian schools, from Keynesian fundamental uncertainty and Mises–Hayek trade cycle theory, respectively), enlivened with interviews with leading participants (see Snowdon and Vane 2005).

Recurring Themes

Certain issues reappear throughout the history of economics. Do fluctuations result from monetary disturbances, as Hawtrey (1913, 1932) and Fisher argued, or from real productivity shocks such as Schumpeterian innovations? Is unemployment best analysed as the functioning or malfunctioning of the labour market (as in Beveridge 1930; Hutt 1939) or in terms of the demand for and supply of output as a whole (Keynes)? Is there a role for demand management to offset instability caused by volatile private investment reflecting the fundamental uncertainty of future profitability (Keynes) or is government itself the source of instability (von Mises, Hayek)? Should a central bank follow a rule rather than having discretion (as Henry Simons asked in 1936), or need there even be a central bank (as Hayek's student Vera Smith asked the same year)? Are recessions undesirable and preventable disequilibrium phenomena, or, as Arthur Ellis (1879) and Friedrich Hayek (1931) held, are they a normal and necessary part of the equilibrium path of the economy? Should analysis of economic fluctuations should be primarily a study of the statistical properties of the fluctuations, as in Burns and Mitchell (1946) and decades later Sims's vector autoregressions, or should the analysis be explicitly grounded in formal economic theory? As macroeconomists continue to theorize, measure, test, and argue about these issues, they stand, knowingly or not, on the 'shoulders of giants' who discussed these questions before. De Long (2000, p. 83) notes that 'The New Classical research program walks in the footprints of Joseph Schumpeter's *Business Cycles* (1939) [and of Schumpeter 1912; Robertson 1915], holding that the key to the business cycle is the stochastic nature of economic growth [so that] the "cycle" should be analysed with the same models used to understand the "trend"' ,while the name of the New Keynesian research program (which emphasizes frictions that prevent instantaneous adjustment to nominal shocks) indicates its historical antecedents (although, as De Long points out, it also incorporates important features of Milton Friedman's contributions, such as emphasis on policy rules and on monetary rather than fiscal policy). Insights have sometimes long preceded the ability to formalize them; even Adam Smith's famous increasing returns through the division of labour, revived in Allyn Young's 1928 essay on economic progress, did not make its mark on the theories of international trade and endogenous growth until the last decades of the 20th century, when ways were devised to incorporate increasing returns to scale in formal models. The field has experienced major changes, as when Keynes made determining the equilibrium level of national income the central issue, or when monetarism posed inflation as the central problem instead of unemployment, or when attention shifted from fluctuations to long-term growth, but in each case the change was a transformation of a rich heritage.

Macroeconomics: Relations with Microeconomics

Peter Howitt

The lack of clear connection between macroeconomics and microeconomics has long been a source of discontent among economists. Arrow (1967) called it a 'major scandal' that neoclassical price theory cannot account for such macroeconomic phenomena as unemployment. Lucas and Sargent (1979) argued that Keynesian macroeconomics is 'fundamentally flawed' by its lack of a firm microfoundation. Countless students and practitioners alike have complained of the schizophrenic nature of a discipline whose two major branches project such radically different views of the world.

It is not hard to see why this lack of unity should bother economists. Fragmentary explanations are intellectually unsatisfying in any discipline, and are rightly labelled *ad hoc*. Theories that must be altered when moving from one application to another do not provide general covering laws and are liable to break down when new applications are tried or when new data arise.

The urge to close the micro–macro gap has been particularly strong among macroeconomic theorists, whose general desire for unity has been reinforced by at least three special factors. First, there is the reductionist methodological predisposition that economists of almost all persuasions share to some degree, according to which no explanation of economic phenomena is truly satisfactory if it does not reduce the phenomena to a question of individual actions by basic

decision-making units. Second, the lack of decisive empirical tests or experiments in economics has precluded demonstrations that macroeconomic theory is valid within a well-delineated domain of applicability, despite the difficulty of reconciling it with micro principles. This same factor has also forced economists to rely to a large extent upon introspection as a criterion and source of new ideas, a reliance which enhances their reductionist tendencies, since introspection is easier to apply if a theory is cast in terms of individual actions rather than in terms of broad social forces or primitive relationships among aggregate variables. Third, microeconomics was codified and given a well-articulated mathematical structure when macroeconomics was just emerging from its pre-analytical stage. Historically, one of the most fruitful strategies for macro theorists has been to borrow and apply the principles, conventions and techniques that have succeeded in the theoretically more advanced branch of the discipline.

Thus the quest for microfoundations has been a mainspring of development in macro theory. However, this does not mean that macro has been developing into a branch of applied micro. The forces tending to make macro theory conform more closely with micro principles have been opposed by equally important forces requiring those principles to be modified radically before being applied to macro questions.

More specifically, what has restrained the urge to apply micro principles is a widespread recognition that some of the most important macroeconomic phenomena manifest defects in the economic system that standard micro theory rules out with its basic assumption of equilibrium. In a state of general equilibrium, as traditionally conceived by micro theorists, all trading plans are costlessly coordinated by 'the market', whose operation is often heuristically personified by the Walrasian auctioneer. The auctioneer establishes prices such that plans are collectively compatible, with demand and supply equated for each commodity. He also ensures that, given this compatibility condition, all trading plans can be executed at no cost.

With the auctioneer at work, one individual's decisions interfere with another's only to the extent that they affect the vector of equilibrium prices. Thus the only constraint that social interactions are assumed to impose on the formation of trading plans is the single budget constraint requiring the value of purchases not to exceed the value of sales. No one need concern himself beyond this with the possibility of selling less than he had planned, with the difficulty of finding potential trading partners or with the possibility that a collapse of credit markets might make it impossible for him to transform future sales into present purchases at any price.

There has been a natural reluctance among most macroeconomists to use a theory based on this conception of ideal coordination for purposes of explaining business-cycle fluctuations, large-scale unemployment and credit crises. These phenomena are obviously characterized by a gross lack of coordination between different agents' economic activities, and by a widespread concern for just those problems which general equilibrium analysis implies can safely be ignored by all agents.

The story of the development of macroeconomic theory beginning with the Keynesian Revolution is largely a story of the struggle between these two opposing forces: the quest for a microfoundation and the recognition that existing micro theory is inadequate for dealing with macro problems. The major innovations in macro theory have consisted of new ways to use the powerful organizing concepts of micro theory, equilibrium and rational choice, to explain phenomena that have traditionally eluded micro theory.

The main analytical innovation of Keynes's *General Theory* was to develop an alternative concept of equilibrium that allowed modified versions of supply and demand analysis to be applied to macroeconomic questions without assuming a state of ideal coordination. The key to this innovation was the recognition that prices were not the only equilibrating variables. In Keynes's equilibrium, the quantity of aggregate output did the equilibrating. Instead of determining employment by the condition that the supply and demand for labour were equal, Keynes imposed the condition that the quantity of output produced equal the quantity demanded, the equilibrium condition of

the familiar Keynesian Cross diagram. Hicks (1937) showed how Keynes's analysis could be formulated as two equations in the two equilibrating variables – output and the rate of interest – a formulation that became the standard paradigm of macro theory for the next 30 years.

With this new concept of equilibrium, Keynesian economics achieved the immediate goal of having a short-run macroeconomic theory with enough equations to determine the variables of interest. Rather than having to treat fluctuations in output and employment as disequilibrium phenomena, using the cumbersome and problematic dynamic techniques available at the time, macroeconomists after Keynes could use the much simpler methods of comparative statics. Furthermore, with this equilibrium concept in hand, they could begin applying choice theory consisted to the analysis of aggregate demand. From Hicks's essay through the 1960s, the main developments in macro theory consisted of the rationalization and modification of the aggregate behavioural relationships postulated by Keynes, through the application of principles of optimization.

Although there was considerable disagreement over whether a Keynesian equilibrium should really be called an equilibrium, and whether it adequately captured Keynes's central ideas, there was a broad consensus among macroeconomists following the Keynesian Revolution concerning the relative domain of applicability of Keynesian macroeconomics and Walrasian micro theory. Modigliani (1944) had shown how Keynesian results could be derived from an otherwise classical model if the money-wage rate were fixed. Since it was widely believed that wages were less than fully flexible in the short run, it seemed natural to see Keynesian theory as applying to short-run fluctuations and general equilibrium theory as applying to long-run questions in which adjustment problems could safely be ignored. This view came to be known as the 'neoclassical synthesis'.

By the 1960s, however, serious doubts were being raised about the logical consistency of this division. Most notably Clower (1965) pointed out that the Keynesian consumption function, a key concept in Keynes's quantity-equilibrating multiplier process, was incompatible with Walrasian general equilibrium analysis. In particular, it was based on the notion that the typical household takes its income, whether current or prospective, as given, whereas in general equilibrium analysis a household is supposed to choose its income, by choosing how many factor-services to sell. Clower raised the question of how a theory with this kind of consumption function could possibly be reconciled with standard microeconomic theory.

The answer proposed by Clower was that Keynesian 'effective' demands would be transmitted by agents in a Walrasian world when the system was not in equilibrium. If general equilibrium prices have not yet been established, then excess demands and supplies will make it impossible for all agents successfully to execute the trading plans that they had formulated on the basis of a single budget constraint. Once they see that this is the case, they will begin to take into account not just their budget constraint but also the quantity limitations implied by non-price rationing. The unemployed worker will base his demands not on the amount of labour he would like to sell at the going wage but on the amount he is selling or expects to sell.

Clower's suggestion was further developed by Barro and Grossman (1971), who also integrated it with Patinkin's (1956, ch. 13) similar analysis of how the demand for labour would be affected by the quantity of output demanded when the system was not in a general equilibrium. Barro and Grossman showed how these ideas could be combined to generalize Keynes's concept of quantity equilibrium. If prices are held fixed at levels that create excess supplies of labour and output, then the equilibrium will generally be a set of quantities that are demanded when agents take into account the sales constraints implied by those quantities.

To many writers, the Barro–Grossman analysis presented a microfoundation for macro theory that confirmed the neoclassical synthesis. Barro and Grossman labelled their contribution a 'general disequilibrium' analysis to emphasize that it generated Keynesian results only if prices were away from their Walrasian equilibrium values. As the

subsequent literature emphasized, this analysis could be combined with the *tâtonnement* mechanism of general equilibrium theory, according to which the price of any good out of equilibrium rises or falls as a function of excess demand or supply of the good. As prices changed, the quantity equilibrium would change with them. The only long-run rest-point to such a system was a Walrasian equilibrium. In the short run, the system would generally be in a Keynesian fixed-price equilibrium.

The major problem with this microfoundation is that it relies on what is generally regarded as the weakest part of micro theory – the *tâtonnement* mechanism. No one has yet successfully integrated that mechanism with the main part of micro theory – the theory of equilibrium. The problem with attempted integrations was posed forcibly by Arrow (1959), who noted that since all agents are assumed to act as price-takers in general equilibrium theory, there is no one who can change prices that are not at equilibrium values. The heuristic device of the 'auctioneer' does more to evade this problem than to solve it.

This problem led several authors in the 1960s and 1970s to turn to the economics of information for a microfoundation. In general equilibrium analysis, the *tâtonnement* can be thought of as the mechanism through which the market collates and disseminates the information required to achieve a coordinated state. When an economy is disturbed by a change in tastes or technology that is at first apparent only to a limited subset of agents, the excess demands and supplies created by this change act as a signal to the rest of society that a changed allocation of resources is called for. The message is passed on to other individuals in the form of a change in relative prices. The neoclassical synthesis pictured macroeconomic problems as arising because this process takes time. The difficulty noted by Arrow was that the informational aspects underlying this process were not present in the decision problems faced by the individuals in the theory. Thus it seemed to many that the way out of the difficulty lay in a more explicit treatment of the role of less than perfect information in individual decision-making.

Considerable progress along these lines was made by various contributors to the famous 'Phelps volume' (Phelps et al. 1970). This volume contained a variety of different approaches to the problem, but the most lasting contribution was the 'island parable' presented in Phelps's introductory essay. According to this parable, the typical transactor trades on a succession of 'informational islands'. Prices on each island always equate demand and supply on that island, but people are unaware of prices and quantities simultaneously prevailing on other islands.

This parable seemed to offer a microfoundation for the neoclassical synthesis without relying on the problematical *tâtonnement* mechanism. In particular, consider an unanticipated purely nominal fall in aggregate demand. According to Phelps's parable, the system would react with a decrease in output and employment and a less than proportional fall in prices in the short run, as in Keynesian theory, but with fully proportional price declines that neutralized any real effects in the long run, as in general equilibrium analysis. The reason for the short-run non-neutrality is that sellers who saw their selling prices fall would tend to read this as a fall in the relative price of their wares, not realizing until later that prices elsewhere in the economy were also falling, and would therefore be induced to sell less. This withdrawal of supply would soften the initial fall in prices. Eventually the realization that this was an aggregate phenomenon, and not just local, would persuade people to supply the same amount as before, and prices would fall all the way to their new equilibrium values.

This apparent microfoundation did not rely on the *tâtonnement* mechanism, but it relied heavily upon the theory of expectation formation. In particular, it postulated that the only impediment to achievement of long-run equilibrium was the slowness with which people formed accurate expectations of the general price level. This postulate left several writers unsatisfied because it implied an incongruity between the formation of trading plans, which agents were assumed to undertake rationally, and the formation of expectations, which they were assumed to do according to a mechanical rule. This dissatisfaction led the

way to the rational expectations revolution in macroeconomics.

The seminal paper in this revolution was Lucas (1972). In this paper Lucas presented an exact model of the island parable, in which agents formed subjective expectations that were the mathematical expectations of the model itself. This expectation scheme was not derived from any explicit optimization scheme; nevertheless, it became known as 'rational' on the belief that people who formed expectations in any other way must be leaving unexploited some opportunities for increasing their well-being. Lucas's model became the analytical paradigm of the school of new classical economics in the 1970s and 1980s, whose research programme was explicitly to base all of macroeconomics upon firm microeconomic principles.

By the early 1980s new classical economics had become the dominant approach in macroeconomic theory. But it was strongly resisted by Keynesian economists, who argued that, although it had firm microfoundations, it was based on a notion of equilibrium that was too close to the frictionless ideal of Walrasian theory. Among other arguments, they objected that the price of avoiding the problems of *tâtonnement* by means of the Phelps island parable was giving up the fundamental Keynesian notion of quantities and other non-price signals as equilibrating variables; hence, giving up hope of explaining many of the obvious coordination problems faced by people in the trough of a business cycle.

In the mid 1980s, however, there has been a resurgence of theoretical support for Keynesian ideas. Specifically, authors like Diamond (1982) and Howitt (1985) have derived models in which all agents are explicitly rational and in which the equilibrium states exhibit Keynesian phenomena. The unifying feature of these models is the assumption that even with perfect price-flexibility, people respond to non-price signals. Specifically, an increase in economic activity on one side of the market (e.g. an increase in aggregate demand) will reduce the costs of trading by making potential trading partners easier to find, and hence will affect the trading decisions on the other side of the market (e.g. will induce an increase in aggregate supply), even if it does not affect market prices. These models are still, however, in their infancy.

It is interesting to speculate on whether or not the quest for a microfoundation will continue to play as important a role in the future development of macroeconomics. The disunity between micro and macro that has motivated so many contributors is shrinking rapidly on the frontiers of research, where micro theory is being transformed by the explicit consideration of informational problems like those so often adduced by macroeconomists, and where macroeconomics without explicit reference to individual transactors, their decision problems and conditions of equilibrium, is becoming increasingly rare.

It is also questionable whether the microeconomic principles of equilibrium and rationality that have been applied so fruitfully in the development of macroeconomics can be of more service. By themselves they are no more than organizing devices; they yield no meaningful empirical propositions in the absence of a great many supporting hypotheses.

Maddala, G.S. (1933–1999)

Kajal Lahiri

Abstract

G.S. Maddala's many publications covered almost every substantive areas of econometrics – distributed lags, generalized least squares, panel data, simultaneous equations, measurement errors, switching and disequilibrium models, qualitative and limited dependent variable models, selection and self-selection models, exact small sample distributions of estimators, outliers and bootstrap methods, robust estimators and more. G.S. became a veritable textbook himself – a pre-eminent teacher in econometrics and an authority on almost every econometrics topic. G.S. was a brilliant expositor – he could cut through the technical superstructure to reveal only essential details, while retaining the nerve centre of the subject matter he sought to explain.

G.S. Maddala (universally known as 'G.S.') was born on 21 May 1933 in the south Indian state of Andhra Pradesh, where he had his high-school education. G.S. held the University Eminent Chair at the Ohio State University when he died on 4 June 1999 due to congestive heart failure.

G.S.'s father was a schoolteacher of modest means, and his mother, though having only an elementary education, was well versed in Sanskrit and the works of the great Indian philosopher Sankara. After graduating from high school in 1947, G.S. had to drop out of college for a few years due to health and other reasons. In 1955 he graduated first in his class from Andhra University with a BA in mathematics, and went on to graduate in First Class from Bombay University with an MA in statistics in 1957. With a Fulbright Fellowship, G.S. travelled to the University of Chicago in 1960 and completed his Ph.D. in 1963 under the supervision of the late Zvi Griliches. In that year, he was offered the job of Assistant Professor of Economics at Stanford University. Before joining Ohio State in 1993, G.S. taught at the University of Rochester (1967–1975) and at the University of Florida (1975–1993). He also held visiting appointments at Cornell, Yale, CORE, Monash, Columbia, Caltech (as the Fairchild Distinguished Scholar), Emory and Oakridge Labs. The fascinating narration of his journey from an early college dropout

in a remote Indian village in 1947 to a faculty position at Stanford in 1963 can be found in the Introduction ('How I Became an Econometrician') to the two-volume selected works of Maddala (1994). More detailed biographical information, his life story and philosophy can be found in Lahiri and Phillips (1999), Lahiri (1999), Griliches (1999), Rosen (2000) and Hsiao (2003).

Beginning with his first published paper (with Zvi Griliches, Robert Lucas, and Neil Wallace) in 1962, through the next four decades, G.S. published 12 books and more than 110 articles covering almost every emerging area of econometrics – distributed lags, generalized least squares, panel data, simultaneous equations, measurement errors, tests of significance, switching and disequilibrium models, qualitative and limited dependent variable models, selection and self-selection models, exact small sample distributions of estimators, outliers and bootstrap methods, robust estimators, and more. The list is practically endless. Throughout his career G.S. used sample theory and Bayesian techniques freely in his research, a rarity in the econometrics profession, and was one of the early proponents of Bayesian approach in econometrics. Through his many books and the breadth of his own research, G.S. became a veritable textbook himself – a pre-eminent teacher in econometrics and an authority on almost every econometrics topic. Not surprisingly, according to the *Social Science Citation Index*, G.S. was one of the top five most-cited econometricians during each of the years 1988–1993, and he was cited more times in 1994 and 1996 than each of the six econometricians who won the Clark Medal during 1970–2000.

During the 1960s, G.S. contributed heavily towards the formulation and estimation of production functions and technical change. His doctoral dissertation was on productivity and technical change in the US bituminous coal industry. His two papers with Jay Kadane in 1966 and 1967 considered, respectively, the importance of alternative exogeneity assumptions in the estimation of the constant elasticity of substitution production functions parameters inclusive of the share equations; and the bias in the estimation of the returns to scale parameter when the production function is incorrectly specified as a Cobb Douglas. The rigour and depth in these papers were undoubtedly ahead of their time.

The early 1970s saw a flurry of activity on efficient estimation methods of alternative distributed lag models. One of G.S.'s widely cited papers (1971a) showed why certain commonly used two-step procedures are asymptotically less efficient than the maximum likelihood estimator in the presence of lagged dependent variables as regressors. This sort of problem is encountered also in dynamic panel data models with individual heterogeneity. The key result in this paper is that in these models the information matrix of the slope parameters and the parameters embedded in the covariance matrix of residuals are not diagonal. Using this as a starting point, Pagan (1986) developed a more thorough and modern characterization of numerous two-step procedures with estimated covariance matrix in the context of various econometric models.

With Dave Grether in 1973, G.S. studied the effects of errors in variables in distributed lag models with serial correlation. They showed analytically that the estimated speed of adjustment can be severely biased, and can give the spurious appearance of a long lag in adjustment. In two influential papers with A.S. Rao in 1971 and 1973, G.S. developed maximum likelihood procedures for Solow's Pascal lag and Jorgenson's rational distributed lag models, and compared the power of tests for serial correlation in regression models with lagged dependent variables. One important conclusion that emerged from the latter study was that the nature of the autocorrelation and trend in the exogenous variable is crucial in determining the small sample behaviour of the test statistics and the estimators – hinting at much of the work on integrated variables that would come in the 1980s.

During the early 1970s G.S. also produced a number of important papers on the use and estimation of panel data models, and rightfully became one of the three 'fathers' (together with Yair Mundlak and Marc Nerlove) of modern panel data analysis in econometrics. In his influential *Econometrica* (1971b) paper, G.S. demonstrated – with his characteristic clarity –

that the error component estimator is a weighted combination of within and between estimators, and thus the use of dummies entails substantial loss of information by ignoring the 'between' variation in the data. In another *Econometrica* (1971c) paper, G.S. discussed the problem of pooling cross-section and time series data, and emphasized tests for consistency between time series and cross-section information. The paper contains a very deep analysis of an alternative Bayesian approach with diffuse priors and concludes that the two approaches should be complementary. (Publishing three full-length articles in *Econometrica* in a year has to be some kind of a record for an economist!) The profession quickly saw the enduring value of these publications and elected G.S. a fellow of the Econometric Society in 1975.

During the 1970s, like many other econometrics stalwarts of the period, G.S. was also involved in the development of econometric methodology in simultaneous equations models. He worked on appropriate estimation strategies in large and medium-size econometric models (1971d), and studied the power characteristics of alternative tests of significance associated with simultaneous equation estimation (1974a). His *Econometrica* (1974b) paper showed that 'diffuse' and 'non-informative' priors might lead to sharp posterior distributions even in under-identified models. Only recently have Chao and Phillips (2002) fully solved the so-called 'Maddala paradox' using Jeffreys prior. They interpret the pathological result in terms of a naive use of the diffuse prior that fails to downweight sufficiently that part of the parameter space where the rank condition either fails or nearly fails. In another potent contribution to an important recent work on weak instruments, Maddala and Jeong (1992) correctly showed that the bimodal distribution of the instrumental variable estimator obtained in the literature is merely due to the illustrative model used, where the correlation between the structural and the first-stage errors is perfect. Phillips (2006) gives a complete characterization of the bimodality problem when instruments are weak.

From the mid-1970s, G.S. was primarily focused on developing estimation and test procedures for qualitative and limited dependent variable models, and produced nearly 40 articles. This line of research also dealt with models with selection, self-selection, disequilibrium and controlled prices. His work at Rochester with Forrest Nelson (1974) on disequilibrium models and with Lung-Fei Lee (1976) on recursive models with qualitative endogenous variables and generalized selection models represents a long and very fruitful period of research on this topic. His 1983 Econometric Society monograph, *Limited Dependent and Qualitative Variables in Econometrics*, was an immediate best-seller and was declared a citation classic in *Current Contents* (vol. 30, 16 July 1993). It has fuelled much of the innovative applied and theoretical research using these tools since the mid-1980s, and has served as a bible to empirical researchers in applied microeconomics. The strength of the book lies in its comprehensiveness, expositional simplicity, and depth. As of June 2006, the Google Scholar reports a record 3,721 citations of this advanced monograph. G.S. also wrote a number of theoretical and empirical papers analysing limited dependent and qualitative variable models with panel data, and wrote widely cited expository articles for use in other disciplines such as accounting, finance, transportation, and health.

It is notable that G.S. can jointly claim a statistical distribution – the Singh–Maddala (1976) distribution – a much better name than the Burr type 12 to which it is related. Maddala and Singh's proposed statistical distribution has triggered much research in describing the actual size distribution of incomes, and is a generalization of the Pareto distribution and the Weibull distribution used in analysis of equipment failures. As aptly noted by Sherwin Rosen (2000) while delivering the first Maddala lecture at Ohio State University on 26 April 2000, 'Coase may have his Theorem, Stigler his Laws, Black and Scholes their Formula, and Lucas his critique, but what economist aside from Pareto (who was just as much a sociologist and political scientist and only one third economist) has half ownership of a distribution? And what an elegant economic derivation it has.'

G.S. had a deep interest in rational expectations models, in the validity of the hypothesis that

can be gleaned from recorded survey data, and in how econometric disequilibrium models play out in this framework. Maddala, Fishe and Lahiri (1983) developed methods to estimate aggregate expectations when available survey data are partly qualitative and partly quantitative. He had done pioneering work (Maddala, 1983a) on the estimation for models with bounded price variation, and with Scott Shonkwiler (1985) applied the methodology to the corn market. With Steve Donald (1992), G.S. studied the disequilibrium model with upper and lower bounds on prices under rational expectations. The latter paper foreshadowed much work on exchange rate determination in a target zone in the 1990s. Undoubtedly, the full potential of this line of research initiated by G.S. is yet to be realized.

With failing health, G.S. spent much of the 1990s working primarily on bootstrap techniques and time series models with cointegration and structural breaks. During this period, he also wrote important papers on tests of unit roots in panel data models, robust inference, errors in variables problems in finance, Bayesian shrinkage estimation, outliers and influential observations, neural nets, and many others. Thus, ill health neither slowed down his research nor dampened his passion for mentoring and supervising Ph.D. students. In total G.S. supervised close to 60 doctoral students, co-authoring more than 65 published articles with them.

While testing the rationality of survey data on interest rate expectations in the context of a multiple-indicator single index model with heteroskedasticity, Maddala and Jeong in the mid-1990s used the weighted double bootstrap method to implement the Wald test in finite samples. His work with Hongyi Li in 1996 explored the use of different bootstrap techniques in cointegration regressions, financial and non-linear models. With Wu (1999) on panel data unit root test, G.S. suggested the use of a novel Fisher test that combines N individual tests with bootstrap-based critical values. Since much remains to be done to extend the Fisher approach to combining individual tests that are correlated, further generalizations of the Maddala–Wu test are certainly to come.

Much of his work on modern time series analysis has been summarized in his seminal book with In-Moo Kim (1998). This book also presents a comprehensive and lucid review of unit root and cointegration tests, and estimation with integrated variables. It discusses problems of unit root tests and cointegration under structural change, outliers, robust methods, the Markov switching model, and Harvey's structural time series model. The book contains a welcome chapter on the Bayesian approach to many of these problems and bootstrap methods for small-sample inference.

G.S. contributed to a number of purely policy-oriented and applied areas. Some of these topics include consumption, production and cost functions, money demand, regulation, pseudo-data, returns to college education, housing markets, energy demand, stock prices, international macro, and cross-country growth analysis. In all these papers, G.S. made serious attempts to grapple with substantive and important issues of the day. However, one common characteristic that flows through all these papers is that they unfailingly reflect the discriminating judgement of a consummate econometrician.

G.S. had the gift of a brilliant expositor – the ability to cut through the technical superstructure to reveal only essential details, while retaining the nerve centre of the subject matter he sought to explain. He loved to write econometrics in plain English. There was magic in how he could cut to the core, strip away all the irrelevant details and illuminate the essence of the issue in a quiet and unassuming way. This exceptional expository capability made him revered by applied and theoretical econometricians alike. This skill was apparent in all his writing and was a central element in his textbook expositions. His 1977 econometrics text redefined the boundaries of econometrics that could be integrated into graduate teaching, and became a new standard for subsequent econometrics textbooks. His advanced undergraduate textbook *An Introduction to Econometrics* has gone into its third edition (2000), and all his textbooks have been translated into a number of foreign languages.

G.S.'s style was to take a critical but constructive look at evolving econometric techniques – in

particular those that have little practical significance. In this, G.S. had something that was close to perfect pitch in econometrics. He was one of the few econometricians who constantly asked whether the questions being answered were worth asking – always maintaining a clear perspective on a wide range of issues in econometrics and their relationship to economic problems. In doing so, he never hesitated to go against the tide of the profession. While much of his work was undoubtedly constructive, much was also critical of many current fads in econometrics. That is also a very important contribution.

Mahalanobis was born in Calcutta of a well-to-do Bengali middle-class family with a reformed outlook on Hindu religion. He was educated first at Presidency College, Calcutta, and then at Cambridge, where he graduated with a First in Natural Sciences from King's College in 1915. He became a Fellow of the Royal Society in 1946 and received many other scientific honours. While Mahalanobis served as Professor of Physics at Presidency College for nearly three decades, his scientific work consisted chiefly of developing statistical theory and techniques that had

I am grateful to Anthony Davies, Cheng Hsiao, Kay, Tara and Vivek Maddala, Thad Mirer, Peter Phillips and others who have contributed to this biography

application to a wide range of subjects, beginning with meteorology and anthropology and ending in economics.

Mahalanobis established a firm international reputation on the basis of his work on the design of large-scale sample surveys (for example, 1944) and thus laid the basis for systematic collection of a large variety of data relating to socio-economic conditions. Mahalanobis's sense of realism was combined with a deep understanding of the problems of statistical inference. This led him to place stress on 'non-sampling errors' in addition to the standard preoccupation with sampling errors. He devised his system of 'interpenetrating network of sub-samples' to derive among other things, an idea of 'non-sampling errors' which are inherently associated with large-scale collection of data.

Mahalanobis's work on experimental designs developed with a view to estimating crop yields (1946) was highly influential in laying down the basis for collection of agricultural statistics in India. In multivariate statistics, Mahalanobis's measure of distance between two populations (1936), usually known as Mahalanobis's D^2 statistic, is a major contribution that is much used in anthropometry and elsewhere.

Mahalanobis maintained a keen interest in problems of national planning even before India had gained Independence. He recognized very early that such planning had to have a firm statistical base, and from the beginning of the 1950s, when the Indian Five Year Plan was launched, began to devote a very large part of his time and attention to questions of estimating national income and the factors determining its rate of growth. His approach to planning issues, with its strong emphasis on quantification, was significantly different from the qualitative approach favoured by the Indian economists of his generation. However, Mahalanobis was no exclusive believer in narrowly conceived quantitative techniques. He developed an important blend between qualitative and quantitative considerations, which is reflected in his 'Approach of Operational Research to Planning in India' (1955).

The second Five Year Plan, whose analytical structure was largely the handiwork of Mahalanobis, stands out as a very distinguished document in the development of planning theory. Mahalanobis is generally regarded as one of the prominent advocates of the inward-looking strategy of industrialization, along with Raul Prebisch. But the analytical foundation of the Mahalanobis approach was derived from somewhat different premises. While Prebisch began his theoretical study from what he thought was a historical fact, that is, the secular decline in terms of the trade of primary producing countries, Mahalanobis developed a two-sector model of growth to deduce a strategy of industrial development which he thought was best suited to India. The classification of the economy into sectors resembled in some respects Marx's famous Departmental Schema, although they were not identical.

Mahalanobis's sector-schema (1953) distinguished between 'capital goods' and 'consumer goods', but the assumption of vertical integration made in the interest of simplicity made statistical implementation difficult. The essential point of the model is that the capacity of the capital goods sector determines the potential rate of expansion of the consumer goods sector, and not the other way round. Further, at any given instant, capacities are not directly transferable from one sector to the other. Labour is not considered to be a constraint on expanding production. The model was developed initially for a closed economy but has been subsequently extended to open economies, with an exogenously given profile of export earnings. Mahalanobis used the model to illustrate the nature of the trade-off between present and future consumption, given the objective characteristics of the two sectors.

For the dynamic closure of the model he used the ratio of the output of the capital goods sector that is ploughed back into itself ('λ_k' in his notation), to deduce a 'gradualist growth' path of consumption. For any given value λ_k maintained over time, the rate of growth of aggregate output tends, over a sufficiently long period, to a magnitude $\lambda_k\beta_k$, where β_k is the output–capital ratio of the capital goods sector. The Mahalanobis model was subsequently freed from the assumption of an exogenously stipulated λ_k Exercises carried out by Stoleru (1965), Chakravarty (1969),

Dasgupta (1969) and others introduced explicit intertemporal social utility functions along with a production technology of the Mahalanobis type. They deduced the characteristics of optimal growth paths with the help of variational calculus. $\lambda_k(t)$ was deduced as a solution of the optimizing exercise. It was shown that while the assumption of 'non-shiftability' critical to Mahalanobis's model could in several cases give rise to a preference for capital goods sector in early stages of growth (a strategy preferred by Mahalanobis himself), one could not obtain a universal rule of priority for capital goods irrespective of initial conditions, or the nature of social utility functions over time.

In all these exercises, the coefficients pertaining to the 'capital goods sector', sometimes identified as the 'machine tool sector', turned out to be an important determinant of the growth process. Earlier literature on business cycle theory originating with Marx, Tugan Baranovsky and Adolph Lowe had placed emphasis on the 'machine tools sector', without linking it up with an explicit growth model. In the growth-theoretic area Fel'dman alone appears to be the true predecessor of Mahalanobis, as is evident from Domar's discussion (1957).

Mahalanobis extended the two-sector model to a four-sector model, to focus on issues of reduction in unemployment along with increases in income. Mahalanobis came to the 'dual development thesis', which consisted in assigning high weights to the capital goods sector in the interests of long-term growth, and emphasis on the highly labour-intensive consumer goods sector in the short run. In the literature on planning, this has on occasion been referred to as the strategy of 'walking on two legs', with authorship occasionally ascribed to Mao Tse Tung.

Towards the end of his life, Mahalanobis returned to issues of statistical methodology and concentrated on developing what he called 'fractile graphical analysis' (1960), which is based on a geometrical concept of error and can also provide a generalized measure of separation between two 'different universes' of study.

Mahalanobis's work remains important for economists who are working on quantitative approaches to problems of plan formulation, especially in the context of large-sized economies. His work on sample surveys has generated a very valuable literature to which economic statisticians from India and elsewhere have made notable contributions.

Maine, Sir Henry James Sumner (1822–1888)

O. Kurer

Maine studied classics at Cambridge, was Professor of Civil Law at Cambridge (1847–54) and was appointed Reader at the Inns of Court in London (1852). The years from 1862 to 1869 he spent as Legal Member of the Council of India. After his return he became Professor of Law at Oxford (1869) and Cambridge (1887) and was elected Master of Trinity Hall, Cambridge in 1877. In addition, Maine was an active journalist.

Maine's most important work is *Ancient Law* (1861), where he introduced the historical method of jurisprudence to an English audience. He is best known today for his proposition of the 'movement of progressive societies from Status to Contract'. In early society, man's rights and duties were rigidly determined by his position at birth by his parents' position. In modern society, voluntary contractual connections predominate. Of particular interest to him was the mechanism by which legal change occurs: he postulated a progression from legal fictions (pretending there is no change) to equity (exceptions in particular cases) to direct changes of the law by virtue of the authority of power.

Maine was a resolute opponent of democracy. Progress in his view was achieved by enlightened minorities, the extension of democracy to the mass of men threatened stability and progress. He strongly resented interference with the freedom of contract, a retrogressive step according to his view of evolution.

Maine greatly influenced the English historical school, in particular through Cliffe Leslie. With them he believed that scientific historians were in a position to discern clues as to the processes governing historical change.

Maintaining Capital Intact

K. H. Hennings

The purpose of economic activity is normally to produce a surplus which can be distributed (or appropriated) as income. But only that part of total output can be reckoned as surplus and distributed as income which is not needed to provide for the continuation of economic activity on the same level. Thus in an economy producing only corn (from abundant land and labour) an amount of total output equal to what was required to produce it has to be set aside as seed, and only the remainder can be distributed as income and is at the most available for consumption. If more is distributed, the economy cannot continue on the same level as before, that is, becomes less viable, and will ultimately become unviable so that economic activity comes to an end. To set aside as

much output as is required to continue economic activity on the same level as before (or, to provide for simple reproduction) is thus a principle which may be violated in the short run, but which endangers the viability of economic activity if not adhered to in the long run. If economic activity involves stocks which are considered as 'capital', this principle requires that such capital be maintained intact. Capital is maintained intact if an amount of total output is set aside for its maintenance which ensures that the remaining output is on a level that can be kept up forever. The principle that the viability of economic activity be maintained which requires that capital be maintained intact, thus implies the Hicksian income concept (Hicks 1936, ch. 14).

This formulation of the principle assumes that it is desirable to maintain the current level of economic activity. While it is reasonable to assume that it is not desirable to 'eat up capital' over more than a short period (despite exceptions such as wars), it is often considered desirable to consume less than the maximal possible amount, i.e. to accumulate capital and thus to increase the level of economic activity that can be permanently maintained. The principle that the viability of economic activity be maintained therefore sets a minimum standard. By comparison with propositions about the optimum accumulation of capital such as the golden rule, it is a proposition about the minimum maintenance of capital.

As here formulated the principle is empty as long as what it means to maintain capital intact is not defined. How this should be done has been the subject of long-standing debates among accountants and business economists in the guise of determining the correct principles for drawing up business accounts and calculating business income. Much the same issues have been discussed by social accountants from a macroeconomic perspective. In economic theory they have been the subject of an important debate between A.C. Pigou and F.A. Hayek in the 1930s and 1940s.

It will be useful to begin with the accountants' perspective. It has often been maintained, reasonably enough in view of the legal obligations of a firm to its creditors, that business accounts should be drawn up such that the amount of money capital invested in the firm be preserved, and that business income should be reckoned as distributable only after allowance has been made for its maintenance. This raises a host of valuation difficulties (see Parker and Harcourt 1969), but the principle is reasonably clear: what should be preserved is the net present value of the firm, corrected for price level changes, i.e. measured in real terms. That is what matters from the point of view of someone who has invested in the firm. It is obvious that this implies that assets are valued not at historical cost, nor at replacement cost, but rather according to their most probable expected future contribution to business income. That means taking account of such factors as business risks as well as planned obsolescence when the expected physical life of an asset is longer than its expected use. Nor does preserving the net present value of a firm imply that any particular asset be preserved, or maintained intact. It may be more profitable to run down an asset deliberately, i.e. shorten its physical life (and even productivity) by neglecting to keep it in good working order, or even get rid of it altogether. For what is to be preserved is not capital in the sense of a stock of physical objects (capital goods), but net wealth. In an accountant's perspective, maintaining capital intact means preserving net wealth, and not a stock of capital. This can be done in a variety of ways, including a change in the stock of capital. Hence there is no necessary connection between preserving net wealth and maintaining a stock of capital, from the point of view of a firm. The same holds true for any other microeconomic unit, in particular households. In a microeconomic perspective, therefore, income is whatever is earned minus what is necessary to preserve, given current expectations, the net present value of the firm or household in real terms.

In a macroeconomic perspective, economic activity can without loss of generality be considered as production which involves capital goods such that at any moment there exists a stock of capital. Consider an arbitrary time period. Both at the beginning and the end of the period there will exist capital stocks which consist of different types of capital goods of different ages. Some of

the capital tools existing at the beginning of the period will have been used up, or have been discarded, during the period. Others will have been used during the period, and will normally have been subject to wear and tear; whether they have been maintained in good working order or not, they are all older at the end of the period. Finally, there will be new capital goods, produced during the period. So in general the capital stock existing at the end of the period will consist of different capital goods than those which formed the capital stock at the beginning of the period. However, if the economy is in a stationary state, the size and composition of the capital stock in the same at the beginning and the end of the period. As the age structure of all types of capital goods will be constant, replacing the oldest items of each type of capital good will ensure that all losses are replaced and all wear and tear is made good. Where that is not possible because the period is too short, and the durability of capital goods so long that none is due to be replaced, a fund can be set up to accumulate what is required for replacement. In such a stationary situation no investment decisions need to be taken. Because the structure of production is well integrated, all types of capital goods needed for replacement are produced, and can be used for the purpose for which they were produced. Similarly, all consumption goods will be used for consumption, and will together constitute the income of the economy.

Much the same will be true in an economy growing in a steady state as long as there is no technical change. There will be investment, but investment decisions will be confined to decisions to produce more of everything. The capital stock at the end of the period will be larger than that at the beginning, but its composition will be the same: all outgoing capital goods will simply be replaced by a larger amount of the same type. Income will consist of all consumption goods and the excess of new capital goods over what would have been required in a stationary situation.

In both these cases the meaning of 'maintaining capital intact' is clear. In a stationary economy it means keeping the size and the composition of the capital stock constant. In a steady state without technical change it means letting the capital stock grow while keeping its composition constant. In all other situations, i.e. if there is technical change or the economy is in a non-steady state, both the size and the composition of the capital stock will change, and maintaining capital intact can no longer be defined with respect to identical types of capital goods. Hence it was sought to specify 'maintaining capital intact' in a different manner.

Pigou (1932, 1935) proposed that 'maintaining capital intact' should be defined in such a way that a capital stock should be considered as constant if the capital goods which were used up or discarded during the period are replaced by other the production of which requires an amount of real resources equal in that period to what would have been required to reproduce the same types of capital goods as the used up or discarded ones. Because he supposed that the replacements are 'so chosen that the maximum possible addition is made to the present value of the stock of capital' (1935, p. 239), Pigou considered the capital stock as 'an entity capable of maintaining its quantity while altering its form and by its nature always drawn to those forms on which, so to speak, the sun of profits is at the time shining' (1935, p. 239). Maintaining capital intact thus meant to Pigou the replacement of outgoing items by items with the same real cost of production. It did not include provisions for making good wear and tear. Moreover, Pigou distinguished 'normal' maintenance form replacements made necessary by capital losses due to 'the act of God or the King's enemies', or acts of Parliament, which are not covered by consideration of the risks attached to the normal conduct of business (1935, p. 240). Real income, in his conception, was then total output minus what was required for 'normal' maintenance.

Hayek (1935, 1941a, b) criticizes Pigou's proposals on several grounds. First of all Hayek objected to the backward-looking nature of Pigou's capital concept and pointed to the absurdities it could entail. Instead, he insisted on a forward-looking concept in which capital goods are valued (in real terms) on the basis of their prospective quasi-rents and not their costs of production. This point Pigou accepted, and later

defined a capital stock to be constant if the items which replace outgoing capital goods are 'expected to yield the same income' as those they replace (1941, p. 274). Hayek also objected to Pigou's failure to include the making good of wear and tear in what was required to maintain capital intact, and argued at the same time that in a changing economy (which is subject to technical change, or in a non-steady state, or both) obsolescence is far more serious than physical wear and tear. Where obsolescence is planned, or expected, not to include allowances for it would underestimate what is required to maintain capital intact, and overestimate income. Where obsolescence is unexpected, attempts will be made to adapt as far as possible capital goods which were produced for one purpose to other uses. Not to make allowance for such attempts, or to do so only when such capital goods are finally discarded and replaced (as Pigou's proposal implies), would equally distort the calculation of both maintenance and income. Hayek also pointed out that all expected changes in the prospective quasi-rents of capital goods, say as a result of technical progress, or of unexpected price changes, represent capital gains or losses in real terms. Such windfalls should in his view affect maintenance rather than income. Hayek emphasized strongly that maintaining capital intact was not an end in itself, as Pigou seemed to imply, but a means to achieve a constant flow of income in order to avoid what D.H. Robertson (1933) had called unintended stinting or splashing, i.e. consuming either too little or too much to maintain the present level of consumption. Hence he argued that windfall gains and losses should affect income only in so far as they can be converted into permanent increases or decreases in the flow of income.

Hayek's main point was thus that in a changing economy changes in prices and expectations will lead to both real and price Wicksell effects, i.e. changes in the methods of production and in the valuation of capital goods. Both will cause entrepreneurs to adapt their investment behaviour because, aiming at a constant flow of income, they will not allow windfall capital gains and losses to affect their income beyond what can be converted into permanent increases and decreases in income. Hence precisely because entrepreneurs aim at a constant flow of income they will again and again adapt the capital stock required to produce that flow. There is thus no reason why the capital stock should in some sense be constant. Moreover, changes in capital stocks between the beginning and the end of a period reflect not so much physical wear and tear as obsolescence and adaptations due to changed circumstances and expectations. Hence maintenance cannot be distinguished from net investment, and attempts to define income by taking account of what is required to maintain capital are bound to fail. Hayek's argument thus amounts to a demonstration that in a changing economy, maintaining capital intact in the sense of keeping a stock of capital constant in some sense or another was incompatible with the Hicksian income concept, i.e. with maintaining income constant. Pigou (1941, 1946) responded to Hayek's capital theoretic critique by restating his position. Writing from the point of view of welfare theory, and dealing with what would now be called ex post aggregates, Pigou insisted that some method, however rough and ready, of separating maintenance from new investment should be found. That is what Hicks (1942) attempted in his contribution to the debate. While accepting Hayek's critique, he doubted the appropriateness of maintaining a constant flow of income in a changing economy, and at the same time proposed a method, based on Lindahl (1933), designed to separate ex post the consequences of expected from unexpected changes in the value of capital goods, so that the former could be charged to maintenance, and the latter as windfalls to income (see also Hicks 1958, 1969, 1973, ch. 13; and especially 1979). More recently, Scott (1984) has made a similar attempt, placing the dividing line between depreciations and appreciations due to relative price changes which should fall on income, and other changes which should fall on maintenance.

Despite some constructive efforts Hayek's critique is essentially negative. As Hicks (1974) has pointed out, Pigou's position can be associated with the attempt to provide a concept of a capital stock which corresponds to the flow of income it helped to produce. From the point of view of the

construction of a production function, such an attempt is valid; but it does come up against the twin problems of technical progress and non-stationary conditions. So the problem which Pigou originally attempted to answer is still unsolved. Progress may be expected from extending recent advances in capital theory, which so far have been confined to comparative static analysis, to the analysis of a changing economy. A beginning has been made with the development (Hicks 1973) of the concept of a 'transition' from one steady state to another, but more work needs to be done. Only when we know more about the behaviour of firms and households in an economy which is not so well integrated that all goods are used for the purpose they are produced for, and in which obsolescence and hence windfall capital gains and losses are widespread, can we decide whether it is possible to give precise meaning to the notion of maintaining capital intact. Until then the notion is useful only in the analysis of steady states which are not subject to technical change – which excludes most situations of interest to the economic theorist.

Helen Makower was educated at Cambridge and obtained her doctorate from London University. From 1938 until her retirement in 1973 she taught at the London School of Economics and Political Science. In collaboration with Jacob Marschak she made a pioneering contribution to modern asset portfolio theory and to the study of labour mobility. After the Second World War her analytical insights and interest in work then being

performed at the Cowles Commission in Chicago led to her being one of the important links through which such techniques as activity analysis entered the academic scene in Britain. Her 1957 book and other papers made original contributions to the application of linear methods in economic analysis. One of her important insights was into the analogy between production and consumption, a precursor of later work on the household production and characteristics approaches to consumer theory.

Malthus and Classical Economics

S. Rashid

Thomas Robert Malthus is known to economists primarily as the author of the *Essay on . . . Population* as well as the *Principles of Political Economy*, first published in 1820. In addition, Malthus wrote some pamphlets and contributed articles to established periodicals. His first pamphlet was on the high price of provisions and contains an explicit, if rudimentary, construction of a market demand curve. Although later scholars have found much curious matter in it, the pamphlet died unnoticed. Malthus wrote some articles on monetary economics for the *Edinburgh Review* which are chiefly notable for their moderation in espousing a middle ground between the Bullionists and their opponents. His pamphlets on the Corn Laws have gained him fame as a co-discoverer of the differential fertility theory of rent. However, not only was the theory of differential rent clearly expounded by James Anderson in 1777, but also Malthus did not formulate the theory with the clarity of either David Ricardo or Edward West. Malthus's contributions to the *Quarterly Review* (1823–4) consist largely of sharper formulations of the differences between himself and the Ricardians, points which had already been raised in the *Principles*. For these reasons, my focus will be primarily upon the *Principles*. The shadow of controversy lay over almost everything Malthus wrote and Malthus's contributions will be set in sharpest focus by occasionally using Ricardo's critical comments on the first edition of Malthus's *Principles*, the *Notes on Malthus*. As both editions of Malthus's *Principles* will be quoted, the first and second editions will be referred to as *Principles* I and II respectively.

As the second, revised edition of the *Principles* was (posthumously) published in 1836, one would naturally assume that a study of the *Principles* would suffice to tell us about Malthus's principal contributions to classical economics. While the dictates of a summary article enforce such an approach, it is important to point out that several complexities of Malthus's overall impact are thereby ignored. For example, the methodology, and sometimes the substantive conclusions, of the *Essay* and the *Principles* are very different. The tendency to extremes that Malthus deplores in the *Principles*, he exemplifies in the *Essay*. Secondly, several of the positions later espoused in his pamphlets, or in the *Principles*, were originally broached in the *Essay*. One such example would be the chapter on bounties on corn in the *Essay*. Thirdly, Malthus began as a strong supporter of Agrarianism, of the superiority of Agricultural over Manufacturing wealth, and quietly modified his position so as to occupy a middle ground as time went on. Fourthly, the claim of Malthus to be the heir to Adam Smith became highly questionable after the rise to fame of David Ricardo. Finding himself on the defensive,

Malthus increasingly turned to proclaiming that he was following Smith and that Ricardo was not. Such repeated claims served to hide the fact that, on some important issues, Malthus broke sharply with the corpus of Smithian thought. Both in the *Essay* and in the second edition of the *Principles*, Malthus challenged the idea that all nations would necessarily prosper through Free Trade. He insisted on the significant qualification that the products of such countries must be complementary if mutual gains are to be assured.

> It is . . . a just and general rule in political economy, that the wealth of a particular nation is increased by the increasing wealth and prosperity of surrounding states; and that, if these states are not successful competitors in those branches of trade in which the particular nation had excelled, their increasing wealth must tend to increase the demand for its products, and call forth more effectively its resources. But if this rule be repeatedly insisted upon without noticing the above most important limitation, how is the student in political economy to account for some of the most prominent and best attested facts in the history of commerce? How is he to account for the rapid failure of the resources of Venice under the increasing wealth of Portugal and the rest of Europe, after the discovery of a passage to India by the Cape of Good Hope; the stagnation of the industry of Holland, when the surrounding nations grew sufficiently rich to undertake their own carrying trades . . . It is not favourable to the science of political economy, that the same persons who have been laying down a rule as universal should be obliged to found their explanations of most important existing phenomena on the exceptions to it. It is surely much better that such a rule should be laid down at first with its limitations (*Principles* II, 10–11).

Method

The principal difference in method between Malthus and Ricardo lay in the extent to which they believed simple models could satisfactorily illuminate reality. Both sides were agreed as to the operation of multiple causes in economic affairs but drew quite different conclusions therefrom. In the Introduction to the *Principles*, Malthus directed his strictures at the Ricardian model:

> In political economy the desire to simplify has occasioned an unwillingness to acknowledge the operation of more causes than one in the production of particular effects; and if one cause would account for a considerable portion of a certain class of phenomena, the whole has been ascribed to it without sufficient attention to the facts, which would not admit of being so solved (*Principles* II, 5).

While Ricardo fully assented to the operation of multiple causes, he drew the opposite conclusion from this fact – namely, that complex models cannot be adequately handled and, rather than build models one could get no definite conclusions from, it was more illuminating to build simple models, which, despite their simplicity, were somehow 'representative'. Malthus could not agree. To him, 'The principal cause of error and of the differences which prevail at present among scientific writers on political economy, appears to me to be a precipitate attempt to simplify and generalize' (*Principles* II, 4).

For example, the discussion of wages in the chapter on Wages in Ricardo's *Principles* is much more sophisticated than his use of an iron-law of subsistence wages in his subsequent policy analysis. Wesley Mitchell attributes this limitation of Ricardo's policy analysis to his primitive analytical apparatus, which forced him to treat one variable as a constant when dealing with a problem involving two or more variables. This limitation was reinforced by Ricardo's insistence upon definite results. In Mitchell's words, Ricardo 'was never patient with any proposition that was surrounded by a lot of "ifs" and "buts" and "to a degrees". He wanted a clear-cut view.' Malthus was well aware of this pitfall and wrote of 'a still greater disinclination to allow of modifications, limitations and exceptions to any rule or proposition' (*Principles* II, 6).

Ricardo's great partiality for single causes may be more clearly seen from his dispute with Malthus over the determinants of profits. In Ricardo's 'corn-model' the actual profit-rate is left indeterminate but it is predicted that the rate will fall over time. This prediction is based upon the necessity of having to take recourse to poorer land with the growth of population. Since more labour is required to grow a bushel of wheat on the marginal no-rent land, and since wages are fixed, profits must of necessity fall. Malthus did

not deny the truth of such an analysis but questioned its relevance. For practical problems Malthus felt that the rate of profit was effectively set by the causes which determined the final price at which a commodity would sell, i.e. by forces akin to those describing a 'brisk' market. Malthus contrasted thus the respective strengths of the two forces.

> . . . But though this [Ricardian] principle is finally of the very greatest power, yet its progress is extremely slow and gradual; and while it is proceeding with scarcely perceptible steps to its final destination, the second cause is producing effects which entirely overcome it, and often for twenty or thirty, or even 100 years together, make the rate of profits take a course absolutely different from what it ought to be according to the first cause (*Principles* II, 282).

In the *Notes on Malthus*, Ricardo sometimes appears to agree that some concessions may be in order. Despite such wavering in the *Notes*, the concluding paragraph of Ricardo's chapter on Profits in the third edition of his *Principles*, which was issued after the above controversy, begins as follows:

> Thus we again arrive at the same conclusions which we have before attempted to establish: – that in all countries, and all times, profits depend on the quantity of labour requisite to provide necessaries for the labourers on that land or with that capital which yields no rent. The effects then of accumulation will be different in different countries, and will depend chiefly on the fertility of the land (*Principles*, 126).

Not only did Ricardo's method limit him to the study of one variable at a time but also his analysis was further handicapped by his refusal to analyse other than equilibrium positions. This limitation often prevented Ricardo from appreciating the importance of the specific stimuli and the short-run dynamics that are the stuff of economic life. Malthus had argued that 'It is the natural tendency of foreign trade . . . immediately to increase the value of that part of the national revenue which consists of profits, without a proportionate diminution elsewhere' (*Principles* I, 460). To this, Ricardo replied with an example proving nothing other than that, at a new equilibrium, the supernormal profits will have been whittled away (*Notes* 418–19).

Price Theory

Malthus borrowed most of his price theory from Adam Smith and the Physiocrats. Malthus's excellence shows itself in the systematic application and extensions he made of these sources. Smith had spoken of natural price, a long-run concept, and market price, a short-run concept; typically, Smith applied the former to factor markets and the latter to commodity markets. The former was determined by the cost-of-production and the latter was determined by demand and supply. Malthus pondered over the matter and then directly asked himself why supply and demand analysis should not be used to determine natural price as well as short-run market price? Malthus had asked the right question and further thinking led him to the right answer, namely, that the cost of production was influential only as it affected the supply curve:

> . . . when we come to examine the subject more closely, we find that the cost of production itself only influences the prices of these commodities, as the payment of this cost is the necessary condition of their continued supply in proportion to the extent of the effectual demand for them (*Principles* II, 71).

It followed that there was no longer any need to have two theories of price formation – one for the short run and one for the long run: 'But if this be true, it follows that the great law of demand and supply is called into action to determine what Adam Smith calls natural prices, as well as what he calls market prices' (*Principles* II, 71).

Malthus, having extended demand and supply to explain factor prices, was able to make a very telling criticism of the theory that cost of production determines price. Since the constituents of the cost of production, i.e. rents, profits, and wages, were themselves set by the operation of demand and supply, one could hardly escape the operation of demand and supply by appealing to the cost of production.

> But if it appear generally that the ordinary cost of production only determines the usual prices of commodities, as the payment of this cost is the necessary condition of their supply; and that the component parts of this cost are themselves determined by the same causes which determine the whole, it is obvious that we cannot get rid of the

> principle of demand and supply, by referring to the cost of production. Natural and necessary prices appear to be regulated by this principle, as well as market prices; and the only difference is, that the former are regulated by the ordinary and average relation of the supply to the demand; and the latter, when they differ from the former, are determined by the extraordinary and accidental relation of the supply to the demand (*Principles* I, 78).

Ricardo, on the other hand, maintained an implicit dichotomy between goods and factor pricing as his comments on the above passage indicate:

> In this account of necessary or natural price Mr. Malthus has in substance said the same as Adam Smith has done, in all which I fully agree, but is he not inconsistent in maintaining that natural price is regulated by supply and demand (*Notes*, 52).

The major bone of contention between Ricardo and Malthus was the cost of production theory of price. Perhaps because of his emphasis upon the long-run, Ricardo believed that an explanation based on cost of production provided a deeper understanding than the superficial demand and supply arguments. This Ricardian belief prevailed as the orthodox view for much of the 19th century.

In the *Principles* Malthus emphasized the central importance of demand and supply among the analytical tools of the economist: 'It must be allowed that of all the principles of political economy, there is none which bears so large a share in the phenomena which come under its consideration as the principle of supply and demand.' As though foreseeing the subsequent controversy that was to arise, Malthus made clear that he did not wish to emphasize either demand or supply at the expense of the other: '. . . when prices are said to be determined by demand and supply, it is not meant that they are determined either by the demand alone, or by the supply alone, but by their relation to each other' (*Principles* II, 62).

To the superb exposition of price theory contained in this chapter. Ricardo's usual answer is to speak of the role of demand and supply as real but ephemeral and transient: '. . . The market price of a commodity may from an unusual demand, or from a deficiency of supply, rise above its natural prices, but this does not overturn the doctrine that the great regulator of price is cost of production' (*Notes*, 39). The subsequent pages, however, show that Ricardo was not entirely happy with this admission. A little later, when Malthus says that a fall in the cost of production will lower equilibrium price, Ricardo seizes it as an admission of the superiority of the cost-of-production theory (*Notes*, 40): as the chapter continues, Ricardo shifts the question from the determination of market price to the determination of the supply curve (*Notes*, 42–5).

In arguing the case for demand and supply Malthus says that manufactured goods, whose production at constant costs he implicitly accepts, provide the best example of commodities whose price is determined by the cost of production. Even here, however, cost comes into play only insofar as the payment of costs is 'the necessary condition of their continued supply' (*Principles* I, 84). But if costs only act through supply, then it is valid to claim that 'the great principle of supply and demand is called into action to determine . . . natural prices as well as market prices' (*Principles* I, 75). To this Ricardo replies as follows:

> The author forgets Adam Smith's definition of natural price or he would not say that demand and supply could determine its natural price. Natural price is only another name for cost of production. When any commodity sells for that price which will repay the wages for labour expended on it, will also afford rent, and profit at their then current rate, Adam Smith would say that commodity was at its natural price. Now these charges would remain the same, whether commodities were much or little demanded, whether they sold at a high or low market price (*Notes*, 46).

Ricardo is correct in claiming the existence of a dichotomy of product and factor markets as one part of the Smithian heritage. Malthus would have done well to have emphasized that he was correcting Smith and not following him. Of the merits of his emphasis upon demand *and* supply one can only say that, if accepted, it would have rendered much of the Marshallian synthesis superfluous.

The Measure of Value

A question that occupied much, perhaps most, of Malthus's later years was that of finding the best

'measure of value', i.e. a commodity which would, at all times and places, provide an accurate account, in some absolute sense, of a nation's 'richness'. The answer clearly revolves around what one means by 'richness'. Malthus decided that the amount of labour a nation could command was the truest measure of the welfare content of its GNP, the justification being that the extent of leisure a country could devote itself to was the best measure of its well-being. In the second edition of the *Principles*, Malthus argued that the capacity to demand leisure was best measured by the units of common, agricultural labour that a country could command, because (a) adequate food being everywhere a prerequisite for the existence of leisure, the relative command over the labour that thus made leisure feasible was a good indicator of real wealth; (b) the disutility incurred by common agricultural labour was believed by Malthus to be relatively uniform across time and space, and accordingly command of one unit of it always represented the same acquisition of wealth; and (c) such labour entered directly or indirectly into the production of all commodities and therefore whatever affected it would affect the value of all commodities. Thus far, it must be said, Malthus has provided a sensible approximate solution of an insoluble problem.

Malthus, however, could not leave well enough alone. He also wanted the measure of value to serve as a unit of exchange. It is an elementary proposition that any commodity with a positive price can serve as the *numéraire* in a market; if ordinary labour has a positive price, it can of course serve as *numéraire*. The several pages Malthus devotes to this trivial point provides a curious illustration of how a mind possessed of strong common-sense can become ensnared in a near-tautology.

A more fruitful outgrowth of this concern with finding the best measure of 'richness' came about in Malthus's defence of material goods as the true repository of wealth. In opposing the more modern notion of wealth as exchangeable value, Malthus provided the following arguments. (i) What an individual is willing to consider exchangeable can vary with circumstances, for example, musical talents that were developed for their own sake can be used to teach others if the possessor feels like doing so or is compelled to do so by circumstances. (ii) Large amounts of commodities are raised in agricultural districts for domestic consumption. These goods are neither raised for exchange nor ever exchanged. But these are surely wealth in the common signification of the term. (iii) Most importantly, however, non-material goods just cannot be accounted for with satisfactory precision:

> Of the quantity and quality of the material commodities here noticed it would not be difficult to make an inventory. Many household books indeed furnish one; and knowing pretty nearly the quantity and quality of such articles a fair approximation to their value might be attained by estimating them according to the market prices of the district at the time. But in regard to immaterial objects, the difficulty seems to be insurmountable. Where is an inventory to be found, or how is one to be made of the quantity and quality of that large mass of knowledge of the individual possessors and their friends? Or supposing it were possible to form such an inventory, how could we make any moderate approaches towards a valuation of the articles it contained? (*Principles* II, 27).

It is important to note that Malthus approached the question of defining wealth solely with (somewhat narrow) accounting considerations in mind. He was so purist as to insist that only market values were acceptable and explicitly rejected the modern practice of imputing values to non-marketable outputs by using the costs of producing such outputs. If two students paid the same fees for attending school, could we say that they had both gained equally? Malthus even rejected the salaries of government clerks from the national income. While such clerks often performed exactly the same duties as a clerk in a commercial firm, only in the latter case could we be sure that the clerk was a necessary employee because he served a profit-maximizing firm.

In the process of defending the notion that material goods should be the sole components of the national income, Malthus is driven to pointing out all the difficulties national-income accountants would have to face if they adopted the broader (and more modern) notion of exchangeable value. Even though Malthus himself never estimated the national income, his careful study of the issues involved entitle him to be considered the first methodologist of national income accounting.

Say's Law

Malthus's objection to the idea that supply creates its own demand arise from his claim that, in the short run, the desires of mankind are easily satiated and may be practically considered as fixed. Since the desire to consume is thus quite limited in the short run, if the power of producing commodities be steadily increasing, then the consumers will become satiated and refuse to purchase further goods. The drop in sales resulting from this refusal to purchase causes a fall of profits and leads to a cumulative downward movement and a general stagnation of trade. Malthus's basic point is that while the increase in the supply of commodities is an ongoing, self-propelling process, since there is no similar mechanism for 'updating' the desires of consumers, the prospect for profitable sales of commodities are bleak. Yet another way of stating the argument is to say that technological progress in supply guarantees an increasing amount of commodities but wherefrom comes the technological progress in demand that would ensure a market for such produce?

The model used by Malthus to argue for the plausibility of general gluts postulates an economy consisting of only three classes, farmers, capitalists and workers. For the workings of the model, Malthus assumes that workers throughout earn a subsistence income. The remainder of what is produced is exchanged between farmers and capitalists, who thus form complementary markets for each other. Now, says Malthus, if both farmer and capitalist simultaneously decide to curtail consumption and to accumulate then the market for final products will rapidly die off. Goods become unsaleable, profits drop and general glut of commodities ensues. It is true that the desire to accumulate will initially generate a demand for investment. But investment is the auxiliary of consumption and is, in the final analysis, undertaken only to provide consumption. If the final products look unsaleable, then why should one invest at all? The entire argument is complete and self-contained; there is no need to appeal to monetary factors.

The essence of Malthus's model is indicated by the quote below:

> It is undoubtedly possible by parsimony to devote at once a much larger share than usual of the produce of any country to the maintenance of productive labour; and suppose this to be done, it is quite true that the labourers so employed are consumers as well as those engaged in personal services, and that as far as the labourers are concerned, there would be no diminution of consumption or demand. But it has already been shown that the consumption and demand occasioned by the workmen employed in productive labour can never *alone* furnish a motive to the accumulation and employment of capital; and with regard to the capitalists themselves, together with the landlords and other rich persons, they have, by the supposition, agreed to be parsimonious, and by depriving themselves of their usual conveniences and luxuries to save from their revenue and add to their capital. Under these circumstances, it is impossible that the increased quantity of commodities, obtained by the increased number of productive labourers, should find purchasers, without such a fall of price as would probably sink their value below that of the outlay, or, at least, so reduce profits as very greatly to diminish both the power and the will to save (*Principles* II, 314–15).

The greatly increased productive powers of the post-Napoleonic era placed Britain somewhat in the position of the economy described above. That people would eventually come to desire more goods Malthus had no doubt; but he was equally convinced that such desires could not be taken for granted:

> That an efficient taste for luxuries and conveniences, that is, such a taste as will properly stimulate industry, instead of being ready to appear at the moment it is required, is a plant of slow growth, the history of human society sufficiently shows; and that it is a most important error to take for granted, that mankind will produce and consume all that they have the power to produce and consume, and will never prefer indolence to the rewards of industry, will sufficiently appear from a slight review of some of the nations with which we are acquainted (*Principles* II, 321).

Since the critical reason for a general glut was the satiation of wants in the short run, the remedies suggested by Malthus naturally described ways of raising the short-run marginal propensity to consume. One way of achieving this end was by redistributing income towards the working classes, since the poor had much less trouble spending their money than the rich.

> Thirty or forty proprietors, with incomes answering to between one thousand and five thousand a year, would create a much more effectual demand for the necessaries, conveniences and luxuries of life, than a single proprietor possessing a hundred thousand a year (*Principles* II, 374).

Political considerations however prevented Malthus from seriously advocating systematic redistribution as a cure for economic depressions. Another possible remedy, and one much more amenable to Malthus's partialities, was the existence of a large group of 'unproductive consumers', i.e., individuals who had incomes but did not produce market-oriented outputs. Clergymen formed a good example of a group who contributed to the aggregate demand without adding to the market supply. It is worth noting that the role of defence expenditures as a means of maintaining aggregate demand is a direct application of this argument, a point frequently missed by radicals who have followed Karl Marx in refusing to see substantial merit in Malthus's economics.

Malthus felt unable to state any determinate proportion between productive and unproductive consumers required for the maintenance of aggregate demand. Ricardo would have none of this. Perhaps because he failed to grasp Malthus's specific definition of the term, Ricardo believed unproductive consumers to be as useful as fires and the determination of their exact proportion was no puzzle.

> I should find no difficulty to determine. They may be useful for other purposes but not in any degree for the production of wealth (*Notes*, 422).

A final remedy suggested by Malthus for gluts, and one reflective of his emphasis upon short-run dynamics, was the creation of new wants. One of the great benefits of finding new markets, according to Malthus, was that new commodities would be introduced, which in turn would stimulate consumers desires and make them more eager to spend. Referring to the depression of the cotton industry of Glasgow, Malthus said,

> It is specifically to overcome the want of eagerness to purchase domestic commodities that the merchant exchanges them [with foreigners] for others more in request. Could we but so alter the wants and tastes of the people of Glasgow as to make them estimate as highly the profusion of cotton goods which they produce, as any articles which they could receive in return for them under a prosperous trade, we should hear no more of their distresses (*Principles* II, 392–3).

It would be a mistake to consider the satiation of wants argument as peculiar to Malthus. Many of his contemporaries made the same point, although perhaps with less forcefulness. It would even appear to be the main objection to an acceptance of Say's Law by many political economists of the period 1820–1840. The prevalence of such objections was perhaps responsible for the clarification of the insatiability argument in this period. Both Nassau Senior and W.F. Lloyd spelled out at length the fact that satiation for each good was reasonable; it was only the continuous creation of new goods that made the insatiability argument acceptable. Malthus was aware of this point and had noted that the creation of such desirable new goods was precisely the root of the difficulty:

> It will be readily allowed that a new commodity thrown into the market, which, in proportion to the labour employed upon it, is of higher exchangeable value than usual, is precisely calculated to increase demand . . . But to fabricate or procure commodities of this kind is the grand difficulty; and they certainly do not naturally and necessarily follow an accumulation of capital and increase of commodities (*Principles* I, 356).

The belief that Malthus attributed gluts to a shortage of aggregate income is a later and incorrect construction. Supporters of Say's Law had pointed out that since everything that was produced was income to somebody the aggregate of rent, wages and profits must suffice to buy aggregate output. Malthus fully accepted the point that the income was there; what he questioned was whether people would spend their incomes.

> It has been repeatedly conceded, that the productive classes have the power of consuming all that they produce; and, if this power were adequately exercised, there might be no occasion, with a view to wealth, for unproductive consumers. But it is found by experience that, though there may be the power, there is not the will; and it is to supply this will that a body of unproductive consumers is necessary (*Principles* I, 489).

Whatever the workers may desire to consume, they certainly did not possess the ability to

purchase the entire output; the landlords and unproductive consumers were not numerous enough to keep demand high while the capitalists produced not to consume but to gain prestige and save money for their children. Since the last class did most of the producing, their niggardly wants contributed to the rise of a general glut.

The persistence of Say's Law as one of the dogmas of classical economics is largely due to the unwillingness of Ricardo and Say to follow through the consequences of the concessions they were forced to make to Malthus. When asked where the increased productions were to find consumers, Ricardo replied:

> If they were suited to the wants of those who would have the power to purchase them, they could not fail to find purchasers, and that without any fall of price (*Notes*, 303–304).

John Chipman (1965, p. 3) has aptly noted the greatly reduced significance of this version of Say's Law: '[Ricardo's] version of the classical principle takes much of the punch out of Say's Law; supply creates its own demand, yes – provided, of course, that not more is supplied than will be demanded.' J.B. Say made a similar concession and this makes the continuance of 'Say's Law' in the published works of both Ricardo and Say an unfortunate anomaly.

In more recent times, a failure to understand Malthus has been largely fostered by the eulogy of Lord Keynes. By stating that 'Malthus is dealing with the monetary economy in which we happen to live', Keynes suggested that Malthus's analysis was somehow concerned with monetary factors, which is not the case at all, and the search for monetary influences has misled some later scholars. If we must use Keynesian concepts, then Malthus's argument was that the Consumption Function became horizontal (in the short run) at levels of income greatly in excess of those consumers are habituated to. As producers myopically extrapolated an increasing consumption function, expectations were bound to be dashed if the economy were sufficiently productive. The tendency to ask whether Malthus was an early Keynesian has also been fruitful in generating mistakes regarding Malthus's thoughts. Since the satiability of wants plays no role in Keynesian analysis it is easy to answer such questions in the negative, but it is essential to note that such questions miss the real point. Malthus tried to analyse the British economy between 1810 and 1820 and his analysis should be judged primarily in terms of the problem he set out to solve.

Conclusion

Thomas Robert Malthus made several notable contributions to economic theory. He provided the first clearly reasoned arguments for basing National Income accounts solely on material goods; in the process he discovered most of the problems that later generations of National Income Statisticians have had to solve. He deserves some credit for re-discovering the differential fertility theory of rent. Malthus greatly extended the scope of demand and supply as fundamental economic concepts. In particular, he provided a treatment of factor markets in these terms, thereby advancing economic theory well beyond the stage at which Adam Smith had left things. He was equally inventive in observing some major limitations to the body of Smithian analysis. The most famous such exception is the possibility of a general glut of commodities whenever accumulation becomes overly rapid; equally challenging was Malthus's statement that free International Trade was a boon only to countries which produced complementary and not competitive goods. Apart from these specific contributions, his balanced and judicious methodological guidelines provide useful reading even today. Even after making allowance for exaggeration, the basic truth of Lord Keynes's conclusion appears sound: 'if only Malthus, instead of Ricardo, had been the parent stem from which 19th-century economics proceeded, what a much wiser and richer place the world would be today.'

Malthus, Thomas Robert (1766–1834)

J.M. Pullen

Abstract

A brief biographical sketch precedes a discussion of important methodological features of Malthus's work, especially his 'doctrine of proportions' and the need for moderation and balance in economic principles and policies. His principle of laissez-faire admitted exceptions; and, although his principle of population warned of over-population, he acknowledged the potential advantages of population growth. His ideas on the Poor Laws, the Corn Laws, Say's Law, and the relation between saving and investment are discussed; and the roles given to effective demand and to distribution as a factor of production, especially the distribution of landed property, are emphasized.

Malthus has the unusual distinction not only of being a founder of classical economics – mainly because of his principle of population – but also of being instrumental in attempts to overthrow classical economics, mainly because of his principle of effective demand and its influence on John Maynard Keynes.

The most comprehensive and authoritative source of biographical information on Malthus is James (1979), from which the following brief details have been largely derived. Additional information can be found in the first edition of *The New Palgrave: A Dictionary of Economics* (Pullen 1987), Malthus (1989b, pp. xv–lxix), and the *Oxford Dictionary of National Biography* (Pullen 2004). Malthus was born on 13 February 1766, near Wotton, in the county of Surrey, England, and died on 29 December 1834, at Bath. He was buried in Bath Abbey where there is a commemorative plaque. Although he was baptized Thomas Robert, he used his full name only in formal situations; in less formal correspondence he signed himself T. Robert Malthus or Robert Malthus, and was known to family and close friends as Robert or Bob.

He was the son of Henrietta (née Graham) (1733–1800) and Daniel Malthus (1730–1800). The latter, having inherited independent means, cultivated literary, artistic, scientific and theatrical interests. He was an admirer and correspondent of Rousseau, who once visited the family home soon after Malthus's birth. The extensive library of Daniel Malthus was eventually passed on to Malthus and, supplemented by acquisitions of his own and other family members, is now held in Jesus College, Cambridge.

Malthus graduated in 1788, and in 1789 was ordained deacon with title to a stipendiary curacy at the small chapel at Okewood in the parish of Wotton. He was ordained priest in 1791, was appointed non-resident Rector of Walesby in Lincolnshire in 1803, and succeeded to the perpetual curacy of Okewood in 1824. He married in 1804 and had three children, but no grandchildren. In 1805 he was appointed to the East India College as 'Professor of General History, Politics, Commerce and Finance', a title later altered to 'Professor of History and Political Economy'. He held the post for the rest of his life, residing in the College at Haileybury, near Hertford. As well as performing his teaching duties, he preached regularly in the college chapel. The important collection of Malthus manuscripts held at Kanto Gakuen University in Japan (Malthus 1997, 2004) contains four of his sermons. They corroborate the statement of his colleague William Empson: 'Mr. Malthus was a clergyman – a most conscientious one, pure and pious. We never knew one of this description so entirely free of the vices of his caste' (Empson 1837, p. 481). His main publications were *An Essay on the Principle of Population,* first published in 1798, with five further editions in 1803, 1806, 1807, 1817 and 1826, and *Principles of Political Economy,* first published in 1820 with a posthumous second edition in 1836. He also published at least 20 smaller works – his authorship of a 21st is disputed – and evidence he gave at two public enquiries can be found in the published reports. There is a full list of his publications in *The New Palgrave* (Pullen 1987) or in Malthus (1986, vol. 1, pp. 41–4). He engaged in extensive correspondence throughout his career, with Ricardo and many others. More than 230 letters to and from over 50 correspondents are known to have survived.

Malthus's Methodology: 'The Doctrine of Proportions'

Before considering particular aspects of Malthus's political economy, it is important to understand some of the peculiar features of his methodology. Failure to do so has resulted in many misunderstandings and unnecessary disagreements among commentators.

One of the most important, but one of the most unrecognized, aspects of Malthus's methodology was the principle that he called the 'doctrine of proportions'. This was the traditional ethical notion of the just mean or middle way. As Leslie Stephen (1893) said, in the first *Dictionary of National Biography,* Malthus was always 'a lover of the golden mean'. The distinctive innovation of Malthus lay in applying the concept to political economy, and in giving it such a prominent and consistent role.

He stated that his aim was to show 'how frequently the doctrine of proportions meets us at every turn, and how much the wealth of nations depends upon the relation of parts'. It was his view that 'all the great results in political economy, respecting wealth, depend upon *proportions'*, and warned that the 'tendency to extremes is one of the great sources of error in political economy, where so much depends upon proportions'. He added that 'It is not, however, in political economy alone that so much depends upon proportions, but throughout the whole range of nature and art' (1989b, vol. 1, pp. 352, 432; vol. 2, pp. 252, 269, 278).

Malthus's doctrine of proportions is thus essentially the same as the concept of the optimum. Although he did not use the term 'optimum', he must be recognized as having been one of the first to introduce the concept of the optimum into economics. In giving this central role to the doctrine of proportions, he has in effect said that *the* economic problem is the problem of balance, not the problem of choice.

But, despite his widespread use of the doctrine of proportions, Malthus recognized that precise determination of optimum points would be difficult. In discussing the optimum level of saving, he acknowledged that 'the resources of political economy may not be able to ascertain it' (1989b, vol. 1, p. 9), and, in discussing the just means for saving and the division of landed property, he said 'the extremes are obvious and striking, but the most advantageous mean cannot be marked' (1989b, vol. 1, p. 10).

The moderation and balance implied by the doctrine of proportions was evident in Malthus's

personal temperament. Bishop Otter, who knew Malthus for nearly 50 years, said that he 'scarcely ever saw him ruffled, never angry, never above measure, elated or depressed', and that Malthus possessed 'a degree of temperance and prudence, very rare at that period, and carried by him even into his academical pursuits' (in Otter 1836, pp. xxxii, xlix); and William Empson said in reference to the doctrine of proportions: 'The lesson which he sought to impress on others, he faithfully applied to himself; and so successfully, that few characters have ever existed of more perfect symmetry and order' (Empson 1837, pp. 476–7).

Malthus has been given credit for introducing or propagating, either alone or with others, a number of key ideas in the history of economics; notably, the principle of population, the law of diminishing returns, and the role of effective demand. The doctrine of proportions could be added to the list.

Limitations and Exceptions

Another facet of Malthus's methodology was his insistence on limitations and exceptions to the general principles in political economy. This could be seen either as a corollary of his doctrine of proportions or as another way of expressing the same doctrine. He believed that there are some general principles in political economy to which exceptions are 'most rare', but added 'yet there is no truth of which I feel a stronger conviction than that there are many important propositions in political economy which absolutely require limitations and exceptions' (1989b, vol. 1, p. 8). In this respect, he departed from the absolutist and universalist aspirations of some of his contemporaries, who, anxious to promote the scientific credentials of political economy, pretentiously declared them to be 'laws'. He was critical of the 'precipitate attempt to simplify and generalize', which he regarded as the 'principal cause of error, and of the differences which prevail at present among the scientific writers on political economy' (1989b, vol. 1, pp. 5–6).

Malthus has been accused, in his own day and now, of lacking in logic, especially by comparison with Ricardo. The accusation that his views did not constitute a logical and coherent system appears to have emanated from a failure to appreciate that his views were formulated in the context of his doctrine of proportions, and that he believed exceptions and limitations frequently have to be admitted when principles are used to formulate policies for application to particular real-world circumstances.

Laissez-Faire and Government Intervention

Malthus strongly supported the principle of laissez-faire or freedom of trade: 'the wealth of nations is best secured by allowing every person, as long as he adheres to the rules of justice, to pursue his own interest in his own way', and 'governments should not interfere in the direction of capital and industry, but leave every person, so long as he obeys the laws of justice, to pursue his own interest in his own way'. He described this as a 'great principle' and as 'one of the most general rules of political economy' (1989b, vol. 1, pp. 3, 13, 518).

But he also argued that some exceptions to the principle of laissez-faire have to be recognized, and that the principle of non-interference is 'necessarily limited in practice' (1989b, vol. 1, 18–19, 525). He believed that there are certain duties that belong to the government – for example, in areas such as education; support of the poor; construction and maintenance of roads, canals, and public docks; colonization and emigration; and the support of forts and establishments in foreign countries – although he recognized that there may be differences of opinion about the extent to which government should share in such matters. In particular, the 'necessity of taxation ... impels the government to action, and puts an end to the possibility of letting things alone' (1989b, vol. 1, pp. 18–19).

Thus, although Malthus strongly supported the principle of laissez-faire, his support, like that of Adam Smith, was pragmatic and conditional rather than dogmatic and absolute. There was, however, a major difference in their conception

of the laissez-faire principle. In what Donald Winch has described as 'an attack on a central feature of the *Wealth of Nations*' and as 'a major qualification to Smith's system of natural liberty', Malthus doubted whether economic growth has always been, or will always be, advantageous to the mass of society. Malthus criticized Smith's view that the economic growth of Britain during the 18th century had improved the living standards of the labouring classes; he recognized that investments in trade and manufacturing had benefited individual capitalists, but argued that they were of less benefit to society as a whole. Thus Malthus raised the possibility of conflict between economic growth and human happiness, and implied that interventionist welfare policies by government might be justified. In this respect, as Winch has argued, 'if general allegiance to the system of natural liberty, as interpreted by Smith and upheld under the different circumstances by some of his followers, is the hallmark of an orthodox political economist during the first half of the nineteenth century, Malthus occupies a decidedly ambivalent position' (Winch 1987, pp. 32, 59–61, 76–7).

Population

Malthus's first published work – *An Essay on the Principle of Population* (1798) – was written primarily to controvert the perfectibilist notions of Godwin and Condorcet. He believed that the growth of population presented a major obstacle to unlimited human progress. He argued that population will constantly tend to exceed the food supply, with the result that human progress will be neither rapid nor unlimited, and will be accompanied by sufferings and evils arising from the operation of unavoidable checks to population growth.

To support his views on the threat of overpopulation to human progress, Malthus introduced the notion of the two ratios. He argued that population will tend to increase in a geometrical ratio (1, 2, 4, 8 ...) doubling every 25 years; but the food supply will increase only in an arithmetical ratio (1, 2, 3, 4 ...). He believed that the population of 'this Island' was then about seven million, and that after the first 25 years it would reach 14 million, after 50 years 28 million, after 75 years 56 million, and so on. But the utmost that could be expected for the supply of food is that there would be sufficient to feed 14 million after 25 years, 21 million after 50 years, 28 million after 75 years, and so on. Thus, after the first 25 years, the food supply would become insufficient, and any further progress in the size of the population and the standard of living would be impossible. He concluded that this argument is conclusive against the perfectibility of the mass of mankind.

Opinions differ on whether Malthus's principle of population depends essentially on the empirical accuracy of these ratios or whether they were intended merely as approximate tendencies, or as a mathematical metaphor. Whatever his intention, there is no doubt that the ratios have exerted a powerful rhetorical influence in promoting his message and his fame.

Malthus was not the first writer to issue a warning about the dangers of overpopulation, as he himself acknowledged, but for a variety of reasons his arguments have become the best-known, and have exerted a great influence on human thought and human affairs. He alerted the world to the problem of overpopulation, and his views continue to affect the population policies of governments through the world today.

Having presented his basic arguments in the first two chapters of the *Essay,* Malthus then proceeded to discuss the 'checks' to population. As he said in his first postulate, people cannot live without food, and therefore it would be impossible to have a situation where 28 million people were in existence but the food supply was adequate for only 21 million. There must therefore be some mechanisms or checks whereby populations are prevented from exceeding the food supply. The bulk of the *Essay*, especially in the much enlarged later editions, was devoted to a detailed description of the checks that have operated in different countries and at different times.

He classified the checks as either positive checks that reduce normal life expectancy and increase the death rate, or preventive checks that

reduce the birth rate. Among his list of positive checks he included common diseases, epidemics, wars, plagues, pestilence, famines, infanticide, unwholesome occupations and habitations, severe labour, exposure to the seasons, extreme poverty, bad nursing of children, great cities, and excesses of all kinds.

The preventive checks, described in circumspect language ('vicious customs with respect to women'), included prostitution and birth control, but the only preventive check that he approved of and advocated was prudential restraint, by which he meant delaying marriage until sufficient resources of food, accommodation and other necessaries are available to provide the parents and the expected number of children with an acceptable standard of living. He noted that prudential restraint is practised, and should be practised, by those who want to maintain after marriage the social and economic status they enjoyed before marriage. The case for prudential restraint was even more vigorously argued in the later editions, where those who marry and raise children without ensuring that they have sufficient resources are accused of irresponsible and immoral behaviour.

He also classified the population checks as either vice or misery, but did not clearly show how the vice-and-misery classification is related to the positive-and-preventive. Presumably he meant that, among the positive checks, some, such as war and infanticide, are vices, and all lead to misery; and among the preventive checks all except prudential restraint are vices, and all are likely to lead to misery; and although prudential restraint is a virtue, not a vice, it often leads to vice.

> Restraints upon marriage are but too conspicuous in the consequent vices that are produced in almost every part of the world; vices, that are continually involving both sexes in 'inextricable unhappiness'. (1986, vol. 1, p. 28)

In admitting that prudential restraint might also be a cause of misery, he might have been speaking from personal experience, being in 1798 a 32-year-old bachelor with an income as a curate insufficient to support a wife and family in a socially acceptable manner.

In the second and later editions, he introduced the expression 'moral restraint', by which he meant prudential restraint conducted in accordance with Christian moral precepts regarding premarital sex, but the *concept* of moral restraint is *implicit* in the first edition. It is unlikely that, in advocating prudential restraint, Malthus as a Protestant clergyman would have intended to condone prudential restraint that was accompanied by immoral sexual behaviour.

In the second (and later) editions of the *Essay,* he softened some of the harshest conclusions of the first by arguing that, if people could be made aware of the harm done by improvident procreation, then moral restraint, though still a difficult challenge, could be practised without causing misery and without leading to vicious practices. He objected to contraception on moral grounds and also because, by facilitating control of the birth rate and reducing the pressure of population, it would remove one of the incentives needed to overcome our natural indolence, to promote economic growth, and to encourage the 'growth of mind'. It is ironical that the expression 'Malthusian practices' became synonymous with contraception, and that contraception has become the method most commonly adopted throughout the world to control population. The world has responded to Malthus's warnings of the danger of overpopulation by adopting a remedy he strongly rejected.

Arguments in Favour of Population Growth

The popular and superficial view of Malthus is that he was opposed to population growth. But there are numerous instances in his writings which show that he regarded an increase of population, under certain conditions, as desirable in itself, and as a necessary cause of economic growth. For example, he spoke of the 'pursuit of the desirable object of population' (1986, vol. 3, p. 455); and, referring to the possibility of a great increase of population in Ireland in the 19th century, he said 'so great an increase of human beings, if they could be well supported, would be highly

desirable' (1986, vol. 4, p. 32). In a similar vein he said: 'That an increase of population, when it follows in its natural order, is ... a great positive good in itself, ... I should be the last to deny' (1989a, vol. 1, p. 439). And those who use Malthus to support a policy of population reduction forget that on one occasion he argued that a diminution of population would be harmful: 'It is evidently therefore regulation and direction which are required with regard to the principle of population, not diminution or alteration' (1989a, vol. 2, p. 94).

Some of his most forceful statements in favour of population growth occurred in the appendices added to the third (1806) and fifth (1817) editions of the *Essay,* in response to critics who had accused him of being anti-population. The fact that these appendices have been omitted from some modern reprints of the *Essay* might explain the limited awareness of his pro-population ideas.

Malthus's pro-population views can even be seen when he was advocating prudential restraint: 'Prudential habits with regard to marriage carried to a considerable extent, among the labouring classes of a country mainly depending upon manufactures and commerce, might injure it' (1989b, vol. 1, p. 236; vol. 2, p. 215). This is a surprising argument, given that he had said that the preventive check of prudential restraint should be a principal remedy for overpopulation. It shows that he wished the doctrine of proportions to be applied as a check to the preventive check!

Malthus's pro-population views can also be seen in his statements on population as a *necessary* cause of economic growth. He admitted that population growth alone will not promote economic growth; for example, he argued that 'the increase of population alone ... does not furnish an effective stimulus to the continued increase of wealth' (1989b, vol. 1, pp. 347–8), 'population alone cannot create an effective demand for wealth' (1989b, vol. 1, p. 350) and 'encouragements to population ... will not alone furnish an adequate stimulus to the increase of wealth' (1989b, vol. 1, p. 351). But he also stated:

> That a permanent increase of population is a powerful and necessary element of increasing demand, will be most readily allowed. (1989b, vol. 1, p. 347; in the second edition, 'permanent' was changed to 'continued')
>
> and
>
> That an increase of population, when it follows in its natural order, is ... absolutely necessary to a further increase in the annual produce of the land and labour of any country, I should be the last to deny. (1989a, vol. 1, p. 439)

In other words, although Malthus recognized that population growth is not a *sufficient* cause of economic growth, he nevertheless regarded it as a *necessary* cause.

In some circumstances, according to Malthus, an increase in population will bring about a decrease in living standards; but in other circumstances it will bring about an increase in living standards, and a decrease in population will bring about a decrease in living standards. Living standards can be both a direct and an inverse function of population. Some critics would regard this as self-contradictory, as proof of his lack of logic, and as a justification for William Cobbett's epithet 'muddle-headed Malthus'. Others would see it as a reasonable, parabolic application of the doctrine of proportions.

Theological Aspects of the Principle of Population

The early chapters of the first edition of the *Essay* have a rather pessimistic tone. They appear to be saying that the pressure of population against the food supply will keep the mass of the population at or near subsistence level, and that this struggle between food and population will be accompanied by miseries and vices. However, in the last two chapters of the first edition of the *Essay* Malthus explored the theological implications of his principle of population. His published contributions in theology are too limited for him to be considered as a theologian in a professional sense, but his theological views are interesting in their own right, because of their heterodox nature, and because they seem to have been presented, not as a mere afterthought or pious homily, but in an attempt to integrate his principle of population into a comprehensive world view, in opposition to that of Godwin and Condorcet. As a Christian

minister he would have been concerned to show that his view of population did not conflict with Christian ideas about the nature of God. He had due cause for concern. In saying that misery and vice can come from obeying the biblical injunction to go forth and multiply, he was accused by some critics of blasphemously denying the Creator's omnipotence, omniscience and benevolence.

However, in the last two chapters of the first edition of the *Essay* he argued, on the contrary, that population pressure is providentially ordained by God as a means whereby human development ('the growth of mind') is stimulated. He argued that the constant pressure of population against food supply, although it might produce some moral and physical evils, would also produce an overbalance of good. The first edition of the *Essay* thus finished on a note of moral and theological optimism.

The last two chapters were omitted from subsequent editions of the *Essay*. Comments contained in his correspondence (1997, pp. 73–7) and remarks from other contemporaries indicate that the omission occurred at the instigation of friends. Some commentators interpret the omission as a recantation. Others find traces of his theology in the later editions, and argue that his growth-of-mind theology remained an essential, if only implicit, framework throughout all editions of the *Essay*. They argue that to ignore its theological aspect is to ignore an essential element of his total population theory and, contrary to his intentions, to reduce the *Essay* to a mere economic or political tract.

Poor Laws

Although Malthus believed that population pressure was a phenomenon common to most societies, he argued that the problem had been exacerbated in England by the Poor Laws. They were intended to alleviate poverty, but only succeeded in creating the poor they sought to maintain. They encouraged people to marry too early and have large families, in the expectation that food and accommodation would be provided for them; and they discouraged hard work and the development of productive skills.

In his earlier writings Malthus had argued for abolition of the Poor Laws, both as a principle and as a practical policy; but in later writings and in correspondence (see James 1979, p. 450; Winch 1996, pp. 320–1) his position moved from complete abolition to gradual abolition, and then to administrative reform, arguing that a fundamental change involving complete abolition would present practical and political difficulties, and that the most that could be achieved in the current circumstances would be an amelioration of the present system through improved administration.

This is an example of his insistence on the need for limitations and exceptions in the practical application of general principles. He did not see any contradiction in subscribing to the idea in principle while at the same time rejecting it as a practical policy for a particular place and time. Another example of this feature of his methodology occurred in his views on the Corn Laws.

Corn Laws

Although Malthus strongly supported the principle of laissez-faire, he published a pamphlet in 1815 supporting the retention of the Corn Laws which prohibited for example, the import of wheat when the home price fell below 80 shillings a quarter. This radical departure from laissez-faire caused dismay among other political economists and among his Whig friends who opposed the protectionist policy of the Tory government. In admitting this exception to the principle of laissez-faire, he was in effect reaffirming his view that, unlike the laws of mathematics, the principles of political economy should not be applied in an absolutist and universalist manner.

It has been argued that in his later years Malthus changed his mind and recanted his earlier support for the Corn Laws. The arguments for and against this change-of-mind hypothesis have been elaborated elsewhere (Hollander 1992, 1995; Pullen 1995), and are too detailed to be repeated here. It would probably be fair to say that, on the basis of the textual and contextual evidence so far presented, there is no clear, unambiguous statement of a recantation by Malthus.

But it should also be said that Malthus was strongly in favour of the principle of free trade, and that he strongly regretted the need for an exception in the case of the Corn Laws. It is obvious from his writings and correspondence that, if the circumstances that necessitated the exception were removed, he would have gladly removed his support for agricultural protection.

Economic Growth, Effective Demand and Say's Law

Malthus's views on economic growth are to be found scattered throughout his many publications, with his most systematic (but not comprehensive) treatment of this topic in the final chapter of the *Principles,* namely. chapter 7, 'On the Immediate Causes of the Progress of Wealth'. He divided the immediate causes of progress into two categories: 'the powers of production' and 'the means of distribution'. On the production side he discussed four causes: population, accumulation, soil fertility and inventions (which, by combining the second and the fourth, could be reclassified as labour, capital and land). On the distribution side he discussed three causes: the division of landed property, commerce (internal and external), and unproductive consumers. His views on the production side were unremarkable at the time, and would be quite acceptable in standard texts today, but his views on the distribution side have proved to be controversial because of their emphasis on the role of effective demand.

By effective or effectual demand Malthus meant the *power* to purchase at a price sufficient to cover the vendor's costs and required profit, combined with the *willingness* to purchase. His distinction between power and will, or means and motives, was a recurring theme in his political economy. He stressed that production requires more than the power to produce; it requires also the motive to produce, which comes from effective demand.

> ... the powers of production, to whatever extent they may exist, are not alone sufficient to secure the creation of a proportionate degree of wealth. Something else seems to be necessary in order to call these powers fully into action. This is an effectual and unchecked demand for all that is produced. (1989b, vol. 1, p. 413; vol. 2, pp. 263, 447)

The powers of production will be 'called into action, in proportion to the effective demand for them' and 'General wealth, like particular portions of it will always follow effective demand (1989b, vol. 1, pp. 414, 417). In effect he was saying that demand-side forces are as powerful and as necessary as the supply-side forces of natural resources, capital accumulation, division of labour, and so on.

He believed that an important cause of an adequate level of effective demand was the existence of a body of 'unproductive consumers', who purchase material products but do not produce material products. They would include menial servants, military personnel, actors, clergymen and other service providers. The concept was completely misunderstood by Ricardo who said that unproductive consumption is as useful as a fire in a warehouse or the destruction of war. Malthus later recognized that the term 'unproductive' had pejorative implications, and altered it to 'the provision of services'. However, the concept could also include those who live on their investments in the national debt and those whose wealth enables them to consume without either producing material goods or providing services, thus inviting Marx's description of Malthus as a protector of the ruling classes and the idle rich.

Malthus's views on effective demand were largely rejected during his lifetime, and largely ignored for the next hundred years. It was generally believed with James Mill, Jean-Baptiste Say and others that the purchasing power generated during the production process would be sufficient for all the products to be sold, that aggregate demand deficiency would never be a cause of economic decline, and that a general glut of products would be impossible. This view, known as Say's Law or Mill's Principle, and popularly expressed as 'supply creates its own demand', became a standard theme of classical economics, and still finds its supporters, even though Malthus showed, and Say virtually admitted, that its validity relies on a tautological definition of 'supply' and 'product'. The experience of the depression of the 1930s

and the publication of J.M. Keynes's *General Theory* (1936) cast doubt on this conventional wisdom of Say's Law, and rescued Malthus's views on effective demand from oblivion.

Effective Demand and the Division of Landed Property

Malthus's views on effective demand as a stimulus to economic progress led him to advocate a wider distribution of wealth, because 'Practically it has always been found that the excessive wealth of the few is in no respect equivalent, with regard to effective demand, to the mere moderate wealth of the many' (1989b, vol. 1, p. 431). But this redistribution of property has often been neglected, and sometimes even denied, in the secondary literature. Karl Marx, in particular, misinterpreted Malthus in this regard, and some other commentators appear to have taken their views of Malthus from Marx; and, like Marx, have not bothered to test them against Malthus's text.

Admittedly, there are passages in some parts of Malthus's writings that support a pro-landlordism interpretation. But in other passages he was critical of the distribution of land and other property, and described the existing maldistribution as unjust and as an impediment to economic growth; for example.

> A very large proprietor, surrounded by very poor peasants, presents a distribution of property most unfavourable to effective demand ... Thirty or forty proprietors, with incomes answering to between one thousand and five thousand a year, would create a much more effective demand for wheaten bread, good meat, and manufactured products, than a single proprietor possessing a hundred thousand a year. (1989b, vol. 2, 373–4)

In his view, 'the division of landed property is one of the great means of the distribution of wealth', and without 'an easy subdivision of landed property ... a country with great natural resources might slumber for ages with an uncultivated soil, and a scanty yet starving population' (1989b, vol. 1, pp. 439–40).

He did not propose that either private property in land or the class of landed proprietors should be abolished. He regarded both as necessary. But he did not regard 'the present great inequality of property' as 'either necessary or useful to society'; and added that 'On the contrary, it must certainly be considered as an evil, and every institution that promotes it is essentially bad and impolitic' (Malthus 1986, vol. 1, p. 102). Less inequality in land ownership would mean that rents would be enjoyed by a larger number of proprietors.

However, he did not wish the division of property to be pushed too far:

> The division and distribution of property, which is so beneficial when carried only to a certain extent, is fatal to production when pushed to extremity. (1989a, I, 372)

This argument is an excellent illustration of his characteristic middle-way methodology. He himself regarded the question of the division of property as the most important application of the doctrine of proportions.

> It will be found, I believe, true that all the great results in political economy, respecting wealth, depend upon *proportions* ... But there is no part of the whole subject, where the efficacy of proportions in the production of wealth is so strikingly exemplified, as in the division of landed and other property; and where it is so very obvious that a division to a certain extent must be beneficial, and beyond a certain extent prejudicial to the increase of wealth. (1989b, vol. 1, pp. 432–3)

Distribution as a Factor of Production

Other writers, before and after Malthus, have discussed production and distribution, but generally their approach has been to regard distribution as the process whereby the proceeds of production are shared out after they have been produced by the factors of production. Their theory of distribution is worked out independently of their theory of production.

Malthus also looked at the problem of distribution in this way, with separate chapters analysing the way in which wages, profits and rents are determined. But in addition he looked at distribution from another direction. For Malthus, distribution is not merely concerned

with sharing out the spoils of production. It has a further function. It is an essential determinant of production, and an integral part of the production process considered in its totality. Without a proper distribution, there would be no production – except at a self-subsistence level. He saw distribution as a problem to be resolved *before* (as well as after) production takes place. Whereas others were concerned mainly with how the distribution of the product between wages, profits and rent is affected by economic development, Malthus made a major contribution by stressing that the distribution of the product in turn affects economic development. He was in effect saying, if not in these precise words, that distribution must be regarded as a factor of production, along with the conventional listing of the other factors of production – land, labour and capital. They represent only the supply side of the production process; but, if production is to occur, there must be a motive to produce as well as the means. In an exchange system, there will be no motive for producers to produce unless there are prospects of profits, and there will be no profit prospects unless there is an adequate effective demand for the products. This effective demand from potential consumers will not be forthcoming unless there has been a proper distribution of spending power. As Malthus said, 'there is certainly no indirect cause of production as powerful as consumption' (1989b, vol. 2, p. 34). The effective demand generated by a proper distribution provides demanders with the power or means to demand, and this provides suppliers with the will or motive to supply. It is obvious that, unless there has been production, there can be no distribution. But Malthus insisted that maximum production will not be achieved unless an optimum spread of distribution is established.

The separation and dichotomy between production and distribution that is presented in typical textbooks would therefore have been unacceptable to Malthus, for whom any listing of the factors of production would have to include distribution. It is this relationship of reciprocal causation between distribution and production that makes Malthus's theory of distribution innovative and distinctive.

Saving, Investment and Hoarding

Some commentators have interpreted Malthus as holding that savings are always invested; and have concluded that in Malthus's theory saving is not a leakage from the circular flow, does not constitute a reduction in effective demand, is not an impediment to economic growth, and must always be beneficial. In this respect, they see a major difference between Malthus and Keynes. They deny the claim that Malthus was a precursor of Keynes, and argue that Keynes was mistaken in regarding Malthus as a precursor. This interpretation appears to have been based in part on statements such as:

> it is stated by Adam Smith, and it must be allowed to be stated justly, that the produce which is annually saved is as regularly consumed as that which is annually spent, but that it is consumed by a different set of people. (Malthus 1989b, vol. 1, p. 31)

Malthus appears here to agree with Adam Smith that savings will always find an outlet in investment, and that there will never be a surplus of savings over investment. However, that interpretation is doubtful, given that 'and it must be allowed to be stated justly' was omitted from the second edition of the *Principles* (see Malthus 1989b, vol. 2, pp. 28, 300–1). Ricardo in his *Notes on Malthus* had said that a saving-equals-investment interpretation is inconsistent with the views expressed elsewhere by Malthus on saving. It would be reasonable to conclude that the omission was made by Malthus in response to Ricardo's note (Ricardo 1951–73, vol. 2, p. 15, n. 4).

Another possible source for attributing a saving-equals-investment view to Malthus might be Malthus's statement 'No political economist of the present day can by saving mean mere hoarding' (1989b, vol. 1, p. 32). Some commentators have interpreted this to mean that, in Malthus's view, savings are always invested, never hoarded, and never intended to be hoarded. If correct, such an interpretation would also constitute a major difference between Malthus and Keynes.

But there is another, more plausible, interpretation. Malthus here was not saying that savings are never held as idle cash balances. He was not precluding the possibility that savings might remain uninvested and idle, not on purpose but

because a satisfactory investment outlet cannot be found. This alternative interpretation negates a saving-equals-investment interpretation.

There are numerous instances in Malthus's writings that support this alternative interpretation. They clearly show that, in his view, savings will not always be invested, and that excessive savings are harmful. For example, Adam Smith had said that 'every frugal man [appears to be] a publick benefactor' and that the increase of wealth depends on a favourable balance of production over consumption (Smith 1776, book II, ch. 3, para. 25; book IV, ch. 3, iii, para. c.15), but Malthus disagreed:

> That these propositions are true to a great extent is perfectly unquestionable ... but it is quite obvious that they are not true to an indefinite extent. (1989b, vol. 1, 8)

To say that Malthus identified or equated saving and investment is to ignore his frequent use of expressions such as redundant capital, excessive capital, idle capital, spare capital, premature supply of capital, unemployed capital, vacant capital, capitalists at a loss where they can safely employ their capitals, capitals at a loss for employment, and so on. These expressions refer to funds that arise through savings and are intended for investment but for which an actual investment, at an acceptable degree of profit and risk, cannot be found. Malthus was thus recognizing the possible existence of an inequality between *ex ante* or intended investment and *ex post* or actual investment, because of the exhaustion of profitable investment outlets. This gap between savings intended for investment and savings actually invested could be described as unintended or residual hoarding – although Malthus did not use those terms – as distinct from the intended hoarding of a miser, or 'mere hoarding'.

Malthus and Ricardo

The correspondence between Malthus and Ricardo provides a revealing insight into the minds and characters of two of the most important contributors to the development of political economy in England during its formative years in the early 19th century (see Ricardo 1951–73, vols 6–9). They expressed their arguments forcefully but politely, although at times hints of frustration and exasperation began to appear, as they struggled to comprehend and to counter the other's point of view, especially when in an era without carbon copies and photocopies they seemed to forget what they had previously written. And despite their doctrinal and methodological differences, they remained close friends, with frequent visits to one another's homes. Ricardo's last letter to Malthus concluded with the statement:

'I should not like you more than I do if you agreed in opinion with me' (Ricardo 1951–73, vol. 9, p. 382); and Malthus, after the death of Ricardo, was reported to have said: 'I never loved any body out of my own family so much' (Empson 1837, p. 489). Ricardo had offered to assist Malthus financially by investing money for him in a stockbroking venture; and at one stage Malthus might have been seriously considering a personal involvement in international trading in commodities and bullion, using statistics and advice provided by Ricardo (see Malthus 2004, ch. 3). After Ricardo's death, Malthus defended him against critics who Malthus considered had gone too far in their criticisms; and, in lectures read to the Royal Society of Literature in 1825 and 1827, Malthus developed a theory of value which, while maintaining his previous emphasis on demand and supply as determinants of value, gave greater recognition to Ricardo's emphasis on the cost of production (Malthus 1986, vol. 7, pp. 301–23).

Opinions differ on who was the greater economist - Malthus or Ricardo. Who made the more significant contributions to the development of economics? On the one hand there are those who see Malthus as muddle-headed, and Ricardo as the better logician. On the other hand, there are those who reject the claim that Ricardo was a better logician, and who argue that Malthus's understanding of the multicausal complexity of the real world was of far greater value to the progress of economics than Ricardo's abstract theorizing. The most famous member of the latter group, J.M. Keynes, said that the world would be 'a much wiser and richer place' if 'Malthus, instead of Ricardo, had been the parent stem from which

nineteenth-century economics proceeded'; and that 'the almost total obliteration of Malthus's line of approach and the complete domination of Ricardo's for a period of a hundred years has been a disaster to the progress of economics' (Keynes 1933, pp. 120, 117).

Malthus's Theory of Population

D. R. Weir

It is often said that Malthus was a better historian than prophet. He would be disappointed in that verdict because his intention in formulating his Theory of Population was to create a scientific basis for predicting the future state of mankind, in opposition to the speculations of utopian writers, especially Godwin. His failure to predict the Industrial Revolution is the evidence most often brought against him. But even with the benefit of hindsight, economic historians today still find it difficult to predict the Industrial Revolution from its antecedents. The crucial contribution of Malthus's theory was not its pessimism about innovation but rather its prediction of the demographic consequences of technological change and the inevitable effect of population on the standard of living. Malthus's Theory of Population continues to influence economic thought from popular discussion to policy-making, to model-building – long after many of its classical contemporaries, like the labour theory of value, have passed from the scene.

This essay will focus on the population side of Malthus's theory. We begin with a distillation of his ideas into a simple model in the modern sense of the term. Our intention is not to treat in detail all the nuanced and sometimes contradictory aspects of Malthus's writing. The *Essay on Population*, first published in 1798, was revised six times before the final seventh edition was published in 1872, some 38 years after his death. The model used here aims to portray the most essential and durable aspects of the theory. It also provides an organizational framework for discussing the evidence for and against its predictions from time periods both before and after Malthus wrote.

The Model

Figure 1 portrays the essential elements of Malthusian equilibrium. There are three curves, representing three functional relationships. In the first panel is an aggregate production function showing the standard of living (or real wage, or income per capita) produced by a population of a given size. Its main feature is diminishing returns to labour – a tenet of classical economics not unique to Malthus. The second panel describes demographic behaviour. Mortality (here, the crude death rate, which is the number of deaths per 1,000 persons) rises as the standard of living falls. This is the positive check. Fertility (here, the crude birth rate), falls as the standard of living falls. This is the preventive check. Population grows when births exceed deaths and falls when deaths exceed births. A rising population lowers the standard of living (through the production function), which in turn raises mortality and lowers fertility, eventually bringing population growth to a halt. Equilibrium in this simple version of the model is attained at zero population growth. At that point, wages do not change, and consequently the birth and death rates do not change. The equilibrium is stable, since any disturbance sets in motion compensating changes.

The stability of the equilibrium is the source of Malthusian pessimism. Imagine an expansion of land area for cultivation. The production function would shift out, raising the standard of living for the current population. Fertility would rise and mortality fall; population growth would continue to devour the gains until the wage fell to its original level. Demographic behaviour is the forge of the Iron Law of Wages. Permanent change in the standard of living can arise only from restraint of fertility (a lower birth rate at each wage) or a worsening of mortality (more deaths at each wage).

The smooth curves drawn above describe the long-run tendencies as envisaged by Malthus. He saw the process of adjustment, however, as anything but smooth. Population growth would tend to overshoot the equilibrium. The positive check, working through disasters like major famines or disease, would be slow to respond but would then overadjust when it did, setting off a new cycle. Malthus offered no specifics on the periodicity or amplitude of the cycle, only the prediction of oscillations around a long-run equilibrium level.

The Evidence

In discussing in detail the component parts of the model, there are three aspects of each to be considered. First if the evolution of Malthus's own ideas on the functional relationship; second, the historical evidence for or against it; and third, its relevance to the major economic and demographic transformations of the last two centuries. The importance of empirical verification was strongly emphasized by Malthus himself. Criticizing the utopians, Malthus wrote:

> A writer may tell me that he thinks man will ultimately become an ostrich. I cannot properly contradict him. But before he can expect to bring any reasonable person over to his opinion, he ought to show that the necks of mankind have been gradually elongating, that the lips have grown harder and more prominent, that the legs and feet are daily altering their shape, and that the hair is beginning to change into stubs of feathers (Malthus 1798).

Much of the work of the later editions of the '*Essay on Population*' was devoted to amassing evidence on the Principle of Population at work.

A central problem with using this or any other equilibrium framework to explain co-variations in economic and demographic variables (across time or space), or with using empirical observations to 'test' the model, is the identification of exogenous shocks as distinct from endogenous responses. Malthus himself was vaguely aware of the problem as early as the first edition of his *Essay*. David Hume, noting the early age at marriage of women in China, had deduced that the population must as a consequence be very large. Malthus, taking age at marriage as endogenous rather than exogenous, concluded that the population must on the contrary be rather small and wages relatively high to induce such early marriage.

Mortality

Malthus gave to mortality's response to wages the name 'positive' check because it was certain and unavoidable once population had grown too large. Fertility offered a 'preventive' check in the sense that if low fertility held back the growth of population, the mortality response could be postponed.

Malthus envisaged two modes of action for the positive check. Associated with declining wages would be increasing 'misery and vice'. Misery and vice included some conditions that would raise mortality as well as lower mortality. This would yield a smooth continuous relationship like that in the diagram. The second mode of action would be sudden mortality crises to greatly reduce a population in a year or two. To put it in modern terms, the probability of a mortality crisis of any given magnitude should increase as the standard of living falls. The expected value of the death rate would show the smooth relationship to wages pictured above. Actual events would be much less regular. Adjustment to equilibrium was inevitable but not constant.

Historical studies of the positive check have approached it from two very different perspectives. One sort examines great crises to determine whether they resulted from population pressure. The other attempts to specify the extent of population pressure on resources over time and look for mortality consequences.

The Black Death of 1347 and 1348 killed between one-third and one-half of Europe's population in a single massive epidemic of bubonic plague. Hatcher (1977) concludes for England that the Black Death was 'not Malthusian', by which he means not a response to population pressure. Evidence abounds that population had been growing: rents and the relative price of basic foods had been rising for two centuries or more. There had been major famines in the 1320s. The 'anti-Malthusian' conclusion is based on the absence of a logical connection between standard of living and the scale of epidemic bubonic plague and on the fact that the mortality response was disproportionate to the population pressure. Economic responses to the Black Death were clearly Malthusian (Hatcher 1977, pp. 101–94). It is certainly consistent with the subtler Malthus to find that an induced (endogenous) mortality response would overreact and become an exogenous disturbance driving population below its equilibrium. The study of a single episode cannot determine whether the probability of its occurrence was raised by the economic conditions preceding it. The persistence of the plague and

continued population declines of the next century or more, clearly were not a consequence of the improved standard of living after the first outbreak.

Half a millennium later the Irish Potato Famine provided a tragic forum for debate over the new Malthusian ideas. Mokyr (1983) traces reliance on the potato to population pressure, through the unique funnel of Irish institutions. As was the case with the plague, the element of chance looms large in the timing and location of the potato blight itself. Unlike the Black Death, however, the means were available to alleviate the heavy mortality consequences. One wonders what might have been the fate of the Irish had not English policy-makers of the 1840s been educated in the science of Malthus's Theory of Population.

The main supporting evidence for the positive check comes from the study of subsistence crises: short-run mortality increases following harvest failures. Meuvret (1946) drew attention to the close association of grain prices and deaths in specific incidents in France. Subsequent studies have shown a regular statistical association over long periods in several countries. Improved marketing and production methods appear to have been successful in nearly eliminating the relationship in England by the end of the 16th century and in France by the middle of the 18th century.

Since Malthus wrote, life expectancy has increased from well under 40 to well over 70 in most of the now developed world. Since the standard of living has also increased, it would appear that Malthus's theory of mortality has been a better prediction than it was a description of prior history. Some scepticism on that point is voiced by Preston (1976), who finds that life expectancy across countries is not closely related to their level of per capita income at any point in time. He concludes that medical and public health technology are more important than income. Since medical technology may well be a function of per capita income in the leading country, or in the average of leading countries, his finding may indicate only that Malthus no longer applies within national boundaries.

There is, in sum, only limited evidence of the income–mortality relation postulated by Malthus. Evidence abounds that most of the variation in mortality cannot be accounted for by so simple a framework.

Fertility

In the first edition of the *Essay on Population* Malthus claimed that 'passion between the sexes was necessary and will remain nearly in its present state'; that is, that fertility was roughly constant and did not vary with living standards. On our diagram, the fertility curve would be vertical. He subsequently advocated delayed marriage as a check to population growth. Being a vicar of the Anglican Church, he condemned both contraception and never-marrying as 'vice'. It is one of the greatest misattributions in human history that associates the name of Malthus with the birth-control movements of the late 19th century. Nevertheless, since fertility restraint offers the only means of raising both the standard of living and length of life within his system, it is not surprising that those who believed his model but not his morals would eventually invoke his science to promote their cause.

The evidence for endogenous fertility responses is growing but is not yet convincing. Wrigley and Schofield (1981) find that long-run trends in English fertility followed long-run trends in real wages from 1541 to 1871. The lag, however, was 40 years, and the two moved in opposite directions for approximately 140 of the 330 years. Moreover, in England, as in the rest of early modern Europe, age at marriage and fertility within marriage were fairly constant, leaving changes in proportions ever-married as the main source of changes in English fertility before the Industrial Revolution (Weir 1984).

The greatest failure of Malthus's Theory of Population is in explaining the fertility transition from high, mostly uncontrolled fertility within marriage to modern low fertility. The process began first in France at the time Malthus was writing. Parts of the United States and Hungary also began at about that time. The rest of Europe

followed sometime between 1870 and 1914. In no case was the long-run downward trend in fertility caused by a downward trend in national income. In today's developing countries fertility decline has sometimes been induced by policy measures without economic development, but sustained economic growth continues to be a prescription for contraception.

Neoclassical theories of fertility, as in the work of Becker (1981), salvage Malthus's theory as an income effect in a model of the demand for children. Substitution effects from a rising price of children relative to other consumption goods may be a more important determinant of fertility trends during development, overwhelming the income effect. Such a model does help explain why the Malthusian model seems to explain cyclical fluctuations in fertility both before (Lee 1981) and after (Easterlin 1973) the fertility transition. Relative prices may not fluctuate as much as income. Marx, a harsh critic of Malthus, would not be surprised. He claimed that Malthus's laws of population were specific to the particular mode of production of pre-industrial Europe. Other modes of production would have other modes of reproduction. Unfortunately, he left no better guide to predicting the changes than did Malthus.

It is perhaps ironic that Malthus's Theory of Population, conceived as a prediction of long-run equilibrium, should be consistent with short-run fluctuations but not with long-run movements. Humankind has not reached the idyllic state anticipated by Malthus's utopian adversaries. Neither have we fulfilled Malthusian predictions. The separation of reproduction from 'passion between the sexes' has led the wealthiest of nations to fertility below the level needed to replace their populations while in the poorest of nations great numbers of children are born into short lives of poverty. Theories of population must acknowledge their debt to Malthus and move on.

Malthusian Economy

Gregory Clark

Abstract

The Malthusian economy was the economic system that characterized almost all economies before the industrial revolution. In this regime fertility and mortality rates at different material income levels determined the average real income level and life expectancy at birth. Thus before 1800 the improvement of production technologies resulted only in population growth, and not in any gains in material living

conditions beyond those that were found in the original hunter gatherer societies.

The Malthusian economy is the economic system which prevails whenever a society's production technology advances so slowly that population growth forces incomes down to the subsistence level. In such an economy material welfare is independent of natural resources, technology and capital accumulation, but instead depends solely on the factors governing fertility and mortality. The resulting subsistence income can, however, vary widely across societies. Some Malthusian economies were rich by the standards of most countries in modern Africa, for example.

Almost all societies until 1800 were Malthusian, from the original foragers of the African savannah 50,000 years ago down through settled agrarian societies of considerable sophistication such as England, France, China and Japan in 1800. The operation of all human societies through history up until the Industrial Revolution can thus seemingly be described by this one simple economic system. An implication of this is that there was most likely no gain in material welfare between the evolution of anatomically modern humans and the onset of the Industrial Revolution.

Government actions, in so far as they change fertility or mortality, can influence material welfare in the Malthusian economy, but in a contradictory fashion. Good governments that reduced mortality through order and security made people poorer. Bad governments that increased mortality through warfare and banditry made them wealthier.

The economic logic of these societies was first, though only partially, appreciated by Thomas Malthus in his famous *Essay on a Principle of Population* of Malthus 1798. Malthus's insights were elaborated by writers such as David Ricardo and James Stuart Mill into the system called classical political economy in the early 19th century. Ironically, this intellectual development happened just as for the first time the rate of technological advance was becoming sufficiently rapid to bring the Malthusian era to a close.

Insight into the Malthusian economy starts from the insight that the biological capacity of women to produce offspring is much greater than the number of births required to reproduce the population. If fertility is unrestricted women can have 12 or more children. Social institutions regulating marriage and contraceptive practices will determine the actual numbers of births per women. In modern societies these institutions and practices vary greatly, so the number of births per women varies greatly. Completed fertility now ranges across the world from a low of 1.15 in Spain to a high of 8.0 in Niger. Only where women happen on average to have two children who survive to adulthood will population be stable. Even small deviations from this number will cause rapid increases or decreases in population. Thus modern populations are not stable.

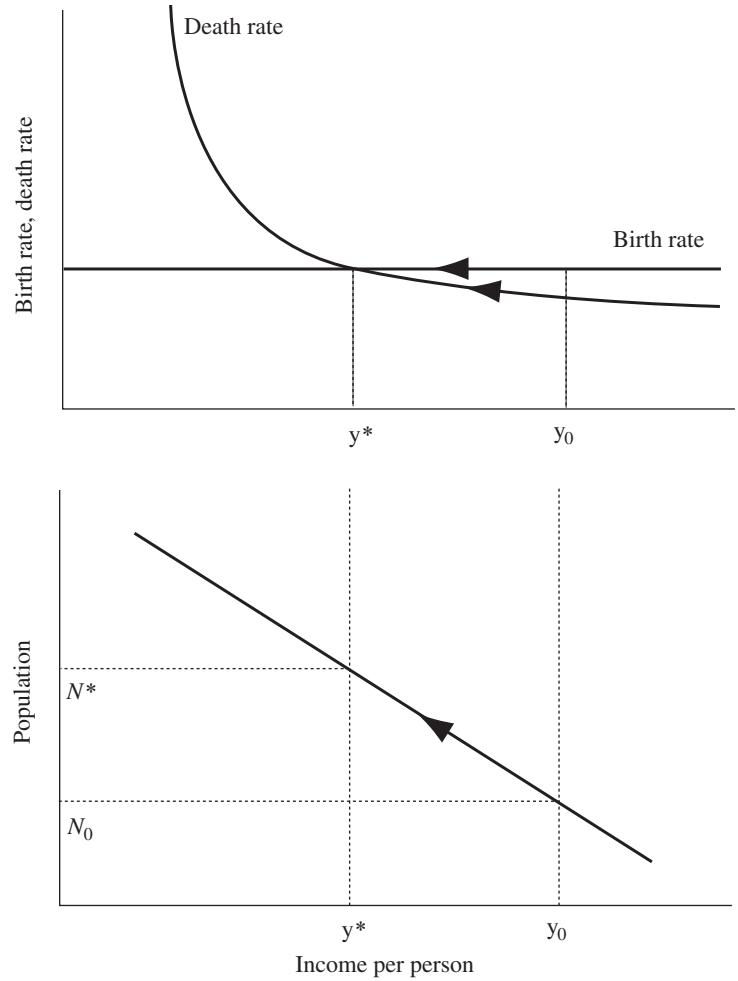
Despite this potential for explosive population growth, pre-industrial populations were remarkably stable over the long run. The average annual growth rate of world population from 10,000 years BC to AD 1800 was 0.05 per cent. The typical woman before 1800 thus had 2.02 children who survived to reproductive age. As an extreme case the population of Egypt, for example, is estimated at between four million and five million at 1000 years BC. The population in Greek and Roman Egypt a millennium later is estimated at this same four million to five million. The first modern census in 1848 suggests a population of 4.5 million. Thus over nearly 3,000 years the Egyptian population growth rate was to a close approximation zero, and women on average had two surviving children. Yet it is estimated that in Roman Egypt the average woman gave birth to six children. Some mechanism kept fertility and mortality in balance in these pre-industrial economies.

The Malthusian Equilibrium

The simple Malthusian model of how pre-industrial society functioned supplies an economic mechanism to explain its population stability. In its simplest version there are just three assumptions:

1. The *birth rate*, the number of births per year per thousand people, is a socially determined constant, independent of material living standards. Birth rates will vary across societies, but in this simplest model they are assumed to be independent in any given society of material living conditions.
2. The *death rate*, the number of deaths per year per thousand persons, declines as material living standards increase. Again, the death rate will differ across societies depending on climate and lifestyles, but it assumed that in all societies it will decline as material living conditions improve.
3. Material *living standards* decline as population increases.

Figure 1 shows the first two assumptions of the simple Malthusian model in graphical form in the upper panel. The birth and death rates are plotted on the vertical axis, material income per capita on the horizontal axis. The first two assumptions of the simple Malthusian model imply that there is only one level of real incomes at which the birth rate equals the death rate, denoted as y^*. And this constitutes a stable equilibrium. Thus y^* is called



Malthusian Economy, Fig. 1 Long-run equilibrium in the Malthusian economy

the 'subsistence income' of the society: it is the income at which the population barely subsists, in the sense of just reproducing itself. This subsistence income is determined without any reference to the production technology. It depends only on the factors which determine birth and death rates. Once we know these factors we can determine the subsistence income.

Another aspect of human welfare is life expectancy at birth, that is, the average number of years a person will live. In the Malthusian era life expectancy at birth also depended only on the factors determining birth and death rates. This is because with a *stable* population, where annual births have equalled deaths for a long time, life expectancy at birth is the inverse of the crude birth rate. With fertility not restricted in any way crude birth rates would be 50–60 per thousand in pre-industrial populations (based on modern experience). This would imply a life expectancy at birth of 20 years or less.

The term 'subsistence income' can lead to the confused notion that in the Malthusian economy people were always living on the edge of starvation. In fact, in almost all Malthusian economies the subsistence income was considerably above the income required for the physiological minimum daily diet. All pre-industrial societies for which we have good demographic records limited fertility below the biological maximum. Differences in the location of the mortality and fertility schedules generated subsistence incomes at very different levels. Thus, both 1450 and 1650 were periods of population stability in England, and hence periods where by definition income was at subsistence. But the wage of unskilled agricultural labourers was equivalent to about 6 lb of wheat flour per day in 1650, compared with 18 lb in 1450. Even the 1650 unskilled wage was well above the physiological minimum. A diet of about 1.33 lb of wheat flour per day would keep a labourer alive and fit for work (it would supply about 2,400 calories per day). Thus, pre-industrial societies, while they were subsistence societies, were not starvation regimes. England in 1450, indeed, was wealthy even by the standards of many modern societies such as those in sub-Saharan Africa.

The bottom panel of Fig. 1 illustrates the third assumption. The panel has on the vertical axis the population, N, and on the horizontal axis the material income. As population increased material income per person by assumption declined. The justification for this assumption is the law of diminishing returns. Since one important factor of production, land, is always in fixed supply in pre-industrial economies, the law of diminishing returns implies that average output per worker fell as the labour supply increased as long as the technology remained static. Thus the average amount of material consumption available per person fell with population.

Figure 1 also shows how an equilibrium birth rate, death rate, population level and real income were arrived at in the long run in a pre-industrial economy. Suppose we start at an arbitrary initial population N_0 in the diagram, greater than N^*. This generates an income y_0, above the subsistence income. At this income the birth rate exceeds the death rate, so population grows until income falls to y^* and population equals N^*.

Changes in the Birth Rate, Death Rate and 'Technology' Schedules

Suppose that the birth rate schedule in Fig. 1 was higher. Then at the equilibrium, real income would be lower, and the population greater. Thus any increase in birth rates in the Malthusian world drove down real incomes and reduced life expectancy. Conversely, anything which limited birth rates drove up real incomes and increased life expectancy. Thus in the pre-industrial era birth rates were a crucial determinant of material living conditions.

If the death rate schedule was higher, so that at each income there was a higher death rate, then the equilibrium real income would be higher. But if the birth rate was not responsive to income then a greater death rate increased real incomes but in the long run had no effect on the annual death rate or on life expectancy at birth.

Thus in this simplest Malthusian model higher mortality risks at a given income were unambiguously a good thing, at least in the long run.

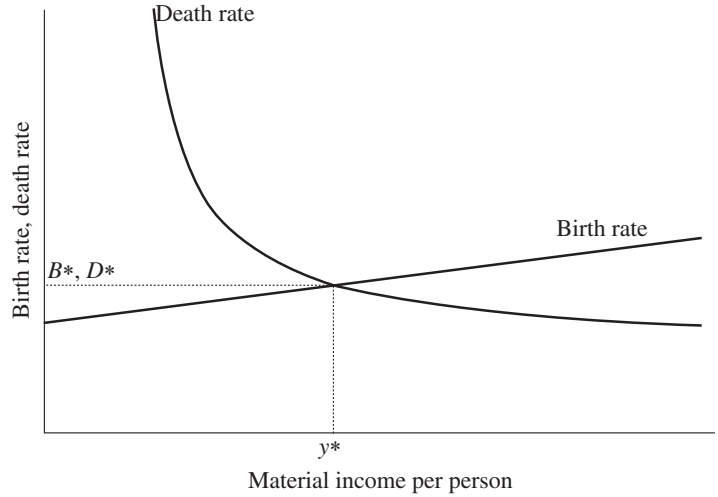
The simple Malthusian world thus exhibits an almost counter-intuitive logic. Anything that raised the death rate schedule, the death rate at a given income, such as war, disorder, disease or poor sanitary practices, increased material living standards without changing life expectancy at birth. Anything that reduced the death rate schedule, such as advances in medical technology, or better public sanitation, or public provision for harvest failures, or peace, reduced material living standards without any gain in life expectancy at birth.

While the real income was determined from the birth and death schedules, the population size depended on the schedule linking population and real incomes. Above I labelled this the 'technology' schedule, because in general the major cause of changes in this schedule has been technological advances. But other things could shift this schedule – a larger capital stock, improvements in the terms of trade, climate improvements, and a more productive organization of the economy. A shift upwards in this schedule, in the short run, since population can change only slowly, would have increased real incomes. But the increased real incomes reduced the death rate, so that births exceeded deaths and population began growing. The growth of population ended only when the income returned to the subsistence level, y^*. At this new equilibrium the only effect of the technological change was to increase the population supported. There was no lasting change in the living standards of the average person.

More Complicated Malthusian Models

An issue that has exercised historical demographers is whether the birth rate in pre-industrial societies was 'self-regulating'. What they mean by this is shown in Fig. 2, which shows the birth and death schedules of a simplified Malthusian model, as well as a modified birth schedule, which slopes upwards with material incomes. In the modified Malthusian model it is assumed that in good times people married earlier and more people married, so that fertility increased, whereas in bad times fewer married, and they married later, so that fertility declined.

It should be clear that a positive association of fertility and income does not change the basic equilibrium of the model. The only difference is that increases in the death rate at any given material income are now not so unambiguously good, since they will be associated with higher fertility and mortality rates and hence lower incomes. The evidence for societies such as pre-industrial England, however, shows no response of fertility to income (Wrigley et al. 1997). Thus the simple model may well describe pre-industrial societies well.



Malthusian Economy, Fig. 2 A Malthusian model where births increase with income

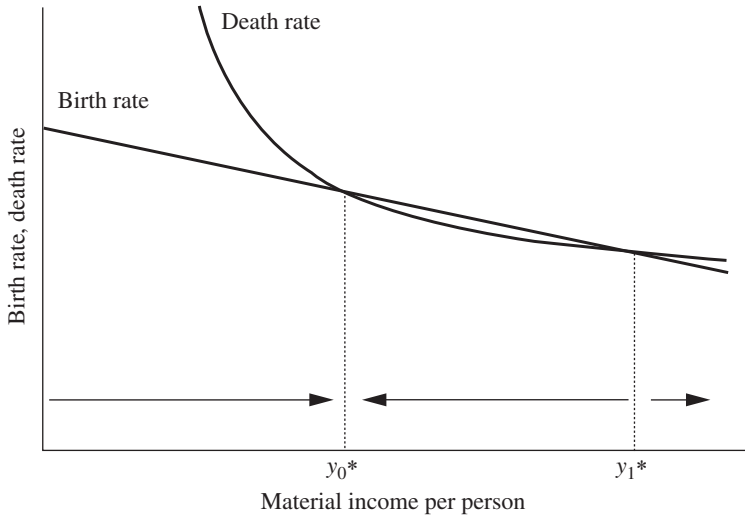
What causes many more potential complications is a birth schedule that declines with material incomes. Suppose that as real incomes go up one of the responses of people is to desire fewer children. With a birth rate that declines with real incomes the model could have multiple crossings between the birth rate and death rate schedules. At those places where the birth rate schedule was declining more steeply than the death rate schedule the equilibrium would be unstable. Figure 3 gives a declining birth rate schedule that twice intersects the death rate schedule. The intersection at the lower real income, y_0, is a stable equilibrium. But the second higher income equilibrium at y_1 is unstable. If real incomes drop below this level by any amount then population starts to grow, leading real incomes all the way down to the stable equilibrium at y_0. Conversely if they increase at all above y_1 then deaths will exceed births and real incomes continue to grow indefinitely. The population will fall eventually to zero.

In this case there is a 'Malthusian trap' in the pre-industrial economy. A society can be stuck in the subsistence income equilibrium unless some jolt such as acquiring extra land, experiencing a much higher death rate, or experiencing faster technological progress pushes up wages enough so that fertility falls permanently. The shock of the Black Death, however, which tripled real incomes for the poorest workers in England by 1450, did not lead to any permanent movement towards lower fertility and the escape from the Malthusian trap. Again, the evidence for pre-industrial demography suggests no declines in fertility with higher incomes.

The Empirical Implications of the Malthusian Model

The most interesting empirical implication of the Malthusian model is that material living conditions for people, including life expectancy at birth, may well have been unchanged between the dawn of humanity and AD 1800. Were the people in sophisticated societies such as England, France, the Netherlands, Japan and China in 1800 really no better off than the original hunter-gatherers? This seems particularly counter-intuitive for England, reckoned to be the richest country the world by 1800.

By then England was a society that would not seem that different from our own. The middle and upper classes in London breakfasted at coffee shops as they read the daily newspapers. They dwelled in homes of brick and glass with water supplied by lead pipes, lighted at night by oil harvested from sperm whales taken thousands of miles away in the oceans. There was extensive trade for luxury products from the tropics – cottons, silks, spices. How could the material condition of humanity not be better then than in the



Malthusian Economy, Fig. 3 A Malthusian model where births decline with income

savage past when our ancestors faced the elements naked, and sought shelter at night in depressions in the ground or in crude lean-tos?

But even in England in 1800 the living conditions of the mass of the population were still primitive. The largest employment was still agriculture, where the average day wage in 1800–9 was the equivalent of 5.7 lb of wheat flour. This was enough to keep a family fed only if most of the income was spent on the cheapest forms of food such as bread. Farm labourers lived in simple structures little better than those of the medieval period. They slept when it was dark because they could not afford lighting. They could afford one new set of clothing per year. English farm labourers six hundred years before, in 1200–9, received a wage which was the equivalent of 12 lb of flour, significantly more than in 1800. And at the best time for pre-industrial workers in England, circa 1450, when the population losses of the plagues which ravaged Europe from 1348 on were their greatest, the real wage was much higher, equivalent to 18 lb of flour. In the years 1200–1800 in England there is no sign of long-run gains in real wages for the mass of workers. We know also the real day wage of farm workers in Roman Egypt circa AD 250 was the equivalent of 5 lb of flour, not much less than England in 1800.

How did English material living conditions around 1800 compare with hunter-gatherer societies such as those that constituted society through the great bulk of human history? We can obtain insight on this in two ways. The first is by comparing living conditions in England in 1800 with those of the few surviving hunter-gatherer groups. Since the diets were very different here we have to use measures such as the number of calories consumed per person per day. In 1787–96 for the families of English farm workers this was a meagre 1,508 calories. For a group of eight hunter-gatherer societies studied in the 1960s to 1980s the average consumption was 2,272 calories, much better than for England. On this measure the English on the eve of the Industrial Revolution seem to have lived less well than the average hunter-gatherer. Another aspect of the quality of life is life expectancy at birth. One measure of this is the fraction of infants that survived the first year of life. In England as a whole this is estimated at 83 per cent in the second half of the 18th century. For modern hunter-gatherer societies survival rates were a little lower at 79 per cent. But this is still not that much lower than for the richest society in the world in 1800. And survival rates for infants in London, the richest part of England, were only 70 per cent because of the health hazards of city life.

A second measure is the average stature of people. Height is a good index of material living conditions, since it depends on both food consumption and the amount of sickness people experience as they grow. Average heights for adult males in England circa 1800 were 67 inches or less. This was very good by the standards of societies just before industrialization. Average male heights in Japan in the late 19th century were 61 inches and in India in the early 19th century 64 inches. Yet these heights in England are little if any better than those recorded from skeletons of hunter-gatherers in the Mesolithic (10,000–5000 BC) and Neolithic (5000–1000 BC) in Europe. Average male height from these skeletons is estimated at 66 inches. So overall, if we look at agrarian societies across the world in 1800 AD, the stature evidence suggests a decline in living conditions from hunter-gatherer society.

Thus, the evidence is that for the mass of humanity on the eve of the Industrial Revolution living conditions were no better and probably worse than in the hunter-gatherer past.

A merchant of English parentage, born in Antwerp at an unknown date, Malynes was a commissioner of trade in the Low Countries about 1586. He came to London and was frequently consulted on commercial questions by the Privy Council in the reigns of Elizabeth I and James I. He became an assay master at the mint and obtained a patent to supply farthings; he was imprisoned for a time, complaining later that he had been ruined by being paid in his own coins. He also served as a spy for England. Called on by the standing commission on trade for evidence on the state of the coinage, he published a series of pamphlets on money and prices. A mercantilist and a bullionist, he was heavily influenced by Scholastic literature.

Malynes viewed individual commodity prices as determined by demand and supply. However, he was more interested in the price level, governed by the quantity of money (Malynes 1601b, 1603). An expanding money supply, associated with a rising price level, decreased interest rates and stimulated the economy (1601b, 1622a). Therefore Malynes viewed usury as at best a necessary evil (see Muchmore 1969, p. 346) and, above all, opposed any export of specie whatsoever.

Rejecting the balance of trade theory, Malynes charged that 'bankers' (exchange dealers) controlled the exchange rate (1601b, 1622a, b, 1623). By their incorporation of usury in the price of a bill of exchange and through speculation, they conspired to undervalue sterling, leading to a deterioration in England's terms of trade ('overbalancing') and a specie outflow (1601b, 1622a, 1623). But overvalued sterling would not lead to a specie inflow, because the export proceeds would be spent on luxury imports (1601b). Yet Malynes (1601b) has a theory of price level changes in response to exchange rates differing from mint parity and money flowing between countries – a price specie-flow mechanism, marred only by the assumption of inelastic demand. His solution to the twin problems of specie outflow and terms of trade deterioration is comprehensive exchange control with enforced exchange dealings at rates fixed at mint parities (Malynes 1601b, 1622a, b; Muchmore 1969, pp. 347–8).

Managerial Capitalism

Alan Hughes

As private enterprise industrial economies evolve, the proponents of the thesis of managerial capitalism argue that changes occur in the technical conditions, and scale, of production of corporations; in the structure of the ownership of their equity, and of the product markets in which they operate; and in their internal governance. The increasingly complex technological and scientific nature of industrial production requires specialist technical management expertise, and management responsibility is delegated to individuals who possess it by an increasingly absentee ownership interest. The associated increase in the scale and capital intensity of production is reflected both in the growth of oligopolistic market structures and, as external funding increases, by an ever more dispersed pattern of share ownership. Thus, the fusion between management and ownership is broken. Those responsible for exercising management responsibility come to constitute a skilled, inside, professional salaried group, essentially propertyless in relation to their own corporations, and hence separate in function and identity from the tens of thousands of shareholders who are its legal proprietors. These share owners, in turn, form an increasingly disparate, unorganized, and uninterested group of principals, unwilling or unable to impose their own self-interested contractual conditions of employment on their manager-agents. Managerial behaviour is therefore discretionary behaviour very weakly constrained by shareholder-owner interests on the one hand, or by a competitive market environment on the other. As a result, corporate behaviour changes, and with it so does the nature of capitalism (Veblen 1924; Berle and Means 1932; Berle 1955, 1960; Dahrendorf 1959; Marris 1964; Williamson 1964; Nichols 1969).

Whilst writers in the managerialist tradition agree that the separation of ownership from control has occurred and does matter, there is disagreement on the nature of the changes it produces. Berle argued that the most likely outcome would be a more socially responsive and socially responsible form of corporate behaviour, a vision shared by a number of other post-war authors (Bell 1961, 1974; Berle 1955, 1960; Drucker 1951; Mayo 1949; Mason 1960). On this view the development of a managerial corporate conscience would ensure behaviour responsive to public opinion and to a wider constituency of interests than the owners of capital alone. This would ensure the acceptability and survival of the corporate system. In the words of Berle and Means

> It is conceivable – indeed it seems almost essential if the corporate system is to survive – that the 'control' of the great corporations should develop into a purely neutral technocracy, balancing a variety of claims by various groups in the community and assigning to each a portion of the income stream on the basis of public policy rather than private cupidity (1932, p. 356).

This pluralist, or in the terminology of Nichols (1969), 'non-sectional' interpretation of the impact of managerialism has formed part of a wider stream of thought mapping out the socio-political and economic development of industrial societies. This has included as one possible outcome, resulting from similar underlying managerial and technical imperatives, a convergence between the socioeconomic systems of capitalism

and socialism (Kerr et al. 1960; Aron 1967). In the work of Burnham (1945) convergence, is based on a 'sectional' interpretation of management objectives. For Burnham, the managerial revolution is associated not so much with a shift from concentrated to dispersed private ownership, but from private to state ownership. This development is then associated with the emergence of a new dominant class of state enterprise managers exercising control in their own interests. Burnham's thesis has been criticized for its lack of clarity over who the managers in this revolution are, and whether it is in any sense reasonable to regard them as an homogeneous class (Dahrendorf 1959; Nichols 1969). The notion of a sectional managerialism, and the behavioural effects it may produce, however, has been taken up and developed separately by economists. Galbraith (1967) combines it with a view that bureaucratic organization is an inevitable feature of industrial life in the East and West, and that those in the organization mould the economic system as a whole to meet their own ends. He adopts an analysis of goal formation which rests heavily on the behaviouralist/organization theorists' view of the modern corporation as an adaptive organization (March and Simon 1958; Simon 1965; Cyert and March 1961). In his analysis, specialized technical and scientific managerial skills lead to the emergence within the large corporation of a loosely defined managerial 'technostructure'. Its members have a strong self-interested commitment to the survival of the organization to which they belong. This self-interest is pursued by adapting corporate goals towards planning the corporate environment, and by the pursuit of growth, and increases in size, subject only to a minimum profit constraint to keep the shareholders happy. This is the story made familiar in the earlier models of Baumol (1959) and Williamson (1964) and particularly in the distinctive dynamic work of Marris (1964).

In these more formal contributions, managers pursue higher salaries and corporate perks and generally attempt to divert corporate resources to serve their own interests. This usually boils down to aiming for greater output levels and faster growth than is consistent with maximizing the current stock market value of the corporation (taken as a direct proxy for stockholder welfare). The extent of management's discretion to do this depends upon a minimum profit constraint imposed by the capital market, or, in one version of Marris's original contribution upon sustaining a market value high enough to forestall a disciplinary takeover bid in the market for corporate control. In these sectional managerial models the essential shift in behaviour at the level of the individual firm is towards lower risk-taking (managers will avoid projects with highly variable profit streams, if downside risk threatens job security whilst superior profit performance has little impact on their remuneration package), and a faster rate of growth. The outcome at an aggregate level is not so clear, since individual corporations may grow by acquiring other existing corporations rather than by investing in new plant and equipment. It has been argued, however, that management discretion combined with institutional circumstances which restrict takeover possibilities has, in Japan for instance, contributed to a more dynamic overall aggregate growth performance (Odagiri 1981).

Opponents of the managerial capitalism thesis have argued that the separation of ownership from control has been over-emphasized or misinterpreted, that managerial discretion could not in any event exist to any significant degree, and that even if it did, it would not lead to significant changes in corporate behaviour since there is a congruence between the behavioural norms and the self-interest of major shareholders on the one hand, and top managers on the other.

The original Berle and Means thesis rested on particular historical, legal, and institutional developments in which the 'power vacuum' left by the emergence of the joint stock company and the dilution of ownership interests was filled by a salaried managerial class. Other outcomes are possible as circumstances differ. Thus, for example, starting from similar views about the emergence of a managerial group in charge of the day-to-day running of corporations, the 'finance capital' theorists have argued that the managers remain subordinate to the wishes of a small group of major shareholders, who retain interlocking

key positions on the boards of industrial companies, and on the boards of the financial institutions responsible for capital market intermediation. Although originally developed in a context in which equity capital markets were less important than the market in loan finance, the re-emergence of major shareownership groups in the form of pension funds and insurance companies (as noted by Berle himself: Berle 1960) and concentrated equity management groups, such as banks, has led to the revival of the theory as a rival to managerialist interpretations of contemporary capitalism (Hilferding 1910; Kotz 1978; Minns 1980; Scott 1986). Whilst the structural changes in capital markets on which this revival is based are clear enough, the extent to which they represent a subordination of managers to ownership or other interests, rather than a form of constraint, upon essentially, dominant 'inside' management is less obvious when account is taken of the way in which 'financial' directors are appointed to the boards of industrial companies, and their relative transience compared to insiders (Herman 1981).

Critiques based on the idea that managerial discretion is limited regard these issues as of second order importance anyway. Such critiques focus on conditions in the product and capital markets, and in the market for managers. They emphasize that the growth of concentrated market structures is the outcome of a competitive process by which the efficient come to account for a greater share of economic activity. In the absence of significant entry barriers no persistent monopoly power is possible. Even if it was, then the market for managers, and the stock market selection process, will together ensure that those in 'control' act so as to minimize costs. Thus, on this view of the world, the natural selection properties of the environment determine which policies have 'survival' value, and the discretionary role of managers is negligible (Alchian 1950; Friedman 1953; Becker 1962; Alchian and Kessel 1962; Manne 1965; Jensen and Ruback 1983; Jensen and Meckling 1976; Fama 1980; Demsetz 1974, 1983). There is sufficient empirical and theoretical analysis to suggest that these arguments cannot be wholly convincing. The evolutionary emergence of product market structures need not reflect dominant profit maximizing, as opposed to satisficing, decision rules (Winter 1964, 1971). The latter, in turn, may reflect the outcome of the activities of coalitions of interest groups internal to the large corporation, and thus re-admit managerial and other interpretations (Cyert and March 1963; Aoki 1984). Neither do the characteristics of the takeover mechanism as a key part of the stock market selection process, suggest that profit maximizing decision rules are superior to others such as growth maximization in avoiding raids by competing managements (Singh 1971, 1975; Mueller 1980). Finally, barriers to entry and the policies of dominant firms may lead to positions of market power, which, whilst not eternal, may be sufficiently persistent in particular cases to make it worthwhile to ask what use is made of any discretionary room for manoeuvre that is created (Scherer 1980; Mueller 1986).

As it happens, direct tests of the impact of patterns of ownership on corporate performance rarely allow for market power effects. Studies which do not control for this, report on average, small or negligible ownership impacts on profitability (e.g. Kania and McKean 1976; Monsen, Chiu, and Cooley 1968; McEachern 1975; Herman 1981). Studies which do allow for it, report mixed results. Thus Palmer (1973) reports manager-controlled companies earning lower profits than owner-controlled companies in markets with substantial market power, whilst Qualls (1976) reports negligible differences. Generally speaking, few studies of ownership impacts directly assess the extent to which such profit differences as do emerge are simply 'quiet life' effects as opposed to a conscious pursuit of alternative objectives such as growth, as hypothesized in the dynamic managerial models mentioned earlier. Multivariate tests, including both growth and profits, suggest an inferior performance in both dimensions for manager-controlled companies rather than a sacrifice of the latter in favour of the former (Holl 1975; Radice 1971). Whether these studies are identifying a supply of finance function rather than a demand for growth function remains, however, a moot point. As does the general assumption behind nearly all the empirical work in this area that 'control' categories can be

drawn up on the basis of identifying one or more minority shareownership groups defined at arbitrary levels of, say, 5% or 10% of total equity. The relative neglect of whether the ownership groups are personal or institutional; are located on-or off-board; are connected with founding family or other financial interests; and are transient or persistent; mean that they can only be a rough and ready guide to likely behavioural difference (Francis 1980a). Similarly, the neglect of the motivational impact of absolutely large, though in percentage terms, relatively small, equity holdings by managers is a further shortcoming. It reflects a general neglect of the underlying assumption of the managerialist models that owners, managers, and financiers have identifiably different objectives and behavioural norms which condition the objectives which corporations pursue when different interests dominate them (Francis 1980b; Baran and Sweezy 1968; Nichols 1969; Cosh and Hughes 1987).

It would be difficult, on the basis of the evidence so far, to make a strong case for, or against, the managerialist position that the separation of ownership from control has produced noticeable behavioural or performance differences between individual corporations with different degrees of separation. That the financial and organizational structure of the modern corporation has changed and is still evolving, is without dispute. The same cannot be said for the view that this has led to either a more soulful or socially responsible capitalism, or to a socio-economic structure in which a distinctly identifiable social group of 'managers' has come to exercise power in its own sectional interests.

B1

The Manchester School was the name given by Disraeli after the event to the leaders of the successful agitation conducted between 1838 and 1846 to abolish the Corn Laws. It is wrongly associated with the arch-advocacy of laissez-faire. The people of the School were not in fact united by any single idea, other than believing in the complete and immediate repeal of the tariff on grain.

Within the School there were five discernible groups in the sense of there being five different reasons why people wanted repeal or purposes that directed them.

Some were compatible with others, and one group could agree with another over what was important but differ over how important it was. The arguments that each group made do not, when taken together, constitute a cogent or even coherent whole but taken separately could be both, and are always interesting. Moreover, the campaign for repeal is itself an instructive event in the history of economic policy.

One group was the mill-owners of Lancashire who provided most of the money for the campaign and formed the National Anti-Corn Law League to conduct it. Some believed that repeal, by reducing the price of bread, would reduce money wages, hence the cost of production in their mills. The belief comes from the Ricardian principle that real wages are constant in the long run. It could have made the businessmen believe the export of grain should be protected, since that too could reduce its price, hence have placed them in the interesting but not unusual position of half-believing in the free market.

They in fact did not support protection because a greater reason for their wanting repeal was to increase the export of manufactured goods. The economic argument most often made was that importing more grain would provide foreigners with more income to spend on British exports, with the result that income and employment would increase at home. The mill-owners were repeatedly accused of simply wanting to cut wages. Cobden privately warned them to stay out of the repeal campaign if they could not come in with clean hands. Publicly he offered to support a Factory Bill of Lord Ashley – the 'universal syllabub of philanthropic twaddle', in Carlyle's description – if Ashley would pay his farm hands what the workers in Cobden's factory were paid. The offer was declined.

Another economic augument for repeal was that it would retard the growth of manufacturing abroad and so keep Britain in its leading industrial position. Why the owner of a small mill would profit by his country's having more mills than any other was not made clear (although he might by way of an externality of some sort). The argument is nevertheless noteworthy. It was revived after 1945, when the undeveloped countries hastened to industrialize in the belief that doing so was a necessary condition of their progress. The argument is also part of the curious notion, entertained by historians, that Britain's free trade was an instrument of its imperialism. They reason that Britain, by keeping others in a non-industrial condition, could dominate them, exploit them, and/or make them dependent on it.

Why one country would choose to be mistreated by another when it could choose a trading partner that did not mistreat it, as in a system of free trade it could do, is not explained. Or is there an explanation of why a dollar's worth of manufactured goods adds more to total welfare than a dollar's worth of goods that are not manufactured?

Among the businessmen working for repeal were those who believed it would make life better for the lower classes. They have been called the humanitarian employers. They did more for their workers than the market or the law required, providing schools for the children, reading rooms and meeting places for the men and women, helping them to form friendly societies, cooperatives and cultural groups. Some employed a 'salaried visitor' (social worker) to call at the homes. These business people also undertook to improve the communities where they were established. One such effort was the Manchester Statistical Society which collected information on living conditions and used it to improve them. The Greg family stood out in this group.

The radical businessmen, working on a larger scale than the humanitarians, aspired to improve the nation and the world. In economic affairs their great end was free trade and after the repeal of the Corn Laws they had a part in the abolition of the Navigation Laws. In politics they looked toward democratic government and worked to extend the franchise until all adult males had the right to vote. The radicals believed free trade would first increase the influence of the business classes, increase their members in Parliament, then (in a way not fully explained) increase the power of the working classes.

John Bright was the leader of this group, which itself was the Manchester version of the middle-class radicalism of the time. It had a finger or a hand or more in most reform movements, great and small, from the abolition of slavery and removal of religious disabilities to the penny post and repeal of the taxes on knowledge. The radicals were disrespectful of authority, indifferent to custom, unmindful of the ridiculous figure they often cut, and they were meddlesome, tiresome, persistent and effective. Like Pancks, what they did, they did, they did indeed, and when they finished there were noble institutions in ruins.

The Philosophic or London Radicals had a different place from that of the radical businessmen, grounding their reform on a considered application of Bentham's utilitarianism and conducting themselves in the mannerly, measured way that made them heard and respected but unheeded and ineffectual. They did not care for the rough and ready way of Manchester and had to be reminded of where they were before it took on the repeal of the Corn Laws. Before them, Charles Villiers, a leading Benthamite, had each year moved in the House that it constitute itself a committee of the whole to consider the repeal of the Corn Laws, and each year the motion was defeated. The leadership of the free trade bloc passed to Cobden when he became a Member of Parliament, an instance, his friends said, of talent giving way to genius. Francis Place, who was on the edge of the London Radicals, put things plainly and said that when the Manchester people wanted something done they did it.

Cobden represented the pacifists of the School. They believed that trading nations had a material interest in peace, an idea Ricardo had stated in his *Essay on Profits* in 1815, and that they were natural friends by virtue of meeting on the market, an idea Ricardo was too realistic to entertain. Oddly, the pacifists seem not to have noticed they could have drawn an argument from the *Wealth of Nations*. No pacifist himself, Smith said Britain should not engage in trade that would diminish its military power. The implication is that free trade makes nations unable to go to war as well as unwilling.

The pacifists, although not the largest group within the School, were even more influential than the radicals. Cobden wanted to graft the peace movement onto the repeal campaign although he would not permit the franchise to be so joined, as Bright wanted to do. After repeal, the franchise had more public support than the peace movement and grew until all adults had the vote. Nevertheless those who believe free trade is conducive to peace can and do point out that the 19th century was a time when trade was freer than ever and was the only century in recent history when there has not been a world war.

Cobden wanted free trade because it would bring peace, Bright because it would bring the franchise. Others in the School had each of them his own purpose. They made common cause for seven years until the Corn Laws were brought down, then returned to their separate ways.

The Manchester School was a coalition around a single issue. It was not a group of ideologues committed to laissez-faire, as historians have carelessly said, nor did it express the pure spirit of the middle class, as some contemporaries believed. It was not a rent-seeking force, as Public Choice economists are tempted to say, nor did it preach the principles of huckstering (Disraeli), nor were its leaders 'bartering Jews' (Engels), nor were they 'the official representatives of the bourgeosie' (Marx). If the Manchester School is to be described simply, it was a remarkably successful effort to remove a major obstacle in the way of the market.

Mandated Employer Provision of Employee Benefits

Jonathan Gruber

Abstract

Mandated employer provision of social benefits is of rising importance in the United States. As highlighted by Summers (1989), the efficiency losses from such mandates may be much lower than those of taxation due to tax–benefit linkages. I review the theory underlying this observation and the empirical evidence which documents full shifting to wages (and therefore little efficiency cost) of mandated benefits. A host of important questions about mechanisms remains unanswered, however.

The provision of social benefits can be financed in a number of different ways: through broad income taxation, through taxation of payroll only, or through mandates on employers to provide those benefits for their employees. The last channel is one of sizable and growing importance in the United States, although less so in other nations that tend to rely more on tax-financed government provision. Yet, until the late 1980s, the impacts of mandates were not much studied. The implicit assumption in economic analysis was that such mandates could be analysed using the standard tools of tax incidence and efficiency.

A very influential article by Summers (1989) changed all that. Summers pointed out that mandating employer provision of benefits to their employees had two effects on labour market equilibrium. On the one hand, a reduction in labour demand naturally accompanies the imposition of extra costs on employers. On the other hand, however, mandates should also cause an outward shift in labour supply, since individuals are now being effectively compensated more highly for their labour; they are receiving their previous compensation plus the mandated benefit. This shifts more of the costs of benefits to workers and reduces the deadweight loss from their provision. Indeed, as Summers pointed out, if employees valued the mandated benefit at its cost to the employer, then these supply and demand shifts would be equal. The end result would be 'full shifting to wages': a decline in wages by exactly the cost of the benefit with no impact on total labour supplied to the market and no efficiency consequences. Employees would simply be buying a benefit they value with their wages.

This article inspired a large follow-up literature, mostly empirical, investigating the equity and efficiency properties of mandates. I review that literature here, in three steps. First, I comment on the theoretical points made by Summers. Second, I discuss the empirical evidence available on the impacts of mandates. Finally, I discuss the key unanswered questions that must be addressed by future research.

Theoretical Background

Summers' analysis was as straightforward as it was insightful, highlighting the impacts of mandates in a simple demand and supply framework. The mathematics behind this analysis is explored in Gruber (1992), Gruber and Krueger (1991) and Anderson and Meyer (1997). These analyses show that the incidence of mandated benefits depends on the elasticities of supply and demand, as with any tax, along with a new parameter: the valuation of the benefit by employees. If valuation is equal to the cost paid by the employer for the benefit, then there is full shifting to wages.

But this analysis misses an important point: Summers' analysis is in no way restricted to mandates. Indeed, the analysis is exactly the same for Unemployment Insurance, a US programme which provides tax-financed benefit to unemployed workers. The key to Summers' analysis is not the form of provision (mandate or tax); rather, the key is that the benefits are *restricted to workers*, generating the labour supply increase that offsets some of the efficiency consequences of the intervention. For example, a payroll tax-financed expansion of health insurance to workers fits into this framework, but a payroll tax-financed expansion of health insurance to all individuals in society does not. In the latter case, there would not be the corresponding increase in labour supply, since individuals would not have to work to receive the benefit.

Another question raised by Summers' analysis is this: if there were full incidence on wages, why wouldn't employers simply provide the benefit voluntarily? Why is government coercion necessary to promote employer provision of a benefit fully valued by employees? The best answer here, as pointed out by Summers, is that there may be market failures that lead employers to not reflect workers' valuation of this programme without a government mandate. Most obviously, adverse selection in the market for benefits could cause employer reluctance to be, for example, the one employer in town that offered health insurance or paid maternity leave. This standard adverse selection problem may keep employers from offering benefits that are fully valued by employees. (Indeed, if there is such a market failure, it is feasible that a programme such as workers' compensation could *raise* the quantity of labour in the market. If workers value workers' compensation at more than its cost to employers – as might be the case if workers are risk averse – the labour supply curve would shift out by more than the demand curve shifted in; workers would be willing to accept a wage cut of *more* than the cost of workers' compensation in order to have this benefit. This would actually raise employment.)

Empirical Evidence

During the 1990s a large number of articles explored the empirical impact of mandates, in particular the extent to which mandated costs were shifted to wages. This literature is reviewed in detail in Gruber (2001); I provide an overview here. The consensus of this literature is that, over the medium to long term, the cost of mandates is fully reflected in wages.

Gruber and Krueger (1991) provide the first such analysis, dealing with increases in the employer costs of Workers' Compensation (WC) insurance across US industries and states over time. WC provides cash benefits and health coverage to workers injured on the job, and much of the variation in costs in the authors' data comes from increases in the health care component of this programme. They focus on workers in five industries for which WC costs are high and rapidly growing; in some industries and states, these costs amounted to over 25 per cent of payroll by 1987, the end of their sample period. They use both micro-data on wages and aggregate data on employment and wages by state/industry. They include state and industry fixed effects in their models, so that they are controlling for general differences in pay across industries and places, and estimating only how that pay changed when the costs of WC rose. In both data-sets, they find that for these sets of industries 85 per cent of increases in workers compensation costs were shifted to wages.

Anderson and Meyer (1997) undertake a similar analysis for Unemployment Insurance (UI),

which provides cash benefits to unemployed workers. This programme is not a mandate, but it should operate in the same fashion as it levies payroll taxes on firms to provide benefits to their workers. Anderson and Meyer's conclusion is similar to Gruber and Krueger: general differences in UI payroll taxes appear to be fully reflected in wages with little effect on labour supply.

There is also a long literature on the impact of payroll taxation on wages that is reviewed by Hamermesh (1987). This literature is much more mixed in its conclusions, although the variation in payroll taxes mostly comes over time, and it is difficult to estimate its incidence separately from other time series factors in the United States where there is little variation across workers in payroll tax rates. More recent evidence is consistent, however, with the notion of full shifting to wages in other countries (for example, Gruber 1997).

Labour supply is not simply a discrete choice, however, but rather a combination of participation and hours of work decisions. Increases in costs will effect both the supply of and the demand for work hours conditional on participation. From the employer perspective, increases in health insurance costs are an increase in the fixed cost of employment and are as a result more costly (as a fraction of labour payments) for low-hours employees. Employers will therefore desire increased hours by fewer workers, lowering the cost per hour of the health insurance for a given total labour supply. Of course, if the wage offset is lower for low-hours workers, workers will demand the opposite outcome: there will be increasing demand for part-time work, with hours falling and employment increasing. Moreover, since part-time workers may be more readily excluded from health insurance coverage, there may also be a countervailing effect on the employer side, as full-time employees are replaced with their (uninsured) part-time counterparts. In this case as well, hours would fall and employment would rise. Thus, the effect on hours of work is uncertain. Several studies have addressed this issue, and the general consensus is that mandating fixed costs of employment leads to rises in hours and falls in employment (Gruber 1994; Cutler and Madrian 1998).

Remaining Questions

While there have been significant gains in our understanding of the impacts of mandates, important questions remain unanswered. The most important is the question of heterogeneity across workers: how do mandates affect workers differentially within the workplace? Consider the example of mandated health insurance. The cost of health insurance will not be uniform throughout the workplace; costs are higher for family insurance than for individual coverage, or for older workers than for younger workers. In the limit, with extensive experience rating, costs vary worker by worker, depending on their underlying health status. Gruber (1992) extends the model of Gruber and Krueger (1991) to the case of two groups of workers, where costs increase for one but not the other. If there is group-specific shifting, then the solution collapses to the one group model. If not, however, the substitutability of these groups will also determine the resulting labour market equilibrium; in general, there will be effects on both the group for which costs increase and the group for which they do not.

In practice, there may be a number of barriers to group-specific, and in particular individual-specific, shifting. Most obviously, there are anti-discrimination regulations which prohibit differential pay for the same job across particular demographic groups, or which prevent differential promotion decisions by demographic characteristic. Workplace norms which prohibit different pay across groups or union rules about equality of pay may have similar effects. Thus, a central question for incidence analysis is *how finely* firms can shift increased costs to workers' wages. If there is imperfect group- or worker-specific shifting, there may be pressure on employers to discriminate against costly workers in their hiring decisions.

Two studies suggest that there is within-workplace shifting to wages. Gruber (1994) studied the effect of state laws (and a follow-up federal law) that mandated in the mid-1970s that the costs of pregnancy and childbirth be covered comprehensively. Before this time, health insurance plans provided very little coverage for the costs associated with normal pregnancy and childbirth, while

providing generous coverage for other medical conditions. This distinction was viewed as discriminatory by some state governments, leading to the state laws mandating that pregnancy costs be covered as completely as other medical costs. These laws significantly increased the insurance costs for women of childbearing age in those states, thereby raising the costs of employing a specific group of workers (or their husbands, who may provide them with insurance). I estimated full shifting to wages for these groups. Further corroborating evidence on this point is provided by Sheiner (1999), who found that, when healthcare costs rise in a city, the wages of workers who have the highest costs (older and married workers) fall the most.

This research suggests that within-workplace shifting to wages is possible. The news here is good for efficiency: mandates which have differential effects across broad groups of workers will not necessarily lead to displacement of the high-cost group. The news is potentially bad for equity, however: other groups will not crosssubsidize the high costs imposed on one group in the workplace. In any case, neither of these studies addresses the extent to which within-firm shifting is possible; in the limit, it is hard to conceive that employers could shift costs to wages on a worker-by-worker basis.

Other questions have not been addressed at all by the literature. First, how rapidly does shifting to wages occur? Despite the evidence that mandates are fully reflected in wages, employers vociferously oppose mandated benefits as costing jobs. The reason for their opposition could be that wages cannot adjust quickly enough in the short run to offset displacement effects; the studies cited earlier show full shifting only over several-year periods.

Second, what are the effects of existing constraints on compensation design in the labour market? For example, for workers already at the minimum wage, firms will be unable to shift to wages increases in the cost of health insurance. Similarly, union contract or other workplace pay norms may interfere with the adjustment of wages to reflect higher costs. These institutional features could increase the disemployment effects of rising health costs.

Third, what is the underlying structural mechanism behind a finding of full shifting to wages? In the simple labour market framework above, there are two reasons why increased costs might be shifted to wages: because individuals value the benefits that they are getting fully; or because labour supply is perfectly inelastic. Disentangling these alternatives is very important for future policy analysis. Consider the example of national health insurance, which is financed by a mandate, with an additional payroll tax to cover non-workers. If the full shifting documented earlier is due to full employee valuation with somewhat elastic labour supply, then national health insurance will have important disemployment effects, since labour supply will not increase in response to a benefit that is not restricted to workers. If full shifting is due to inelastic supply, however, then the population which is receiving benefits is irrelevant; in any case the costs will be passed on to workers' wages, so national health insurance will not cause disemployment. Existing evidence, as reviewed in Gruber (2001), is mixed on which of these channels is at work.

Conclusion

Since the early 1990s there has been a substantial growth in research on mandated benefits. The conclusions from the work to date are clear: the costs of mandated benefits are fully shifted onto wages, with little impact on total labour supply. But important questions about the mechanisms behind such shifting remain unanswered.

Ernest Mandel was born of Jewish parents in Frankfurt-am-Main on 5 April 1923. The family emigrated to Antwerp. By 1939 he was actively involved in socialist and trade union politics. When the Nazis invaded Belgium in 1940, he became a member of the resistance. On three occasions he was arrested and imprisoned, but each time he escaped. He was arrested for a final time in October 1944 and liberated by the Allies in March 1945. He obtained a higher education in Brussels and Paris. His name was prominent in academia in the 1960s and 1970s when Marxism and Trotskyism enjoyed significant popularity, particularly among university students. He died on 20 July 1995.

His *Marxist Economic Theory* was first published in French in 1962 and in English in 1968. When student revolts and labour unrest broke out in the late 1960s, Mandel's text and the much shorter *Introduction to Marxist Economic Theory* (1967) were available for the growing numbers interested in Marxist economics. His *Marxist Economic Theory* was widely praised and his *Introduction* sold over half a million copies and was translated into 30 languages.

His *Formation of the Economic Thought of Karl Marx* was published in French in 1967 and in English in 1971. It was one of the first works in English to analyse Marx's *Grundrisse,* which did not appear in complete form in English until 1973.

In his *Europe* vs. *America* – published in German in 1968 and in English in 1970 – he predicted relative economic decline and increasing 'public squalor' in the United States, sustained rapid economic growth in Japan, and the achievement of productivity levels in the western European 'core' regions to rival those in America.

In his *Late Capitalism* – published in German in 1972 and in English in 1975 – he revisited the idea that capitalism was subject to repeated waves of boom and stagnation in 45–60 year cycles. Not only did Mandel predict the downturn of the 1970s on the basis of this analysis, but also this work help to revive academic interest in the study of long waves, which has continued to the present day. However, his analysis has been criticized for misunderstanding Trotsky's criticisms of Kondratiev (Day 1976) and lacking a plausible mechanism to explain the complete long-wave cycle (Tylecote 1992).

Mandel wrote introductions to the new English translations of the three volumes of Marx's *Capital,* published by Penguin (Marx 1976, 1978, 1981). He was obliged to consider the stormy technical debates in the 1970s over the labour theory of value and Marx's theory of the tendency of the rate of profit to fall (Steedman 1977). However, instead of addressing the detailed critical arguments, he simply brushed them aside.

In 1978 Mandel was invited by the University of Cambridge to give the prestigious Alfred Marshall Memorial lectures. These were published as *Long Waves of Capitalist Development* (1980): a restatement and development of ideas in *Late Capitalism.* Further weaknesses in his position emerged when it became clear that mass unemployment in the West was not leading to political advances for socialism. Instead the period saw a resurgent political individualism and neoliberalism.

Like Trotsky, Mandel opposed the view that the Soviet-type economies were another type of 'capitalism', envisaged a collapse of the Soviet regimes, and expected that the working class would rise up in defence of state planning and nationalized property. Even after their collapse in 1989–91, in his *Power and Money* (1992) he hoped for a new workers' movement in eastern Europe and predicted that capitalism would not be easily re-established. Overall, the theoretical weakness of his outlook became increasingly clear in the last 15 years of his life.

Mandeville was born in or near Rotterdam in 1670 and died in Hackney, London, in 1733. He was awarded the degree of Doctor of Medicine from the University of Leyden in 1961. He took up the practice of medicine, specializing in the 'Hypochondriack and Hysterick Diseases', a subject on which he later published a treatise. Mandeville travelled to England, married there in 1699, and lived in England for the rest of his life. He was very widely read in the 18th century. His writings

have often led to his being referred to as a satirist, but that is an inadequate and misleading classification.

Although Mandeville was not an economist, his writings were influential in shaping the direction of economic thinking in the 18th century. In 1705 he published a pamphlet, in doggerel verse, under the title *The Grumbling Hive: Or Knaves turn'd Honest.* In 1714 it was republished under its better-known title, *The Fable of the Bees: or, Private Vices, Publick Benefits.* This and subsequent editions included extensive expansions, clarifications and 'vindications' of his earlier themes. The grumbling hive was originally a thriving and powerful community. When, however, its inhabitants were suddenly and miraculously converted from a vicious to a virtuous moral condition, the community was swiftly reduced to an impoverished and depopulated state.

Mandeville's central theme is that public benefits are the product of private vices and not of private virtues. His paradox, which was widely regarded as scandalous, was achieved by employing a highly ascetic and self-denying definition of virtue. Since behaviour that could be shown to be actuated by even the slightest degree of self-regarding motive – pride, vanity, avarice or lust – was classified as vice, Mandeville had little difficulty in concluding that a successful social order must inevitably be one where public benefits are built upon a foundation of private vices.

> . . . I flatter myself to have demonstrated that, neither the Friendly Qualities and kind Affections that are natural to Man, nor the real Virtues he is capable of acquiring by Reason and Self-Denial, are the Foundation of Society; but that what we call Evil in this World, Moral as well as Natural, is the grand Principle that makes us sociable Creatures, the solid Basis, the Life and Support of all Trades and Employments without Exception: That there we must look for the true Origin of all Arts and Sciences, and that the Moment Evil ceases, the Society must be spoiled, if not totally dissolved. (Mandeville 1732, vol. 1, p. 369)

What was of more enduring significance in Mandeville's views was his forceful and unapologetic popularization of the belief that socially desirable consequences would flow from the individual pursuit of self-interest. It is an essential part of Mandeville's argument that a viable social order can emerge out of the spontaneous actions of purely egoistic impulses, requiring neither the regulation of government officials, on the one hand, nor altruistic individual behaviour, on the other.

> As it is Folly to set up Trades that are not wanted, so what is next to it is to increase in any one Trade the Numbers beyond what are required. As things are managed with us, it would be preposterous to have as many Brewers as there are Bakers, or as many Woolen-drapers as there are Shoe-makers. This Proportion as to Numbers in every Trade finds it self, and is never better kept than when nobody meddles or interferes with it. (Mandeville 1732, vol. 1, pp. 299–300)

Thus, Mandeville enunciates a vision of an economy that organizes itself and that allocates resources through the market place. Although there is no serious analysis of the workings of the market mechanism, there is the clear assertion that the unregulated market provides a system of signals and inducements such that the interactions of purely egoistic motives will somehow produce results that will advance the public good.

In developing his views, Mandeville offered many acute observations on the causes as well as the consequences of the division of labour in society. He regarded the division of labour as the great engine of economic improvement over the ages. It is the most reliable way for 'savage People' to go about 'meliorating their Condition'. For

> . . . if one will wholly apply himself to the making of Bows and Arrows, whilst another provides Food, a third builds Huts, a fourth makes Garments, and a fifth Utensils, they not only become useful to one another, but the Callings and Employments themselves will in the same Number of Years receive much greater Improvements, than if all had been promiscuously follow'd by every one of the Five. (Mandeville 1729, vol. 2, p. 284)

Although one can identify a number of possible precursors to Adam Smith's celebrated views on the division of labour, it is well established that Smith had in fact read and digested Mandeville carefully. Smith's marvellous description of the extensive division of labour involved in the production of a day-labourer's coat, with which he

closes the first chapter of the *Wealth of Nations,* may be traced to Mandeville's earlier treatment of the same subject – a treatment which, indeed, Smith extensively paraphrases. Moreover, the passage in the *Wealth of Nations* containing the often quoted statement that 'It is not from the benevolence of the butcher, the brewer, or the baker, that we expect our dinner, but from their regard to their own interest' (Smith 1776, p. 14) is in a direct lineage from Mandeville's earlier observation:

> . . . The whole Superstructure [of Civil Society] is made up of the reciprocal Services, which Men do to each other. How to get these Services perform'd by others, when we have Occasion for them, is the grand and almost constant Sollicitude in Life of every individual Person. To expect, that others should serve us for nothing, is unreasonable; therefore all Commerce, that Men can have together, must be a continual bartering of one thing for another. (Mandeville 1729, vol. 2, p. 349)

Thus Mandeville was, in some important respects, an early advocate of laissez-faire (although this advocacy did not extend to foreign trade, where Mandeville's views were still distinctly Mercantilist). He articulated a vision of the role of the division of labour in society, and of the forces making for social change and evolution, as well as for social cohesion, that were in many respects distinctly precocious, and that exercised a powerful influence in shaping the intellectual agenda of economists and other social scientists later in the 18th century.

Mangoldt was born in Dresden in 1824 and died in 1868 of a heart attack after a short life. He was an eminent theorist in economics, yet greatly underrated by his German contemporaries. He received his doctorate in Tübingen (1847) and was afterwards a civil servant in the Ministry of Foreign Affairs – a post he resigned for political reasons – and became editor of the official *Weimarer Zeitung* (1852). His academic career began in 1855 as Privatdozent in Göttingen and ended as Professor of Political Science and Political Economic after only six years (1862–8) at the University of Freiburg (Breisgau).

Mangoldt ranks among those pioneers in Germany, like von Thünen, von Buquoy, von Hermann, Gossen and Launhardt, who applied formal analysis to explain economic phenomena.

Yet the predominant influence of the Historical School diminished the impact of his methods and ideas on German university economists. He shared this fate with Cournot and Walras. A second reason for this underrating of his pioneering achievements at home was his strong interest in classical economics. Thus it is not surprising that his reputation was much higher in England (via Edgeworth and Marshall) than in 19th-century Germany.

In his most important books, *Unternehmergewinn* (1855) and *Grundriss* (1863), he argues in the classic tradition, examines its hypotheses in the light of economic and political reality and modifies them considerably. Like Cournot (earlier) and Marshall (later) Mangoldt uses a novel apparatus of partial analysis – Frisch's microanalysis –to expound originally a mathematical theory of prices that goes far beyond Cournot. He describes in a very modern way the process from one equilibrium to another, analyses multiple equilibria and explains joint supplies and demands, a concept which Marshall would take up later on. Further, he has deeply influenced our theories of profit and rent by interpreting the entrepreneurial gain as rents of differential ability. Indeed, Mangoldt definitely anticipates Schumpeter's theory of the entrepreneur. He clearly distinguishes profit as an independent category of income from interest (of the capitalist), by stressing different elements of gain such as the compensation for risk-bearing or for new goods or techniques of production and sale. The pioneer function of the entrepreneur, motivated also by intangibles, as in Smith's concept, is clearly expressed in the statement

> . . . die Auffindung und Verwirklichung der besten Produktionsmethoden . . . die Ausbeutung der von der Natur gegebenen Hilfsmittel, die Herstellung der Güter in der für das Bedürfnis dienlichsten Weise [the discovery and realization of the best methods of production, . . . the exploitation of natural resources, the manufacturing of goods in a way that is most appropriate for the need]. (1855, p. 68)

This means, of course, novel improvements as well.

Unfortunately, Mangoldt did not attempt to make these realistic and dynamic elements an essential part of his price theory via a notion of *evolutionary* competition as did Smith and Schumpeter. Thus he neglected the different properties and intensities of competition in different stages in the life cycle of a product.

Furthermore, his contribution to allocation theory was as pioneering as his analysis of coalitions on the labour market. Here he objected to profit participation by workers without risk-sharing. Finally, it is notable that Mangoldt originally extended Ricardo's theory of comparative costs by applying, although in rather vague terms, the notion of elasticity of demand and supply in the theory of international trade.

Mangoldt was, no doubt, one of the eminent theorists and rare pioneers in the 19th century whose achievements are still underrated and whose use of mathematics seems to be rather overrated. Though an abstract thinker, he seldom lost the binding ties to reality.

Manoilescu, Mihail (1891–?1950)

Nicholas Georgescu-Roegen

Mihail Manoïlescu was born in Tecuci (Romania) in 1891, the son of two elementary school teachers. His continuous school successes bespoke of the exceptional qualities on which he was to rely for political ambitions as well as for scholarly endeavours. As a top student at the Bucharest Polytechnical School, from which he obtained the engineer diploma in 1915, Manoïlescu became acquainted with the Crown Prince (the future Carol II) while the latter was attending the same class. It was a political asset subsequently enhanced when in 1930 Manoïlescu was instrumental in bringing Carol back from self-imposed exile. Manoïlescu started his reputation as a keen engineer and an astute operator by designing a better cannon and by organizing a successful Industrial Exhibition (1921). He began his catapulting political career by joining the People's Party and thereby becoming Under-Secretary of Finance (1926/27). Thereafter, he switched to the Peasant Party and, after Carol's return, he became in succession Minister of Communications, of Industry and Commerce, and Governor of the National Bank. In 1932, he occupied the newly established chair of political economy at the Polytechnic School.

Alongside that arduous activity he devoted time to his second attraction in life, the political and economic problems which he tackled with the characteristic subjective originality of the non-professional who, as Schumpeter remarked, often sees what the others do not. Several minor articles in Romanian as well as the few papers in foreign periodicals were thin and verbal. In his inaugural lecture (1932) and in his course (1938) he praised the mathematical tool and yet he criticized the Lausanne School for using the concept of *homo economicus* with measurable attributes. And in one corner, he intimated that great personalities decrease the entropy of the community. Worthy of note for his political evolution was his lecture on Neo-liberalism in a signal series of eighteen others on political doctrines (1923). His theory of industrial protectionism which attracted no little attention grew out of the economic situation of Romania, then a predominantly agrarian country facing increasingly adverse international price scissors. Manoïlescu laid bare the root of his philosophy in a 1928 lecture at the Société de Géographie when he stunned many of the French political elite by asserting that no nation, just as no individual, can get rich without exploiting the labour of others. (Almost certainly, he was citing neither John Locke nor Robert Owen.) And he topped it by the quip that the British always placed a gratis copy of the *Wealth of Nations* in each bale of cotton goods exported to India. The English translation of the 1929 French original, *The Theory of Protection* (1931), was reviewed in the foremost periodicals. Only Jacob Viner (1932), 'that unbelievably skillful advocate' of the classical doctrine (as B. Ohlin judged him), threw Ricardo's book at the author. But, as E. Hagen (1958) observed in his balanced examination, Viner did not deal with 'Manoïlescu's argument' which did not refer to the static model of an economy that just strives toward its best comparative advantage compatible with *given, immutable* possibilities. His argument was about the advantage not only of industrialization for an agrarian and overpopulated economy but also of industrialized nations able to purchase food for less labour than that of its exports (a point laid out in 1920 by J.M. Keynes in *The Economic Consequences of the Peace*). He thus went beyond the protectionism of infant industries favoured by J.S. Mill and Alfred Marshall; as he claimed (Preface, 1929), he did better than F. List. Only Ohlin recognized Manoïlescu's merit in his review (1931) and more pointedly in his 1967 monograph. Viner kept decrying Manoïlescu's thesis, as he did in discussing a 1946 independent argument of L.H. Bean (Viner 1952). Yet even Viner (1937) finally weakened, as he sought to justify the classical doctrine by the difference in occupational disutilities. The few theorists who mentioned Manoïlescu's argument lost themselves in a maze of unrealistic and inadequate assumptions. But by now hardly any economist

would deny that industrialization was responsible for economic development from the Tennessee Valley to Korea. Of course, the classical doctrine stands correct as concerns mineral deposits or special climates, but the point has been usually overlooked, as it was by Manoïlescu (1943) in his comparison of labour productivity between oil and other Romanian industries.

Between the two World Wars an atmosphere of dissatisfaction with capitalism reigned all over Europe. In 1936, none other than J.M. Keynes stressed 'the objectionable features of capitalism . . . the inequitable distribution of wealth and income'. As far back as 1848, J.S. Mill recognized its 'crass materialism', even the superiority of pure communism. The interwar circumstances kindled the interest of many economists (R. Kaula, J.M. Clark, G. O'Brien, and A.J. Penty, as examples) for the just price of the medieval principles and the guild system in which the individual had less freedom but was more secure and in which not only the producer but also the consumer was protected. All were only harking back to such authorities as Lujo Brentano, William Ashley and Max Weber. And as in Italian 'guild' is *corporazione* (in French, *corporation*), in the 1930s one Italian political scientist after another (e.g. Ugo Spirito, Filippo Carli, Carlo E. Fermi, and even the eminent mathematical economist Luigi Amoroso) identified fascism with a corporatist state. Manoïlescu (1934) saw in corporatism the imperative doctrine of this century just as, in his opinion, liberalism was for the 19th century. A long argument with numerous quotations from many authors and especially from Benito Mussolini did not produce a satisfactory definition of corporatism, nor of corporation. He opined that even Italian facism could not serve as an instance of a corporatism integral and pure, supposed to represent 'the functional organization of the nation . . . in its supreme interest' (pp. 80, 176). The quotation from Bernard Lavergne, 'The French people are actually represented in the Parliament, but France is not', characterizes the way Manoïlescu envisioned his subject. Curiously though, Manoïlescu presented a summary of his volume at the Stresa meeting of the Econometric Society in 1934.

As an almost natural sequel, there followed his *Le parti unique* (1936), which removed all doubts about the author's sympathy with the dictatorial regimes of the Hitler–Mussolini type. Manoïlescu was certainly not a member of any nazi party, but in this volume he spoke exactly as one, having only praise for all dictatorial chiefs. And he vaunted himself as the chief of 'The National-Corporatiste League' he had founded in Romania. It was a far cry from his 1923 'Neo-liberalism'. The volume has nonetheless some value for its information about dictatorial regimes from the USSR to Portugal and, more interestingly, about the incipient dictatorial parties all over Europe from Norway to Switzerland. It was because of the temper of the 1930s that this volume (just as the other two) was translated into several languages.

As the political tension worsened Carol, counting on Manoïlescu's being in favour with the Axis Powers, swore him in as Minister of Foreign Affairs in 1940. However, when Manoïlescu had to bow to the Vienna *Diktat* by which the Axis allotted a part of Transylvania to Hungary, the careers of both men were brought to a sudden end. Some time in 1948, the Communist regime threw Manoïlescu without trial in to jail where he died, presumably in 1950. His life typifies the fate of many intellectuals during the stormy political circumstances of that time in Europe.

Mantoux, Paul (1877–1956)

R. Forster

Paul Mantoux published *La Révolution industrielle au XVIIIe siècle* in 1906. Since the first translation into English in 1927, the book has gone through not less than sixteen English impressions, the most recent in 1983. In his introduction to the 1961 edition, T.S. Ashton attributed the longevity of Mantoux' book to the author's clarity of thought and expression, his openness to amendment by new evidence, and his scrupulous objectivity. Mantoux' contribution to English economic history can be compared to that of his compatriot, Elie Halévy, to English political and social history. Both historians intended their synthetic accounts for a French audience, but they were even more valuable to English readers because of their freshness of approach and their liberation from national preoccupations and prejudices. Given the prodigious historical literature on the English Industrial Revolution, the continued serviceability of Mantoux' book is extraordinary. Even today, eighty years after the first French edition, Ashton's high praise remains pertinent: '. . . by far the best introduction to the subject in any language . . . a permanent work of reference' (Introduction to the 1961 edition, p. 27).

Of course research since 1906, and especially since 1927, has qualified or corrected many of Mantoux' interpretations. Mantoux' work predates the enormous influence of national-income economics on economic history associated with W.W. Rostow (ed.), *The Economics of 'Take-Off' into Sustained Growth* (1963), and the work of American growth economics especially since the 1950s (R. Fogel and D. North). In England a whole generation of historians, signalled by the three-volume work of J.H. Clapham in the 1930s, employed quantification systematically to measure all aspects of economic growth, including changes in per-capita real wages, and to resolve the 'standard of living' controversy once and for all (P. Deane and W.A. Cole, R.M. Hartwell, T.H. Ashton, A.J. Schwartz, W.O. Henderson, among others). But by the late 1960s, the Fabian Socialist tradition, now ably defended (and amended) by Christopher Hill, Eric Hobsbawm and Edward Thompson, reasserted itself, arguing that aggregate economic statistics only disguised the more fundamental issues of the quality of life in a working class culture.

In a curious way, the historical debates on the English Industrial Revolution have now moved closer to Mantoux' synthesis of 1906. This is not so much because of Mantoux' sympathy for the English Fabians when he was a young professor at the University of London before World War I, but rather because his mode of history-writing was essentially descriptive and developmental rather than hypothesis-testing or statistically oriented. On the other hand, although Mantoux emphasized that the Industrial Revolution 'gave birth to social classes whose progress and mutual opposition fill the history of our times' (1920s), the greater weight of his book was 'to show the continuity of the historical process underlying even the most rapid changes' (p. 476).

Recall that his was a history of the industrial revolution in the *18th century*, and that a good third of the book treats the 'evolution of traditional industry', English commercial growth from the 17th century, and the agricultural revolution of the 18th century – all 'preparatory changes' before the rash of inventions and the beginnings of the factory system at the end of the 18th century. Mantoux regarded the First Industrial Revolution as the culmination of trends in the English economy at least two centuries in the making. Mantoux had great respect for such venerable English institutions as the Poor Law and the humanitarian response of evangelical groups to child labour and other abuses of the new factory system. In the end, while he did not minimize the social dislocations created by the Industrial Revolution, Mantoux, not unlike David Landes in *The Unbound Prometheus* (1969), acclaimed this 'revolution' as an English achievement of momentous consequences – technological, economic, and social – for the entire world in the centuries to follow.

Paul Mantoux was not only an economic historian. He acted as the Interpreter of the Supreme War Council and of the Peace Conference at Versailles in 1919. A committed internationalist, he served as Director of the Political Section in the Secretariat of the League of Nations. Mantoux' article on 'Lost Opportunities of the League' in *World Crisis* (Geneva, 1938) struck a less optimistic tone than the one pervading his great work of 1906.

Manufacturing and De-industrialization

Ajit Singh

Industries in advanced countries have expanded and contracted in response to changes in technology and demand since the beginning of the industrial revolution. However, the phenomenon of de-industrialization, usually identified with the contraction of output or employment in the manufacturing sector as a whole, has only caused concern in these countries during the last decade or so. It has spawned a large academic literature, particularly in the UK, which was among the first industrial countries to manifest symptoms of de-industrialization (Singh 1977, 1982; Blackaby 1979; Beckerman 1979; Thirlwall 1982; Martin and Rowthorn 1986). It has also led to an important public debate on industrial policy in the UK, the US and in other industrial countries (for the UK, see Ball 1982; Eatwell 1982; Matthews and Sargent 1983; Singh 1979; Stout 1979; Godley and Cripps 1981; for the US, see Thurow 1980, 1984; Branson 1982; Krugman 1983; Schultze 1983; Norton 1986).

Significantly, 'de-industrialization' has long been a subject of great interest in developing countries like India. Several Indian economic historians have argued that as a consequence of free trade with Europe and economic policies of the colonial government, India suffered de-industrialization during the 19th century. Instead of industrial expansion, both the proportion of output and employment contributed by manufacturing industry fell in this period (see Bagchi 1976; for a sceptical view of this argument, see Little 1982; for a theoretical discussion, see Hicks 1969).

At an analytical level, the phenomenon of de-industrialization raises two central issues. Firstly, why should some industries rise and others fall, or more interestingly, why should the manufacturing sector as a whole decline absolutely, or in terms of its share of national output or employment? Secondly, does de-industrialization, defined in these terms, matter? As Singh (1977) asked in one of the first papers on de-industrialization: 'What is so special about industry that one should be concerned about de-industrialization? There has also been a considerable loss of employment from agriculture, but not much has been said, at least by economists, about de-ruralization.' In other words, the main question is whether de-industrialization can be regarded simply as a normal response to changing technology and tastes, or does it signify some structural disequilibrium in the economy as a whole with malignant overall consequences. The proponents of an industrial policy to correct de-industrialization in countries like the UK and the US clearly regard it as a manifestation of a structural disequilibrium.

Insofar as 'de-industrialization' in advanced countries is understood in terms of an absolute decline or a falling share of the manufacturing industry in total output and employment, the main stylized facts may be summarised as follows (Singh 1977, 1981, 1982; Blackaby 1979; Martin and Rowthorn 1986, which are the main sources of the figures below).

First, in the first decade or so of the long post-war boom (1945–73), the share of manufacturing in total employment increased in almost all industrial countries, including old industrial countries like the UK which already had a large proportion of their labour force employed in manufacturing. (As long ago as 1860, nearly 33% of the UK labour force was employed in manufacturing: Feinstein 1972.) The manufacturing employment share reached its peak (36.1% of civil employment) in the UK in 1955, but since then it has been in decline. The share fell marginally over the next decade (it was 34.8% in 1966), at a somewhat faster rate to 32.3% until 1973, and at a much faster rate since then (the 1981 figure was 26.4%). In countries like Belgium and Sweden, the pattern of change in the proportion of labour force employed in manufacturing was broadly similar to that of the UK, i.e. a slow decrease up to 1973 and an accelerated decline subsequently as the world economy slowed down after 1973. However, it is significant that in France and Germany, there was no evidence of a trend decline in the manufacturing industry's share of employment until 1973, although since then the share has fallen markedly in both countries. In Italy and Japan, the share actually expanded up to 1973, but even in these countries there has been a trend decline since then. In the US, the proportion of labour force employed in manufacturing fell from 28.5% in 1955 to 24.8% in 1973 and to 21.7% in 1981.

Second, in relation to the numbers employed in manufacturing and their rates of growth, manufacturing employment increased in all industrial countries in the post World War II period (including the UK) up to the mid-1960s. Between 1966 and 1973, although it fell in a few countries (e.g. the UK, the Netherlands, Belgium), manufacturing employment continued to grow in most OECD countries, including the US, Japan, Italy, France and Germany. However, during the decade 1973–83, manufacturing employment has fallen in almost all industrial countries, the rate of decline ranging from 0.04% per annum in Japan and the US to a massive 3.1% per annum in the UK and 3.4% per annum in Belgium. Thus, in the UK the numbers employed in manufacturing industry have fallen from their historical peak of 8.4 million workers in 1966 to 5.4 million at the end of 1984, a drop of 35%, half of which occurred in the five-year period 1979–84.

Third, turning to manufacturing production, the share of manufacturing in total production *at constant prices* did not show any trend decline in most industrial countries, including the UK, during the period of the long boom (1945–73). In the US, Japan, Italy, France and Germany, manufacturing's share at constant prices, reached its peak in 1973. However, between 1973 and 1983, the g.d.p. in all the leading industrial countries has expanded at an appreciably faster rate than manufacturing production, thus indicating a fall in the share of manufacturing in g.d.p. over this period. The abysmal record of the UK manufacturing industry again stands out: despite the slowdown in world economy after 1973, all the leading industrial countries other than the UK managed to expand their manufacturing production during the decade 1973–83, albeit at a far slower rate than before. However, manufacturing output in the UK in 1983 was 18% lower than it was a decade earlier.

Fourth, in contrast to the behaviour of manufacturing in constant prices, when the share of manufacturing in total production is measured *at current prices*, it shows a trend decline in a large number of industrial countries even before 1973. In the UK, the share fell from 36.1% in 1960 to 31.0% in 1973; in the US the corresponding decline was from 28.4 to 24.9%. The main reason for this difference in the constant and current prices shares of manufacturing lies in the fact that in many advanced countries because of the faster growth of productivity in manufacturing than in services, the terms of trade tended to move in favour of the latter.

In short, the empirical evidence indicates that before 1973, there was a small decline in the proportion of the labour force employed in manufacturing in some of the advanced countries. However, no country showed a trend decline in the share of manufacturing in output at constant price. Since the slowdown in world economic growth in 1973, the share of manufacturing in both output and employment has fallen to a greater or smaller degree in most industrial countries.

The falling share of manufacturing in total employment and output is predicted by the theorists of the post-industrial society or of the so-called 'service economy' as a natural outcome of the long run process of economic development (Fuchs 1968, 1981; Bell 1974; for a critical view, see Gerschuny 1978). Time series as well as cross-section studies of both developed and developing countries show that there is a striking similarity in the pattern of structural change as a society becomes more wealthy. Rising per capita incomes are accompanied by continuing falls in the share of the agricultural sector in national output and employment; the share of the manufacturing or of the broader category of industry as a whole, increases until a high level of per capita income is reached and then it begins to decline; the service sector's share continuously increases. Thus, on the basis of regression analysis of time series data for the US for over a century (1870–1978) as well as cross-section data for the OECD economies, Fuchs (1981) found that the share of industry in total output typically reaches its peak at a per capita income level of $3000 to $3500 (at 1972 prices). Both the OECD cross-section study and the US time series analysis yielded a broadly similar conclusion. (See also U.N. (1979), which is based on data from both advanced and developing countries.)

Analytically, the reasons for the observed changes in the sectoral shares of agriculture, manufacturing and services in the course of economic development lie in two factors: (a) the relative rates of growth of productivity, $\dot{p}$, and (b) the relative income elasticities of demand, η, for the products of these three sectors. η is usually much greater in manufacturing and services than in agriculture, where it typically has a value of less than 1; η is also thought to have a higher value in services than in manufacturing. On the other hand, $\dot{p}$ tends to be very much higher in manufacturing and agriculture than in services. (For instance, over the period 1929–65 in the US, Fuchs (1968) found that $\dot{p}$ in industry increased at the rate of 2.2% per annum, compared with 1.1% per annum in services. Such a large difference in $\dot{p}$ between industry and services over the long time period examined in this study, cannot be accounted for by the well-known problems of measurement of output in the service sector.) If these stylized facts about the relative values of η and $\dot{p}$ in the three broad sectors of the economy

hold, it is not difficult to see that as per capita g.d.p. increases, the share of services in output and employment will tend to increase first at the expense of agriculture and subsequently at the expense of manufacturing industry (Martin and Rowthorn 1986).

In considering the fall in the share of industry in the advanced countries in terms of the above analysis, there are two points which deserve attention. First, the observed decline in the share of manufacturing in total employment is much more due to the effects of differences in $\dot{p}$ than in η between manufacturing and services. In the US, for the period 1948–78, Fuchs (1981) ascribe three-fourths of increase in service sector employment relative to that in manufacturing to the much greater value of $\dot{p}$ in manufacturing than in services, and only one fourth to the relatively higher income elasticity of demand for services than for manufacturing. Secondly, it is important to bear in mind that although η may be higher in services than in manufacturing, as noted earlier, prices tend to rise more slowly in manufacturing than in services. This 'price effect' is likely to compensate in part for the disadvantage of manufacturing with respect to the 'income effect', η, so that overall there may not be much difference in the rates of growth of demand for the output of manufacturing and services. This suggests that in the long run in the advanced countries, manufacturing's share in output at constant prices is likely to fall relatively little compared with its share in employment. In the limit, the latter share (whose primary determinant, as noted above, is the sectoral differences in $\dot{p}$ may be expected to become as small as that of agriculture, i.e. tend towards zero.

If the fall in the industry's share of output and employment is simply due to structural features common to all modern economies, de-industrialization in this sense should not be regarded as a matter of serious concern. However, it is conceivable that for a particular economy, the extent of the fall in the share of industry in either output or employment may go beyond what may be expected at that economy's level of per capita g.d.p. To the extent that the manufacturing sector is regarded as an 'engine of economic growth' (Kaldor 1966; Cripps and Tarling 1973), such reduction in the size or contribution of manufacturing may be expected to lower the economy's future growth potential.

More importantly, Singh (1977) argued that in an *open* economy, the question whether de-industrialization can be regarded as a manifestation of structural disequilibrium in the economy, 'cannot be properly considered in terms of the characteristics of the domestic economy alone'. Such a proposition, he suggested, has a sensible meaning only in the context of the interactions of the economy with the rest of the world, i.e. in terms of its overall trading and payments position in the world economy. Since trade in manufactures is a major determinant of the current account balance of most advanced countries (usually much more important than the trade in services), an analysis of de-industrialization necessarily entails an examination of the performance of the country's manufacturing sector in the international economy.

With these considerations in mind, to give precision to the concept of structural disequilibrium, Singh defined an efficient manufacturing sector in the case of the UK economy, in the following terms: *Given the normal levels of the other components of the balance of payments*, an efficient manufacturing sector is one which (*currently as well as potentially*) not only *satisfies the demand of consumers at home at least cost*, but is *also able to sell enough of its products abroad to pay* for the *nation's import requirements*. This is, however, subject to the qualification that an 'efficient manufacturing sector' must be able to achieve these objectives *at socially acceptable levels*, of *output, employment, and the exchange rate*. The latter restrictions are extremely important since at low enough levels of output and employment, or more arguably at a sufficiently low exchange rate, almost any manufacturing sector may be able to meet this criterion of efficiency. (The exchange rate should be regarded here as an indicator of the acceptable levels of inflation and inequality of income distribution.) It is also necessary to emphasise the significance of the condition that, to be efficient, the manufacturing sector must be able to fulfil the

above requirements not merely currently, but also in the long run. For instance, a windfall gain to the balance of payments (e.g. from the discovery of North Sea oil) may put it temporarily into surplus (at desired levels of output, employment, etc.), although manufacturing industry may be incapable of ensuring this when 'normal' conditions return. Cairncross (1979) has rightly pointed out that an implication of this conception of an efficient manufacturing sector is that even when 'manufacturing output was actually growing in proportion to g.d.p. (as on one measure it did up to 1973), or even when manufacturing employment was growing in proportion to total employment', there may be de-industrialization, i.e. a structural disequilibrium in the sense of a progressive failure to achieve sufficient exports to pay for full employment level of imports at a 'reasonable' exchange rate.

There is a large body of evidence that during the last two decades the UK manufacturing industry has not only been 'inefficient' in these terms, i.e. characterised by long-term disequilibrium, but more importantly, this disequilibrium has been growing worse over time (Blackaby 1979; Singh 1977, 1982, 1986; CEPG 1976–82). It is important to distinguish the period before 1979 with the period after 1979. There are two important characteristics of the latter period which are significant: (a) a new Conservative administration came into office in May 1979 and embarked on a rather different set of economic policies than had been followed hitherto by successive governments of both the major political parties (Reddaway 1982); (b) from being a net importer of oil, Britain progressively became a significant exporter of oil.

Even before 1979, it was evident that, mainly because of the decline in the performance of the UK industry in the world economy, there had been a trend deterioration in the country's current account balance at full employment. Between 1964 and 1978, the UK's share of world manufacturing exports was nearly halved whilst the industry suffered a huge increase in import penetration in its own home market; significantly, this was despite the fact that over this period UK's costs and prices, expressed in terms of a common currency, had *fallen* relative to those in the competitor countries. The main long term problem of the economy before 1979 was that the current account was increasingly going into deficit well before full employment was reached. To illustrate, in 1965–66, the country was able to achieve a rough balance on the current account although there was near full employment (rate of unemployment of 1.5%). A decade later, in 1975, although nearly 4% of the labour force was unemployed, there was a current account deficit of £1700 million. Part of this was, indeed, due to the effects of the rise in oil prices in 1973. However, as CEPG (1976) showed, even assuming that the terms of trade had remained constant at the pre-1972 level, there would have been a current account deficit of £2000 million at full employment in that year. By 1977 the UK's current account deficit at full employment had soared to nearly £6000 million.

Disaggregated analyses show that the main reason for the above disequilibrium did not lie in the UK's trade in services or invisibles, but in visible trade in finished manufactures. Equally importantly, this deficit arose from the UK's trade with other advanced countries rather than with the Third World. With the latter, it in fact recorded a growing surplus (Singh 1982; see further section VI below).

Since 1979, the situation of the UK manufacturing industry in the world economy has deteriorated even further. The period of North Sea oil in the 1980s (by 1983, the UK's oil exports amounted to nearly 20% of her total merchandise exports) *could* have been used to restore the position of industry; instead, this period has coincided with industry's accelerated decline. In 1980, as a consequence of the North Sea oil, and the government policy of monetary and fiscal restraint with consequent high interest rates and economic slowdown, sterling appreciated sharply leading to an enormous squeeze on manufacturing industry. Manufacturing production fell in a single year by 9.3%, the largest such decline ever recorded in the UK in a twelve-month period – larger than those during the Great Depression after 1873 and after 1929. The maximum annual fall in manufacturing production in the first Great Depression occurred

between 1878 and 1879 and was 5.5%; that in the second Great Depression was 6.9% between 1930 and 1931 (Singh 1986). Manufacturing production fell further by over 6% in 1981. In 1982, for the first time in a century of its industrial history, Britain, the erstwhile workshop of the world, recorded a deficit on its manufacturing trade. In 1985, even after three years of economic recovery, the level of manufacturing output was $5\frac{1}{2}\%$ lower than in 1979 and 5% lower than in the first quarter of 1974 when, as a result of the miners' strike, the country was working only on a 'three-day week'. (For a fuller discussion of the relationship between oil, the government economic policy and de-industrialization, see Singh 1979; Forsyth and Kay 1980; Barker 1981; Coutts et al. 1986.)

In view of the fact that Britain's North Sea oil resources are limited, and their contribution to the balance of trade has most likely already reached its peak, the prospects for the future of the UK economy with a weak manufacturing industry are grim indeed. Coutts et al. (1986), on the basis of certain optimistic assumptions about the future expansion of world trade and competitiveness of British industry, project that Britain's current account balance would move from a surplus of £4 billion in 1985 (achieved at a rate of unemployment of 13%) to a deficit of £20 billion (at 1985 prices) in 1995 if non-oil output grows at a rate of $2\frac{1}{2}\%$ per annum (which is the minimum required for unemployment not to increase further). On the basis of the past econometric relationships, it is shown that much of this deficit will be due to an increase in the manufacturing deficit from £3 billion in 1985 to £23 billion (at 1985 prices) in 1995. Such a large current deficit, amounting to nearly 5% of g.d.p. in 1995, would clearly be unsustainable for any length of time, and most likely the government would have to lower the non-oil rate of economic growth to perhaps one and a half per cent per annum to achieve a satisfactory balance. This would imply a further sizeable rise in unemployment.

To sum up, the UK economy had been undergoing a long-term process of de-industrialization – in the sense of a progressive failure of the manufacturing industry to earn enough to pay for the full employment level of imports – even before the new Conservative government of Mrs Thatcher came into office in 1979. The economic policies of this government, despite the benefit of North Sea oil, instead of reversing this process, have managed greatly to accelerate it, with serious consequences for current and potential production and employment.

As for the reasons for de-industrialization in the UK, there are a number of passionately held views about the causes of this 'original sin', ranging from the laziness of British workers, the deficiencies of the educational system, the peculiarities of the English 'class system', the weaknesses of the managers, etc. However, there is no general agreement among economists on the reason or reasons for the poor performance of UK industry. In this connection, the Cambridge school of economists have put forward an important thesis (Singh 1977; CEPG, various issues; see also Cairncross 1979). It is argued that whatever the underlying cause of the long-term structure of disequilibrium of UK industry, if Britain continues to participate in the world economy on the same kinds of terms as before, and/or if it does not change the domestic production system, the long-term disequilibrium will keep on becoming more acute over time. This thesis is based on Myrdal's (1957) theory of circular and cumulative causation. It is suggested that the weaknesses of the British industry have led to a slow overall growth of the economy over the last quarter century relative to that of the competitor countries. This, in turn, is regarded as being responsible for the lack of dynamism in the country's productive system. Economies that grow quickly have higher investment, achieve faster technical progress, more product innovation and improvements in other important non-price spheres of competition. In addition, the take-home pay of workers in a fast-growing economy will generally also be growing more quickly. Other things being equal, this is likely to lead to better relations between workers and managers, with consequent benefits to productivity and performance. On account of its slow growth, UK industry has suffered on both these counts. The result has been a vicious circle of causation by which industry is increasingly unable to hold its own in either overseas or

home markets. The Cambridge economists further argue that because of the size of the structural disequilibrium of the UK industry, and the nature of the wage-price relationships in the economy, such disequilibrium cannot be corrected by currency depreciations.

Turning to the US, can the definition of an efficient manufacturing sector and of de-industrialization in the sense of structural disequilibrium of the economy (as outlined in section I) be applicable to that country as well? On the face of it, US industry is confronted with problems similar to those of UK industry: loss of world export markets, increasing import penetration and an enormous current account deficit brought about in large measure by the failure of industry to compete adequately either at home or abroad. A number of American commentators have argued that the US has been 'losing the economic race' (to use Thurow's (1984) phrase), particularly to Japan. The country is thought to suffer from institutional sclerosis which is reflected in declining supply elasticities and rising rates of core inflation (Scitovsky 1980). Kindleberger (1973) referred to 'the dynamic failure of the [US] economy to produce new exports to replace those now being eroded by the product cycle'. Similarly, Abramovitz (1981) asked in his presidential address to the American Economic Association in 1980: 'Can we mount a more energetic and successful response to the challenge of newly rising foreign competition after 1970 than Britain did after 1870?' More recently, the competitive failings of US industry have been documented in the *DRI Report on the US manufacturing industries* (Eckstein et al. 1984) and in the Report of the US President's Commission on Industrial Competitiveness (1985).

Nevertheless this view of the decline of US industry in the world economy is very much disputed in a number of other studies (Branson 1981; Lawrence 1984; Summers 1983; Bergstrom 1983; Norton 1986, which provides a very useful survey of this literature). Lawrence in particular argues that the problems of US industry in the 1980s stem largely from macroeconomic policies of the US government. He suggests that the fiscal deficit, leading to high interest rates and large capital inflows, has been responsible for the sharp appreciation on the dollar. This, together with the faster growth of US economy after 1982 compared with that of Europe, have led to the huge merchandise and current account deficits. Lawrence, however, estimates that a relatively small depreciation of the dollar, 'an improvement of less than 0.25% per year in relative US prices would suffice to ensure balanced trade in manufactured products'. The correctness of this optimistic view of US industry will be tested by events.

A widely held view about de-industrialization in the advanced countries of the North like the UK is that it is being caused by the industrialization of the South and particularly of the so-called newly industrialising countries (NICS), e.g. South Korea, Taiwan, Brazil, Mexico, India. It is suggested that the comparative advantage in a whole range of industrial products has shifted to the NICS and this has inevitably led to a reallocation of resources from the manufacturing industry in the North to other economic sectors as well as to the South through multinational investment (Beenstock 1984). In less sophisticated terms, the trade unions and business groups in the North ascribe the decline in manufacturing employment and the increase in overall unemployment in the industrial countries to the competition of cheap labour products from the South.

It is, indeed, true that during the 1960s and 1970s, the South achieved rapid industrial progress. The southern countries' share of world manufacturing production, although still quite small, increased by nearly 50% over the period 1960–1980, from 6.3 to 9.9%. Significantly, the South's share of world production rose not only in consumer goods but across a wide spectrum on industries, including capital goods products like steel, ship-building and engineering. Equally importantly, the South's share of world manufactured exports increased from 3.9% in 1960 to just over 5.0% in 1970 and to 9.0% in 1980. During the 1970s the advanced economies' imports of manufactures from the South expanded at twice the rate as their imports from each other (Singh 1982, 1984; UNIDO 1979).

It is important to emphasise that industrialization in one part of the world need not necessarily

take place at the expense of industrial development in another part of the world. Sayers (1965) made a useful distinction between 'complementary' and 'competitive' aspects of world economic expansion for any particular country or region. Economic growth elsewhere is 'complementary' to the extent that it raises demand for the country's exports, but it becomes 'competitive' insofar as it leads to the development of alternative sources of supply. So, from the point of view of a country or a region, the development of the world economy may be characterised by a changing balance between 'complementarity' and competitiveness'. During 1960–1980, not just the South, but the socialist countries of Eastern Europe industrialised very fast; the latter's share of world industrial production increased from 17% to 27% over these two decades. Nevertheless, it would be difficult to maintain that East European industrialization was achieved at the expense of the older industrial countries of Western Europe. On the contrary, most observers would agree that, if anything, West European industrial development was most probably positively helped by industrial demand from the East.

The question remains whether industrialization of the South, and in particular, of the NICS, has been more 'competitive' rather than 'complementary' to the North and, hence, responsible for the loss of manufacturing jobs in the advanced countries. A host of empirical studies answer this question in the negative (see OECD 1978, for a useful review of this research). More specifically, a number of these studies, particularly for the UK and the US, which follow a similar methodology, suggest, broadly, two kinds of conclusions. First, relative to the growth of productivity and changes in domestic demand in advanced countries, manufacturing trade as a whole (with both the developed and developing countries) has a relatively small effect on reducing manufacturing employment in these economies. Secondly, the net effect of manufacturing trade with the less developed countries on aggregate unemployment in the North, though negative, has been more or less negligible. Thus, the Foreign and Commonwealth Office (1979) concluded on the basis of an analysis of UK's trade in manufactured products with the NICS between 1970 and 1977 as follows: 'Any net displacement (of labour due to trade with the NICS) appears to have been quite small.' The main reason why the observed effects are so small is that although manufacturing imports from the NICS *ceteris paribus* reduces employment, the NICS have a very high propensity to import which leads to increased northern exports and, hence, employment. The overall effect tends to be slightly negative since the southern imports generally affect the relatively labour-intensive industries in the North whilst North's exports to the South occur in the relatively capital-intensive sectors.

Although these conclusions are not unreasonable, the underlying methodology of the above studies is open to serious reservations. The common analytical model on which they are based, makes changes in employment in an industry a function of changes in home demand, trade and productivity. Thus, in this research, increases in productivity *always* lead to a reduction in employment, which is clearly unsatisfactory. It is more acceptable to envisage that the growth of productivity leads to a reduction in prices which increases both domestic and export demand and, hence, generates a rise in output and employment. Moreover, the theoretical model does not take into account the fact that at least some of the advanced countries (e.g. the UK) during the reference period were balance of payments constrained. For such economies an increase in trade imbalance will have a multiplier effect on output and employment. The deterioration in the trade balance in a particular industry, or with a particular country, means that, *ceteris paribus*, unless there is an equal improvement of the balance in another industry, or with another country, the Government (through fiscal and monetary policies) is forced to run the economy at a lower level of output and employment than it otherwise would.

Singh (1981, 1982) used a rather different analytical model to study the effects of the UK's trade with the NICS over the period 1963–77. His methodology was more in keeping with the conception of de-industrialization discussed in section IV, i.e. the notion of long-term structural or trading disequilibrium. He concluded that

manufacturing trade was indeed the main cause of Britain's de-industrialization in this sense and, hence, responsible for the slow growth of output and employment in the economy. However, it was imbalance in the manufacturing trade with Japan and other advanced countries which was the chief source of this disequilibrium rather than Britain's trade with the Third World. Britain enjoyed trade surplus in manufactures with the NICS which had in fact progressively increased over the period studied, while with Japan and other advanced countries, Britain's trade balance had sharply deteriorated. Thus, despite the fast pace of industrialization in the NICS and the huge increase in their manufacturing exports to the UK, the UK's trade in finished manufactures (SITC 7 and 8) with the NICS during the 1960s and 1970s led to an increase in domestic output and employment rather than a decline. Nevertheless, Singh also found that there was evidence that in the case of some of the NICS, there were likely to emerge *in the future* imbalance in trade of a kind similar to UK's trade with Japan and other advanced countries, although this had not actually happened so far.

More generally, the OECD (1978) study for a group of advanced countries and a sub-set of NICS found that OECD's trade balance in manufacturing with NICS increased over the period 1970–77. The tentative general conclusion which emerges from this analysis is that even if in some balance of payments constrained advanced countries manufacturing trade with NICS had become disequilibrating in the 1970s, it is likely in general to have been a far smaller source of disequilibrium than the trade among the industrial countries themselves.

Turning to policies to reverse de-industrialization, there has been an intense economic policy debate on the subject on both sides of the Atlantic, particularly in the UK. With the UK's rates of unemployment during the mid-1980s approaching those recorded in the worst years of the 1930s Great Depression (if unemployment rates are measured on a comparable basis: see Tomalinson 1982), the central economic policy issue is how to reduce unemployment. It is generally agreed that a substantial sustainable increase in employment, other than through temporary make-work schemes, will require much faster economic growth than the trend rate experienced during the 1970s and 1980s. This in turn will necessitate a veritable reindustrialization of Britain – much faster growth of manufacturing production than has been achieved since 1973 – in order to sustain a current account balance at a time when the contribution of oil exports to the balance of payments will most likely be decreasing. (This is true despite the relatively greater contribution to the balance of payments which may be expected from the 'services' in the future; in view of the relative dimensions of manufactured exports and credits from services and the high income elasticity of demand for manufactures, the UK current account balance cannot be maintained at the desired growth rate simply by a faster expansion of services. See Singh 1977; Blackaby 1979; Coutts et al. 1986.)

Not surprisingly, however, there is no general agreement among economists about how faster economic growth can be realised, if at all. There are two major institutional parameters which constrain economic policy in Britain: (i) international economic arrangements which essentially consist of more or less free trade, free convertibility of currency and more or less free capital movements; and (ii) despite its set-backs in the 1980s, there is still a strong trade union movement with a major influence on wage-price determination. (In particular, the second constraint makes it difficult for a government to resort to the classic device of devaluation without risking inflation.)

There are a number of economists who believe that the long-term structural disequilibrium of the economy is now so acute that faster economic and industrial growth to reverse de-industrialization can only be achieved if one or the other of the above institutional constraints is relaxed. On the one side it is suggested that a further weakening of the power of the unions as well as more market-oriented supply-side policies are required to initiate a process of sustained economic growth. On the other, in a series of papers over the last decade, the Cambridge Economic Policy Group economists have argued that it is the international economic constraint which needs to be relaxed: Britain requires a long period of comprehensive

import controls as well as capital controls to permit sustained industrial and economic recovery without running into current account disequilibrium (Cripps and Godley 1978; CEPG 1976–82). These import controls are regarded as a necessary but not a sufficient condition for achieving faster economic growth. They would need to be supplemented with appropriate supply-side policies, which can, however, be either of the free-market or dirigistic variety depending on the political preferences of the policy makers (see Singh 1980, 1986, for a fuller analysis of these issues). The CEPG economists argue that the purpose of import controls is not to seek an improvement in the current account balance above its sustainable level but rather to expand production and employment by limiting the *propensity to import*. Over the medium term, it is shown that import controls in fact make possible a much larger volume of imports than under free trade. (The reason for this apparent anomaly is simply that the primary determinant of imports is the level of economic activity which would be much higher under a regime of import controls.) The CEPG economists suggest that this perspective should make it possible to negotiate a programme of control with Britain's main trading partners without inviting retaliation.

Several British economists, however, still believe that Britain can reverse de-industrialization within the present institutional framework of the economy (Hopkins et al. 1982; Matthews and Sargent 1983). They suggest a standard Keynesian policy of reflation coupled with currency depreciation and an incomes policy. However, the record of incomes policies in the UK during the last two decades has been unpromising (Tarling and Wilkinson 1977). Moreover, detailed empirical analysis (CEPG 1982) suggests that in view of the weaknesses of manufacturing industry and expected reduction in the contribution from oil exports, even if the incomes policy is reasonably successful, such a programme will run into balance of payments constraint at a relatively low rate of economic growth. These policies would not therefore lead to a significant reduction in unemployment; they would also be accompanied by a relatively high rate of inflation.

In the US, the economic policy debate concerning de-industrialization has centred around the so-called issue of 'industrial policy'. The advocates of an industrial policy (Thurow 1982; Bosworth 1983; Etzioni 1983) have suggested that the US needs major fiscal policy changes to raise the rate of investment and to modernise the social infrastructure as well as a targeted industrial policy to make the US industry regain its competitiveness. However, other US economists have questioned these arguments (Krugman 1983; Schultze 1983; Lawrence 1984). These scholars insist that the lack of competitiveness of the US industry in the 1980s has essentially been due to the appreciation of the dollar. Therefore, what is required in this view is more appropriate macroeconomic policies rather than an industrial policy. (For a recent comprehensive review of this US debate, see Norton 1986).

In conclusion, de-industrialization in the sense of falling levels or shares of manufacturing output and employment, need be of no greater concern than de-ruralization if it does not imply any structural disequilibrium of the economy which constrains it from achieving full utilization of resources or the desired growth of production. Agreeing with what he called the Cambridge view, Cairncross (1979) noted,

> a contraction of industrial employment is a matter for concern if it jeopardizes our eventual power to pay for the imports we need. . . . it is the loss of economic potential that is the crux of the matter. But whether that loss arises from the reasons given in Cambridge, whether it can be made good in the way propounded there, and whether it might yield to other, more familiar, but less agreeable treatment are matters on which there is not likely to be general agreement.

Mao Zedong [Mao Tse-Tung] (1893–1976)

Peter Nolan

Mao led the Chinese Communist Party (CCP) in its revolutionary struggle pre-1949 and was pre-eminent in the post-revolutionary leadership for most of the period from Liberation (1949) until his death in 1976. The degree to which Mao personally dominated China's post-revolutionary development is illustrated by the dramatic changes that have occurred since his death. It seems reasonable to speak of a 'Maoist model' to characterize China's development path for much of the period from 1949 to 1976.

There were a number of influences underlying this model. Nationalism was central to Mao's thinking. He was proud of China's historical achievements and angry at her humiliations in the century before 1949. He wished to build a powerful modern economy so that China would 'never again be an insulted nation'. China's cultural tradition permeated Mao's thought; his analysis of problems in terms of 'contradictions' owes as much to the traditional Chinese dialectic of *yin* and *yang* as to Marxism.

The Leninist–Stalinist application of Marxism in the USSR also influenced Mao (not always positively). From this tradition he accepted the notion of a post-revolutionary vanguard party overseeing all aspects of socio-economic life. From it too he absorbed the view of a 'socialist' economy as the antithesis of capitalism, i.e. no private ownership of the means of production and economic decisions determined not by market forces but by planners' administrative directions ('with us plans are primary and price is secondary . . . the law of value has no regulating function'). The adverse consequences of administrative planning under Mao were the same as those in economies with similar systems (e.g. low incentives for technical progress or to improve the range and quality of products; high incentives to hoard resources).

Mao was convinced of the possibility (and desirability) of changing popular consciousness, so that the main force motivating social action might become collective interests rather than personal gain. Although he wanted modernization and material progress, Mao stood outside the Marxist–Leninist tradition in thinking that 'socialist' values ('fighting self' and 'serving the people') might be more successfully developed among poor people ('poor people want change, want to do things, want revolution') and in the villages more easily than in the 'corrupting' cities. For Mao, Liberation marked the beginning of a long process of both economic development and 'permanent revolution' in China's class relations.

Mao's economic policies may be examined under four headings: (1) population; (2) economic growth; (3) rural institutions; (4) the international economy.

After 1949 Mao initially considered population control unnecessary. He was persuaded eventually of the problems of rapid population growth, but a sustained campaign to control population

growth was not implemented until the 1970s, so that China's population grew rapidly for most of the 1950s and 1960s.

Although Mao did not produce a rigorously formulated theory of economic growth, certain aspects of his thinking on this question can be identified. He considered a high rate of investment a necessary condition of rapid growth. Administrative planning via physical controls, direct control over the urban wage bill, and the CCP's influence on rural collectives' income distribution, together permitted a high rate of investment – China's 'accumulation' rate stood at over 30 percent of national income in most years from 1957 to 1976.

Mao's writings suggest that under him China broke away from the heavy industry emphasis of other 'socialist' countries. Unfortunately, the high investment rate, microeconomic inefficiency, slow technical progress and a vicious circle of self-expansion within the capital goods sector, together helped produce an alarming fall in the incremental output–capital ratio from the 1950s to the 1970s. From 1949 to 1957 heavy industry's investment share rose rapidly, and thereafter generally absorbed 45–55 per cent of state units' 'basic construction investment'. Many Chinese economists (when permitted) criticized the system that produced this result, but Mao refused to make the sweeping changes required to shift away from the heavy industry bias.

Mao considered microeconomic relationships to be important for economic growth. He argued that in a cooperative environment 'workers will look upon the enterprise as their own and not the cadres". This, he believed, would release the vast areas of human creativity left untapped by capitalism's antagonistic class relations. For Mao, a socialist enterprise was one in which workers had a powerful say in enterprise decision making, managers and technicians discarded their 'haughty airs' and participated in manual labour, the competitiveness of piece rates was replaced by time rates, differences in basic wages were kept within strict limits, and the proportion of income allocated 'according to need' rose over time. With the partial exception of Yugoslavia, these utopian ideas had not received such attention in the 'socialist' countries since the first months of War Communism in the USSR.

Despite their intrinsic problems, in a different setting such policies might have produced better results. However, in China they were often crudely applied (e.g. 'integrating' managers and technicians with ordinary workers by forcing them to wear dunces' hats in public) and were practised in enterprises with negligible independence and whose workers experienced little long-term growth of real income. These caused serious motivational problems.

The CCP led China's peasants through land reform and on to establish rural collectives which were the basic framework of economic activity for most Chinese people from the mid-1950s to the early 1980s. Mao thought they were an appropriate setting for developing 'socialist' values, avoiding the class conflict of 'capitalist' agriculture, and supporting disadvantaged peasants. He believed too that collectives would benefit from economies of scale. It was to prove much harder to develop 'socialist' values among peasants than Mao had anticipated. The CCP waged a constant, unsuccessful battle to 'cut off the tails of capitalism' in the villages. Moreover, in certain areas of farmwork (especially labour intensive crop cultivation) powerful managerial *dis*economies of scale appeared. Farm efficiency was adversely affected too by state control over key collective decisions, such as the allocation of income between accumulation and consumption. As a result, the micro-level problems were even worse in the countryside than in the cities.

Mao was afraid that extensive contact with the international economy would make China 'dependent' on outside forces. In the 1950s China built a comprehensive industrial system. Trade was viewed as a necessary evil. Exporting firms were denied direct contact with world markets; it made no difference to them whether their products succeeded or failed internationally. Unsurprisingly, China's export performance from the late 1950s to the late 1970s was poor. Mao did not wish China to have a high level of imports, confident that she could produce domestically most of the products she required and could be virtually self-sufficient in technical progress. He did not

permit foreign investment in China or China's acquisition of long-term debt. The economic costs of Mao's extreme position were high.

In the early 1970s, as China emerged from the isolation of the Cultural Revolution, Western economists were increasingly sympathetic to China. Development economics textbooks commonly included a brief section on the 'Maoist model'. While arguing against its transferability to different political systems, it was usually praised for its alleged achievements in combining quite rapid overall growth with the elimination of mass poverty and more equal income distribution than in most developing countries.

Since Mao's death, the mass of newly available statistical and anecdotal information has led to a major reappraisal of the Maoist epoch. There have been shocking allegations of mass starvation after the Great Leap Forward (1958–9) during which Maoist policies were applied in their purest form. China's official statistics show that its population fell by about 14 million from 1959 to 1961, suggesting a demographic disaster. Many Western observers enthused about Mao's utopian goals in the Cultural Revolution but it became clear that these had been pursued in a deeply repressive fashion, involving the imposition of one man's vision upon an increasingly unenthusiastic population. The end of Maoism was greeted with huge relief at all levels of Chinese society.

It can now be seen that the Chinese economy in the mid–1970s was in a state of crisis. Rapid population growth over two decades, an excessively high and unbalanced accumulation rate, pervasive microeconomic inefficiency, and isolation from the world economy, combined to produce little measured improvement in average living standards from the mid–1950s to the late 1970s, and in certain important respects (e.g. housing, cotton cloth, edible oil, entertainment) the situation had deteriorated. Despite some success in ensuring that a basic minimum consumption standard was provided, when Mao died there still were wide regional income disparities and a sizeable minority of the Chinese population was abjectly poor.

These problems were illuminated by the results of the post 1978 economic reforms, which dismantled many important aspects of the Maoist model. After 1978 average living standards rose dramatically and the proportion of the population in poverty declined sharply. It is impossible not to attribute these achievements (and important new problems) to the massive institutional reform (especially that in the countryside), the increased impact of market forces, expanded contact with the international economy, and alterations in the state's investment policy.

It is not surprising that the attractiveness of Mao's development model waned rapidly after his death. Perhaps the most fitting epitaph is that provided in 1978 by the elderly economist Chen Yun:

> Had Chairman Mao died in 1956, there would have been no doubt that he was a great leader of the Chinese people, a respected, loved and outstanding great man in the proletarian revolutionary movement of the world. Had he died in 1966, his meritorious achievements would have been somewhat tarnished but still very good. Since he actually died in 1976, there is nothing we can do about it.

Maoist Economics

Wei Li

Abstract

During the Maoist era (1949–76), China attempted to adopt Soviet-style central planning in her first Five-Year Plan, but soon changed course. Under the heavy hand of Chairman Mao Zedong, China created a unique style of central planning where the centre enunciated broad policy directives in the form of slogans that could be easily passed down to local cadres, who were given strong

incentives to find ways to implement them. This article outlines a consistent framework for analysing the policy changes during the Maoist era and their dramatic impact on the Chinese economy.

> (Chen Yun at the Central Party Work Conference, November–December 1978. Quoted from Lardy and Lieberthal 1983. *Ming-Pao* (Hong Kong) 15 January 1979)

'Maoist economics' refers to the collection of economic policies implemented by the Communist Party of China (CPC) during the Maoist era, which began with the founding of the People's Republic in 1949 and ended shortly after the demise of Chairman Mao Zedong in 1976. Thanks to the CPC's meticulous cultivation of Mao's personality cult, Mao was able to exploit his 'mass line' political strategy by exhorting the masses to follow his vision when the CPC hierarchy was unwilling. As a result, Mao could set major policy initiatives with few checks and balances. But to attribute all major decisions to Mao would be an oversimplification, especially before 1958. The leadership of the CPC in Beijing and local cadres, often split into factions with different policy agendas and preferences (for a detailed historical account of the policy debates within the leadership circle in China in the 1950s and 1960s, see for example, Lardy and Lieberthal 1983; Riskin 1987; Bachman 1997), contributed not only to policy implementation but also to policy formulation. Maoist economics is therefore not synonymous with 'Mao Zedong Thought' on economic matters. ('Mao Zedong Thought' is considered an extension of Marxism–Leninism derived from the teachings of Mao Zedong and the distillation of the experience of the Communist revolution in China. It has been enshrined in the Constitution of the CPC as part of the party's official ideology since 1945. As China has embarked on market-oriented reforms since 1978, 'Deng Xiaoping Theory', which advocated the pragmatic concept of 'socialism with Chinese characteristics', has served as the party's working doctrine.)

The aim of this article is to outline a consistent framework for organizing and understanding the economic policies that were formulated and implemented during the Maoist era.

Agricultural Taxation and the Chinese-Style Central Planning

When on 1 October 1949 Chairman Mao proclaimed that the Chinese people had finally stood up at the ceremony for the founding of the People's Republic, China was a desperately poor agrarian economy ravaged by more than a century of internal turmoil, foreign invasions and civil wars. With most of her industrial assets either destroyed or looted by the Soviet forces that occupied Manchuria at the end of the Second World War, or removed to Taiwan and Hong Kong ahead of advancing Communist troops, China was 'poor and blank', as Mao (1958) put it. With 90 per cent of her population of 550 million living in abject poverty in the countryside and toiling on small plots of land using traditional labour-intensive farming technology, China was barely able to feed and clothe her population.

Since poor peasants made up the vast majority of the population, the CPC under Mao had focused on building its support base among

peasants by, among other things, promising to deliver what every peasant wanted: a private plot of land. Between 1946 and 1953, the CPC launched land reform, first in the territories under its control and then in all ethnically Chinese areas on the mainland after 1949. The process generally involved assigning each rural family a class status; motivating the poor, lower-middle, middle and initially the 'rich' peasants to engage in 'class struggle' against landlords; and expropriating land, draft animals, farm implements and property from landlords and redistributing them to landless peasants (Fairbank 1992). The 'class struggle', which included public trials, denunciations and mass executions of landlords and counter-revolutionaries, created an atmosphere of terror. But the land reform solidified support for the CPC among the poor and middle peasantry. (For an on-the-ground observation of the land reform in a Chinese village, see Hinton 1967.)

As the CPC secured military and political control of the mainland, its priority shifted to managing and rebuilding the war-torn economy. With the economy rebounding quickly, Chinese leaders turned their attention to long-run economic development, aimed at building a socialist, industrial nation. Having secured material and technical support from the Soviet Union, they adopted a Soviet-style, heavy-industry-oriented development strategy in the first Five Year Plan (FYP 1953–7). The plan called for massive industrial investment, including the construction of 156 industrial plants outfitted with imported Soviet equipment. The Soviet contributions to this big push included loans amounting to about four per cent of the total investment, technology transfers and 10,000 Soviet specialists (Fairbank 1992). The success of this ambitious plan therefore hinged on the ability of the government to mobilize investable surplus internally. Without a significant industrial and commercial sector, the government had to extract the needed surplus from the vast agricultural sector.

Throughout Chinese history, agricultural taxes, collected in kind, have been the primary source of government revenue. (Indeed the Chinese character for tax, *shui*, as a portmanteau of grain and convert, refers to a levy on the use of land payable in grain.) In the 1950s, China had a three-tiered agricultural tax structure. At the first tier was an in-kind levy on grain production, known as the 'government grain'. Peasants received no compensation for turning over the government grain to the State Grain Bureau. At a statutory rate of 15 per cent in 1950, this tax accounted for 39 per cent of government revenue. (This figure is calculated using data posted on the official website of China's Ministry of Finance.) In later years, as the price scissors – the differences between the prices on industrial and agricultural goods – widened, and as the industrial sector grew rapidly because of the massive capital expenditure funded largely by agricultural taxes, the share of explicit agricultural taxes dropped to six per cent by 1976.)

At the second tier was an implicit tax, a grain procurement quota, which dictated how much each peasant household had to sell to the State Grain Bureau out of their after-tax grain at below-market procurement prices. After meeting these two obligations, peasants would usually be left with just enough grain to sustain a subsistent living. Markets still existed in the early 1950s, where peasants could exchange some of their surplus produce for other goods. At the third tier was an inkind levy on rural labour. Under the traditional subsistence farming practice in China, peasants would take a break or work less intensively during agricultural offseasons in order to conserve food energy. To the government, this idling was unacceptable. Dams, irrigation systems, roads and other large-scale infrastructure projects could be worked on more intensively during off-seasons by drafting peasants to carry out backbreaking manual labour. Utilizing a mixture of exhortation and coercion, the government mobilized tens of millions of peasants for large construction projects in the 1950s.

Collecting the three-tiered taxes from hundreds of millions of independent peasant households was a daunting task. Tax enforcement became even harder when market prices of grain rose substantially in 1952 as a result of increased demand caused by rapid industrialization and urbanization and by the need to export agricultural products in exchange for Soviet equipment. In response, the government in 1953 closed the grain market and

monopolized grain trade by fiat, making it illegal for anyone other than the government to engage in large-scale grain trade. In 1954, it expanded the control to include oil seeds, cotton, pork, and other key agricultural commodities.

Extracting agricultural surplus was further hampered by the lower level of agricultural productivity in China than in more developed countries. With nearly 90 per cent of the population living in the countryside, China was producing barely enough food and wearable fibres to meet basic domestic needs. Estimates by Ashton et al. (1984) suggest that the daily average food energy intake in China in the 1950s was around 2000 calories per capita, below the 2350 calories recommended by the United Nations.

To further improve its extractive capability and to raise agricultural productivity, the government turned to collectivization. By organizing peasant households into collectives, the CPC could extend its political control down to the village level. The grass-roots party organizations could effectively monitor production to further improve tax compliance. Rooted in the prevailing ideology, Chinese leaders also believed that collectivization would enable peasants to take advantage of economies of scale, to learn best practices in scientific farming, to accelerate the adoption of high-yield seeds and modern inputs, and therefore to realize a great leap in agricultural productivity. (Apparently influenced by Soviet propaganda, Chinese leaders were taken in by the miraculous claims of productivity-boosting farming techniques made by a group of pseudo-scientists who dominated the Soviet agricultural science establishment. Because these pseudoscientific techniques contradicted the farming experience of Chinese peasants, the only way to propagate them was to make it a political task for rural collectives and grass-roots party organizations. For an account of Lysenkoism in the Soviet Union and its influence in China during the Maoist era, see Becker 1996.)

Collectivization, however, represented a radical reorganization of rural life in China. Given the importance of agriculture in the Chinese economy and the traumatic experience of forced collectivization in the Soviet Union (Becker 1996), China's first FYP emphasized voluntary participation and set out a relatively conservative and flexible timetable, calling for socialist transformation in agriculture to be accomplished in 10–15 years. Between 1952 and 1954, collectivization proceeded gradually. By 1954, only 11 per cent of peasant households were enrolled in elementary Agricultural Producers' Cooperatives (APCs), where members pooled their privately owned land, draft animals and large tools and used them jointly. APC members were paid wages for their labour as well as rents for their contributions in land and capital. While wage rates and rents were supposedly set at market levels, actual practice left many richer peasants complaining that the rents were insufficient. Reports of richer peasants exiting the cooperatives, selling and killing their draft animals, and downing trees on their plots in 1954 started to alarm leaders in Beijing. In January 1955, the CPC issued an urgent order for the protection of draft animals. The combination of state monopolization of grain trade and collectivization had, by the authorities' own admission, dampened the 'enthusiasm' of the peasants for production. Emergency measures that the government implemented included fixing procurement quotas and putting on hold any further push for collectivization in the spring of 1955. But any reprieve that peasants got was short-lived.

By the summer of 1955, imbalances in the economy from implementing the aggressive first FYP had reached record levels. The supply of agricultural products, raw materials and consumer goods could not keep up with the growing demand. With tax revenues insufficient to meet the funding needs in the first FYP, the government was running a large fiscal deficit. (In 1955, debt issuance by the government reached a record high of 2.5 per cent of GDP.) Factors that contributed to the imbalances included the agricultural bottleneck exacerbated by the collectivization movement, the ambitious first FYP that allocated massive investment to heavy industry, and the inherent difficulties of managing a centrally planned economy.

Mao's own analysis, however, identified overcentralization as a serious problem of the Soviet-style central planning whereby the planners tried to do what could be done better by local cadres. The solution that Mao put forth was not to stop the

expansion of the role of the state in the economy, but to limit the role of the nascent central planning bureaucracy and expand the role of local governments. He faulted the planners in Beijing for not doing enough to harness the enthusiasm of local cadres, workers and peasants for socialist transformation both in industry and in agriculture. In a policy speech delivered on 31 July 1955, Mao made the argument for accelerating socialist transformation in general and collectivization in particular.

> [Some] comrades fail to understand that socialist industrialization cannot be carried out in isolation from the cooperative transformation of agriculture. In the first place, as everyone knows, China's current level of production of commodity grain and raw materials for industry is low, whereas the state's need for them is growing year by year, and this presents a sharp contradiction. If we cannot basically solve the problem of agricultural cooperation within roughly three five-year plans, that is to say, if our agriculture cannot make a leap from small-scale farming with animal-drawn implements to large-scale mechanized farming, . . . then we shall fail to resolve the contradiction between the ever-increasing need for commodity grain and industrial raw materials and the present generally low output of staple crops, and we shall run into formidable difficulties in our socialist industrialization and be unable to complete it. (Mao 1977, pp. 196–7)

To ensure that Mao's vision was turned quickly into action, the CPC passed in October 1955 a resolution that reiterated the policy directive for accelerating collectivization and authorized the party hierarchy to criticize any party member who disagreed with the policy as a 'right-leaning opportunist'. ('The Resolution Regarding Agricultural Collectivization' was passed in the 6th Plenary Meeting of the 7th CPC Congress held in Beijing from 4–11 October 1955.)

As local cadres who moved decisively and quickly to implement this policy directive were publicly praised, and laggards were publicly criticized, local cadres found themselves locked into a rat race on who could coerce peasants to form bigger collectives at a faster pace. By the end of 1956, 96.3 per cent of all peasant households had joined collectives, more than 10 years ahead of the schedule set in the first FYP.

Mao's administrative decentralization was not a repudiation of the concept of central planning. It was an attempt to redefine central planning in the Chinese context with perhaps an implicit intent to enlarge the sphere of Mao's influence. By weakening the nascent central planning bureaucracy, Mao effectively strengthened his own influence in enunciating broad policy directives in the form of slogans that could be easily passed down to local cadres. To align the interests of local cadres with the centre, Mao offered high-powered incentives: those who found innovative ways to implement the centre's directives irrespective of economic consequences were rewarded with public praise and promotion, while those who ignored the centre's policy directives were punished with the humiliation of public criticism and denunciation. In more serious cases, those who resisted the centre's policy directives could be purged as 'rightists' or 'counter-revolutionaries'. Mao also made frequent use of brutal political campaigns against nonconformists and instilled an atmosphere of terror. (One of the most notorious political campaigns was the 1957 'anti-rightist' campaign; Fairbank 1992.) The resulting political system was one in which Mao could exploit his personality cult in enunciating broad policy directives without the inconveniences of checks and balances. Mao's administrative decentralization thus marked the beginning of the politicization of economic policy formulation and implementation in China. When Mao launched the Great Leap Forward (GLF) movement in 1958, the inaugural year of the second FYP, there was hardly any dissenting voice.

The Great Leap Forward

By setting production targets even more aggressively in the second FYP, the CPC hoped that China would grow out of the imbalances created during the first FYP by exhorting local cadres and the masses to make selfless sacrifices in order to transform China into an industrial, socialist nation. In March 1958, the CPC issued a new directive, calling local cadres to amalgamate smaller cooperatives into larger ones. Zealous local cadres in Henan province created township-sized collectives, dubbed 'People's

Communes'. Each of the communes was an all-encompassing institution that functioned as a local government, an agricultural collective, local government-owned industrial and commercial enterprises (one of the enduring legacies of Mao's administrative decentralization was the policy directive that encouraged the creation of local government-owned enterprises), local schools, and a militia integrated into the national defence system. In these collectives, communalization went beyond all means of production and invaded the private lives of peasants. For example, family kitchens were banned and were replaced by communal kitchens that offered members free meals (Li and Yang 2005). 'People's Communes are good because they are big and communal', declared Mao. By early autumn, communes had spread across China.

Believing that collectivization significantly boosted agricultural productivity, the CPC created a new rat race for local cadres by exhorting them to 'overcome reactionary conservatism' (*People's Daily*, 10 September 1958). Unable to deliver the expected increase in grain output, local cadres started to outdo each other in statistical gamesmanship by making wild claims about grain output. An initial tally of the 1958 grain output after the autumn harvest pegged it at 525 million metric tons (MMTs), up by nearly 170 per cent from 1957. The figure was subsequently revised down to a more modest 375 MMTs. (The downward revisions did not stop here. Two more were made: first to 250 on 22 August 1959 and then to 200 in 1979; Li and Yang 2005.)

With the numbers indicating that collectivization had permanently resolved China's agricultural bottleneck, the government raised agricultural taxes: grain procurement (including government grain) was increased from 46 million metric tons in 1957 to 64 in 1959; 16.4 million peasants, about twice the size of the industrial labour force in 1957, were relocated to cities in 1958 to support the expansion of industry and construction; and more than 100 million peasants were mobilized in the winter of 1957–8 to undertake large irrigation and land reclamation projects, and to operate millions of small 'backyard iron furnaces'. (Built using mud and bricks, these furnaces melted scrap metal – for example, iron woks made obsolete by communal kitchens – to produce iron, which even the government admitted was of useless quality; Becker 1996.) The increase in agricultural taxes allowed the government to raise national savings from 24.9 per cent of national income (measured by net material product) in 1957 to 43.8 per cent in 1959. These savings were almost exclusively invested in heavy industries (Riskin 1987, p. 142). Grain export was raised from an average of 2.11 million tons between 1953 and 1957 to 3.95 million tons in 1959 to meet payment obligations for importing capital goods.

The collectivization miracle was, however, a mirage. Lin (1990) finds that incentive problems within large collectives had deleterious effects on agricultural productivity. With actual grain output significantly lower than the falsified statistics, the agricultural taxes were excessive. Grain retained in rural areas fell sharply from 273 kg per capita in 1957 to 193 kg in 1959, and further down to 182 kg in 1960. Since grain was the primary source of food energy in China at the time, the drop in per capita food availability coincided with the onset of worst famine in human history. (Demographers who extrapolated mortality trends in China estimated the total number of premature deaths during the GLF famine at between 16.5 and 30 million; see Li and Yang 2005.)

As the disastrous consequences of the GLF policies became known in 1959, Mao temporarily stepped aside to let his pragmatic colleagues, Liu Shaoqi and Deng Xiaoping, take responsibility in managing both government and party affairs. The pragmatic leaders started to reverse course: they reduced grain procurement by ten million tons, increased agricultural labour force by more than 50 million between 1958 and 1962 by sending back new industrial recruits back to the countryside, dismantled communal kitchens, downsized the collectives and started to import grain. More importantly, they allowed spontaneous, bottom-up experimentation with market-oriented reforms in 1961. Grain output began to recover in 1961, but did not surpass its pre-GLF level of 195 million metric tons (recorded in 1957) until 1966, the first year of yet another political upheaval – the Cultural Revolution.

The Model

To better understand the trade-offs faced by Chinese policymakers and the key factors that contributed to the GLF disaster, I turn next to Mao's policy directive for accelerating collectivization with the aid of a simple two-sector dynamic model developed in Li and Yang (2005).

A key feature of the Li–Yang model is the explicit dependence of agricultural labour productivity on nutrition. For simplicity, assume that in the agricultural sector labour is the only factor and the technology exhibits constant returns to scale. If L_t is labour allocated to agriculture, the aggregate grain output in year t can be written as

$$Q_t = af(c_t)L_t \tag{1}$$

where $af(c_t)$ measures the contribution of nutrition to the labour productivity of an average worker who consumes c_t amount of grain in year t, and a is a productivity parameter. Experimental and empirical studies have found that $f(\cdot)$ tends to be an increasing, S-shaped function with $f''(c) \geq 0$ at a very low level of food intake, and $f''(c) < 0$ as food intake reaches a sufficiently high level. (For a survey on health, nutrition and economic development, see Strauss and Thomas 1998.) If the government taxes away p_t amount of grain output from each agricultural worker after the harvest in year t, the amount of grain saved for consumption in year $t + 1$ is then

$$c_{t+1} = af(c_t) - p_t \tag{2}$$

The industrial sector uses a Leontief technology that produces one unit of industrial output by employing one unit of labour, d units of capital service and m units of grain as an intermediate input in fixed proportions. Assume that all capital goods must be imported and paid for by exporting grain, and the exchange rate is one unit of grain to one unit of capital service. With abundant grain supply and the economy's labour supply normalized to 1, the industrial output is simply $1 - L_t$. The government is assumed to maximize a discounted flow of industrial output, $\sum_{t=0}^{\infty} \beta^t (1 - L_t)$, subject to the following budget constraint:

$$p_t L_t \geq (d + m + n)\ (1 - L_t), \tag{3}$$

where $\beta < 1$ is the government's discount factor and n is the food entitlement of each industrial worker. (For more discussion on food entitlement, see Li and Yang 2005. In 1956, the national average of monthly ration of grain for labourers assigned to the most physically demanding jobs was 25 kg. Retail prices of food items in stores were set by the government and played little role in resource allocation.) This constraint, which captures China's key bottleneck during the Maoist era, states that the amount of grain procured must be sufficient to meet export demand for the importation of capital goods, industrial demand for intermediate inputs, and food demand from industrial workers.

Given the government objective, the optimal solution calls for allocating just enough labour to grain production, so the constraint (3) is binding in each year. This implies that the optimal allocation of labour to grain production should be $L_t = (d + m + n)/(p_t + d + m + n)$. Substituting this binding constraint into eq. (2), one can show that the government's optimal policy is a solution to the following Euler equation for a given initial level of food consumption c_0:

$$a\beta f'(c_{t+1}) = \left(\frac{af(c_{t+1}) - c_{t+2} + d + m + n}{af(c_t) - c_{t+1} + d + m + n}\right)^2. \tag{4}$$

The optimal steady state policy is to set the food consumption per agricultural work $\bar{c}$ such that $f'(\bar{c}) = (a\beta)^{-1}$. The steady state is asymptotically stable if $f''(\bar{c}) < 0$. This stability condition is satisfied if the productivity effect of nutrition exhibits diminishing returns around the steady state per capita food consumption, which is consistent with previous experimental findings.

Under the stability condition, the steady state grain procurement $\bar{p}$ and industrial output $1 - \bar{L}$ are both increasing functions of agricultural productivity a and the discount factor β. The model therefore validates Mao's claim in his quoted policy speech that raising agricultural productivity would contribute to the relaxation of the agricultural bottleneck and hence permit a faster pace of industrialization. It also proves that patience is a

virtue: a more patient government, one that uses a larger discount factor β (or a lower discount rate) in setting intertemporal policies, can sustain a higher level of steady state agricultural and industrial production. The intuition is as follows. A more patient government, one that discounts future industrial production at a lower rate and is content with a lower growth rate, would set a lower tax rate on peasants, allowing them to improve nutrition and labour productivity. The improved productivity would in turn increase the tax base sufficiently high to more than compensate for any revenue loss from lowering the tax rate. As a result, both the grain procurement and industrial production are higher in the steady state for a more patient government.

Like Stalin, Mao was impatient. (In a speech delivered in 1931, Stalin 1952, used nationalistic rhetoric to demonstrate the imperative to press on with rapid industrialization regardless of the obstacles during the first 5 Year Plan of 1928–1932 in the USSR.) And, like Stalin, Mao saw collectivization as a means to achieve rapid industrialization. Expecting collectivization to raise a, the increasingly impatient planners exhorted local cadres to increase grain procurement and to divert more agricultural labour to industrial production and large infrastructure projects. Since collectivization actually caused a to fall, the GLF policies left many peasants with insufficient amount of grain for consumption. Malnutrition (and famine in several grain-producing provinces) significantly reduced labour productivity, leading to a collapse in grain production. The further reduction in grain output caused malnutrition, and famine to spread from the countryside into cities. The linkage between nutrition and productivity thus offers a dynamic explanation of why the negative incentive effect of collectivization could cascade into a major catastrophe. Empirical investigation by Li and Yang (2005) finds that the GLF policies were principally responsible for this disaster. As the GLF policies were reversed by Liu Shaoqi and Deng Xiaoping, the Chinese economy began to stabilize in 1962. In 1966, when the economy appeared to have fully recovered by 1966, Mao launched another political campaign – the Great Proletarian Cultural Revolution.

The Cultural Revolution

The post-GLF policies had some noteworthy features. First, the centre–province distribution of power was rebalanced in favour of the centre. The task of collecting reliable information on the prevalence and severity of famine was simply too important to be delegated to local cadres. Second, collectives were downsized by making village-level 'production brigades' responsible for their own finances, and communal kitchens were closed. More important, the policies permitted spontaneous experimentation with household responsibility schemes within collectives, allowed peasant families to keep small private plots, and reopened markets in which peasants could sell their surplus produce. These policies arrested the downward momentum and brought about a gradual recovery.

But they represented a humiliating retreat in the campaign towards socialism.

As long as the retreat was tactical, Mao was content standing on the sideline. However, Khrushchev's denunciation of Stalin's rule in 1956 and the subsequent de-Stalinization in the Soviet Union gave Mao reasons to be concerned about his own legacy. As soon as the economy recovered, Mao moved to reclaim power so that he could purge those who had the potential to become China's Khrushchev. In 1966, Mao turned against Liu and Deng. Exploiting his personality cult, Mao kicked off the 'Great Proletarian Cultural Revolution' in 1966 by exhorting the Red Guards, made up primarily of students and other urban youths, to rebel against the power base of Liu and Deng – the government and party hierarchy. Liu and Deng, along with many of their colleagues, were labelled 'capitalist roaders' and were purged in 1968.

Mindful of the fragile conditions in the Chinese countryside, moderate leaders did their best to keep the revolution from spreading into the countryside, preventing a rerun of the famine during the GLF. But the market-oriented reforms permitted under Liu and Deng were nullified. Agricultural productivity continued to stagnate until market-oriented reforms were restarted in 1978. The demand for food, however, continued to grow as a result of the post-war baby boom. Unable to raise grain procurement quotas to meet

the growing demand for food rations in the cities, the government resorted to sending millions of urban youths to the countryside to grow their own food and to receive 're-education'.

The Cultural Revolution brought politicization to every facet of life in China. It was better to be revolutionary (that is, loyal to Mao) than productive. Intellectuals and experts, considered less loyal to Mao, were sent to re-education camps in the countryside. Colleges were closed at first and were reopened later to admit only students from 'revolutionary families' – families of workers, peasants and soldiers – based on recommendations from grassroots party organizations. Seasoned bureaucrats and factory managers were purged by the Red Guards, and 'Revolutionary Committees', comprised of workers, peasants and students, took over government offices and state-owned enterprises.

The revolution paralysed the government and the nascent economic planning apparatus. With neither the plan nor the market to guide the allocation of resources, the economy fell into a state of anarchy. As coordination across regions fell by the wayside, regional self-sufficiency, a policy stance endorsed by Mao, became a necessity. Specialization based on regional comparative advantage gave way to the duplication of industrial structure across provinces. The economy stagnated until 1978, when a rehabilitated Deng Xiaoping restarted market-oriented reforms.

Discussion

One of the classic tenets of Marxian economics is that, with planning eliminating the 'anarchy of production', a planned economy can avoid or at least better manage large aggregate economic fluctuations (Ellman 1989). The experience of the Chinese-style central planning offers little support for this claim. The analysis of the GLF disaster by Li and Yang (2005) suggests that, on the contrary, central planning as practised in China exposed the economy to a new systemic risk. Because policy directives formulated at the centre had to be carried out in all localities, policy failures had generated large economic imbalances, severe economic and political crises, and prolonged stagnation. The source of the risk is the concentration of economic and political power in the hands of the planners. In the case of China, Chairman Mao, a charismatic leader, maintained a near monopoly on economic and political policies. With no effective checks and balances during the Maoist era, the economic and political system in China was incapable of arresting the momentum of apparently deleterious policy directives.

The Maoist era was tumultuous. It saw spectacular post-war reconstruction, the build-up of a rudimentary industrial economy aided by Soviet assistance, and the formation of a decentralized government administration that emphasized regional self-sufficiency on the one hand and economic collapse, stagnation, a personality cult and brutal 'class struggle' on the other. It conditioned a generation of pragmatic leaders who, after the demise of Mao, would restart market-oriented reforms through decentralized regional experimentation, disown the personality cult, ban mass movements and depoliticize economic policymaking, while resolutely maintaining the CPC's hold on power. The historical significance of Maoist economics may lie not in what it is but in what it is not.

The classical political economist Jane Haldimand Marcet was born in London, the eldest of ten children of Anthony (Antoine) Haldimand, a Swiss citizen who was a successful London banker and property developer, and his English wife, Jane Pickersgill. She was tutored at home, studying the same subjects as her brothers, and took charge of the household at the age of 15, when her mother died. In December 1799 she married Alexander Marcet, a London physician from Geneva. Since her father bequeathed all his children an equal share of the family fortune, regardless of gender, she was independently wealthy, with no need to write for money. Nonetheless, she wrote 30 educational books on chemistry, political economy, botany, mineralogy, grammar and history, many written in the form of conversations. Her first book, an introduction to experimental chemistry, was published in 1806 after attending Humphrey Davy's lectures at the Royal Institution and after repeating Davy's experiments at home in Alexander Marcet's laboratory. The book was adapted in the United States as a college text, and its tremendous commercial success is shown by the many plagiarized editions that emerged in a period with no effective international copyright law. It introduced the young Michael Faraday to science.

Jane Marcet encountered the ideas of Adam Smith through Sydney Smith's lectures on moral philosophy at the Royal Institution in 1804 and 1806. Alexander Marcet and David Ricardo were both elected to the Geological Society in 1808. Jane Marcet's younger brother, William Haldimand (who lived with the Marcets), was elected a director of the Bank of England in 1809 at the age of 25, and, like his sister, shared Ricardo's attribution of the rising price of bullion to the excessive issue of bank notes, which was very much a minority view among the directors of the Bank of England. James Mill and Thomas Robert Malthus were also friends of the Marcets. Jane Marcet's *Conversations on Political Economy*, published anonymously in 1816, attempted to make the economic ideas of Smith, Malthus, Ricardo and Jean-Baptiste Say accessible to a wider public. Robert Torrens declared her 'one female, at least, fully competent to instruct the members of the present cabinet in Political Economy', while J.R. McCulloch considered her book 'on the whole, the best introduction to the science that has yet appeared'. Ricardo's daughter read the book at her father's recommendation, and Say wrote for permission to 'translate sizeable passages from her excellent book' for his political economy class (Polkinghorn 1993, p. 55).

Jane Marcet (1816, 1833, 1851) was a successful popularizer of classical political economy, but she was also fully capable of independent judgement, sharing Ricardo's opposition to the Corn Laws rather than Malthus's support for them, and supporting the proposed Factory Act in 1833, contrary to the beliefs of her younger friend, Harriet Martineau. Marcet was more optimistic than Ricardo or Malthus about the prospects for economic growth, being less concerned that the working class would erode gains in the standard of living by heedlessly multiplying. Like Say, she placed more emphasis on utility than labour cost as a source of value: when Malthus, after high praise of her discussion of rent, protested that 'I think you have given too much sanction to Mr. Say's opinion reflecting utility', she cut out and discarded the rest of his letter (Polkinghorn 1986). A talented educational writer and the first woman to expound the principles of economics, Jane Marcet succeeded in bringing classical political economy (and other disciplines such as chemistry, botany and mineralogy) to a wider public.

Marchal, Jean (born 1905)

J. Lecaillon

Marchal was born on 25 June 1905 at Colombey-les-Belles, France. He received his doctorate in economic science with a thesis entitled *Union Douaniére et organisation européene*. He was professor at the University of Nancy in 1935, then at the University of Paris from 1948 to 1972. He was elected member of the Academy of Moral and Political Sciences in 1980.

His initial work on the problem of value led him to make provision for psychological, sociological and structural factors. This concern for realism is found in his studies of the price mechanism (1946) with the introduction of correspondences, of imperfect competition phenomena and diversity of periods of analysis (very short, short, long ...). The same concern reappeared in research on the distribution of national income (1954). This distribution is not considered to be the same as allocation of parts of the National Product to abstract factors of production but as the result of an impact between the social classes defined by their position in the economy.

Marchal has also studied the French monetary system (1964) and the international monetary system (1975).

Marczewski, Jean (Born 1908)

J. Lecaillon

Marczewski was born on 27 May 1908 in Warsaw. He enlisted voluntarily in France during the World War II, and was deported to Germany. On his return to France he became Professor at Caen University in 1950, then at the University of Paris from 1959 to 1977.

After working on monetary policy, where he shows the limits of 'deficit spending' (1941), he developed a critical analysis of central planning (1956), arguing that despite the progress of mathematical programming and information theory, planning does not seem able to replace the market. The application of national accounting techniques (1965) to historical research led Marczewski to underline the prime importance of 'historic variables', unique in time and space, which play the role of exogenous variables in the determination of economic relationships.

Research on inflation and unemployment (1978), tested on French and German examples, led him to analysis of stagflation. A generalization of the analysis of real and monetary flows which compose the circuits of international exchange led to a theory of the movements of expansion and recession of world economy (1984).

Marget, Arthur William (1899–1962)

Donald A. Walker

Keywords
Cash-balance approach; Keynesian revolution; Marget, A. W.; Quantity theory of money; Velocity of circulation

JEL Classifications
B31

A leading monetary theorist during the first half of his career, Marget went on to make an even greater contribution by formulating and implementing government policies regarding international banking and finance. Born in Chelsea, Massachusetts, on 17 October 1899, he graduated from Harvard with AB (1920) and MA (1921) degrees in Semitics, and a Ph.D. in economics (1927). He taught economics at Harvard (1920–1927) and the University of Minnesota (1927–1943; resigned 1948). He died in Guatemala City on 5 September 1962.

As an academician, Marget's principal concern was with the central problems of monetary theory, and since these had been so strikingly shaped by John Maynard Keynes, much of Marget's work

became a critique of his views. Marget regarded himself as building upon an enduring neoclassical tradition, and saw the Keynesian Revolution as a largely misdirected episode that had the merit, however, of making some genuine contributions, and especially of stimulating the sort of re-examinations and refinements of doctrine exemplified by his own writings. His most significant critical contributions were his evaluations of Keynes's *Treatise on Money,* of liquidity preference, of Keynes's treatment of expectations, and of the implications of Keynes's *General Theory of Employment, Interest and Money* for the theory of prices (Marget 1938, 1942). Marget's principal positive contributions were an extension and refinement of the concepts of the velocity of circulation of money and of goods; his reformulation of the quantity equation relating prices, output and money; his argument that the cash-balance approach is useful only in connection with the analysis of changes in the velocity of the circulation of money; and his analysis of the relevance of particular demand curves and their elasticity to the structure of money prices (Marget 1938, 1942). The valuable elements of his critique of 20th-century theory and of his constructive writings have been assimilated into the discipline and are no longer a focus of discussion. Marget also undertook some studies in the history of thought which are among the best work on the subjects with which he dealt. Particularly worthy of note are his examinations of the monetary theory of 19th-century neoclassical economists (Marget 1931, 1935, 1938, 1942).

As an applied economist, Marget was concerned with international financial policies. While a major (1943–1945) and a lieutenant colonel (1945) in the US Army, he devoted himself to preparations to bring about the economic and financial rehabilitation of Austria. He then became chief of the finance division of the US Allied Command for Austria (1946–1949); a member of the US delegation in London that prepared for the treaty with Austria (1947); and a member of the US delegation to the Council of Foreign Ministers, which was charged with negotiating that treaty in London and Moscow (1947). His subsequent career included the positions of Chief of the Finance Division at the headquarters of the Marshall Plan in Paris (July 1948–December 1949), consultant to the US Treasury (1948), and Director of the Division of International Finance of the Federal Reserve Board of Governors (January 1950–April 1961). Among other activities, he represented the Board at meetings of the central banks of the western hemisphere in Bogotá (1956) and Guatemala City (1958). He then became the US representative to the Central American Common Market in Guatemala City and an adviser to the Common Market Bank in Honduras (April 1961–September 1962). In the latter roles he was instrumental in promoting the effectiveness of the Common Market policies.

Marget's scholarly work was distinguished by an insistence on logical clarity and an amassing of scholarly detail in the presentation of his expositions. His bureaucratic work was distinguished by an outstanding ability to suggest workable new financial institutions and procedures.

Marginal Abatement Costs

Ross McKitrick

Abstract

The marginal abatement cost curve (MAC) shows, for every emissions level, a firm or

industry's marginal cost (foregone profits) of reducing emissions, or equivalently, its marginal willingness to pay for the right to emit one additional unit of pollution. The term 'abatement' here denotes a unit reduction in emissions, as distinct from units of specific abating inputs, such as smokestack scrubbers. The MAC is not invariant to the form of the emissions control policy. The aggregate MAC for an industry is only well defined in cases where the policy achieves cost efficiency by equalising MAC levels across all emitters.

Q50; Q52

The marginal abatement cost curve (MAC) shows, for every emissions level, a firm or industry's marginal cost (measured as foregone profits) from reducing emissions by one unit, or equivalently, its marginal willingness to pay for the right to emit one more unit of pollution. It represents, in effect, the firm's demand curve for emissions. The term 'abatement' as used here denotes a unit reduction in emissions, rather than a unit of specific abating inputs, such as smokestack scrubbers.

The MAC is not the same as the marginal cost of any one particular type of abatement equipment. Instead, it is derived as the profit-maximising response to the relaxation of a constraint on emissions, taking into account the availability of emission control devices as well as changes in output and input levels.

The MAC plays a key role in the definition of the optimal level of pollution, which occurs where the MAC crosses the marginal damages (MD) line. However, the MAC is not invariant to the form of the emissions control policy, since some policies are more costly than others at achieving the same reduction in emissions. Where regulators depart from economic instruments (emission taxes and tradable permits) in favour of command-and-control regulations, intensity targets, technology standards or other mechanisms that do not minimise compliance costs, the MAC rotates higher than it otherwise would.

For an individual firm, the MAC can be derived by introducing an emissions function into the description of the firm (see Derivation section below). Abating inputs are assumed to be non-productive (of output) and are used only to reduce emissions. If an abating input is also productive of output, it is assumed to be used already to its profit-maximising level, so further use for emissions-abating purposes would not be marginally profitable; hence there is no loss in generality by simply defining abating inputs as non-productive. In the dual optimisation approach, the firm chooses its optimal level of output and abating inputs subject to a constraint on total emissions. This yields an expression for the marginal profits from relaxing the emissions constraint, or in other words the marginal private value of polluting, which corresponds to the firm's demand curve for emissions. If all firms face the same marginal cost (price) for emissions, the industry MAC is the horizontal sum of firm MACs. If the policy does not yield equivalent MAC levels at the assigned emission reduction targets, then the horizontal summation is invalid and the industry MAC is not well-defined, as will be discussed below.

Unregulated emissions are located at the point where the MAC is zero. In response to an emissions tax the MAC shows the level of emissions chosen in response to each level of the tax. In response to a tradable permits policy it corresponds to the demand curve for permits. The area under the MAC over an interval shows the total cost to the firm, in reduced profits, of reducing emissions by the amount of the interval (or, alternatively, the total benefit of increased emissions). When the quantity of emissions is the constraint variable, the quantity times the associated MAC equals the scarcity rents created by the policy. When price is the constraint variable, the MAC times the associated quantity is the total tax revenue.

This article will present a derivation of the MAC, some key points regarding its interpretation and some empirical estimates.

Derivation

This section presents the derivation in McKitrick (1999), to which readers are directed for more detailed discussion (see also McKitrick 2010, Chap. 3). An example of a MAC is shown in Fig. 1. It is directly analogous to an ordinary factor demand curve, treating the right to emit a unit of pollution as the factor. Suppose a firm produces output y which sells at price p. The firm can employ a non-productive pollution control input a that costs q per unit. Emissions e are a function of output y and abating inputs a:

$$e = e(y, a). \tag{1}$$

For a fixed level of a, emissions are assumed to rise in y at an increasing rate. This arises from diminishing marginal productivity of inputs, which implies increased waste and pollution residuals. For a fixed output level y, emissions fall in a at a decreasing rate, in keeping with the assumption of diminishing marginal productivity of abating inputs; in other words, that the most efficient and cheapest options will typically be used first.

In Fig. 1, unregulated emissions are denoted $\bar{e}$ and occur at the point where the MAC is zero. We do not typically draw the MAC going below zero since that would imply that firms can increase profits by reducing emissions, and we assume they will already have done so if it is possible. If emissions are unregulated the firm sets $a = 0$, which means the profit-maximisation problem reduces to the standard one with a solution where price equals marginal cost. If we denote that output level as y^*, then by Eq. (1), $e(y^*, 0) = \bar{e}$.

The firm's cost function c is written

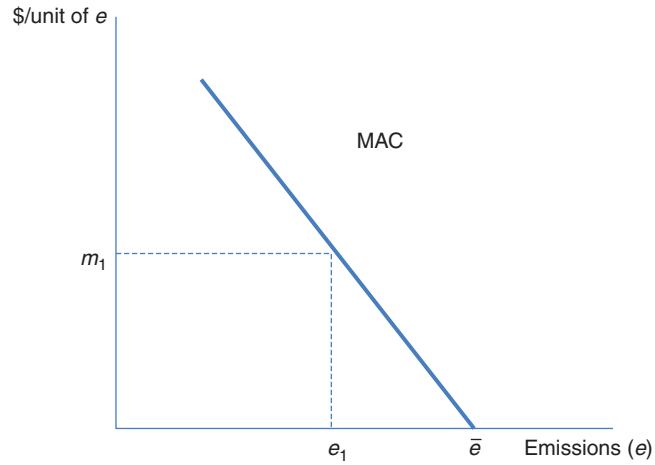
$$c = c(w, y, a) \tag{2}$$

where w is the vector of input costs including q. a appears in Eq. (2) because it is not a productive input, in other words it does not appear in the production function, so its corresponding price is not an element in w. In the absence of an emissions constraint the firm would set a to zero. If an abating input is assumed also to be productive, it must therefore be used already to its profit-maximising level, so without loss of generality we can simply define a as the amount of such an input used beyond its optimal level as a productive input.

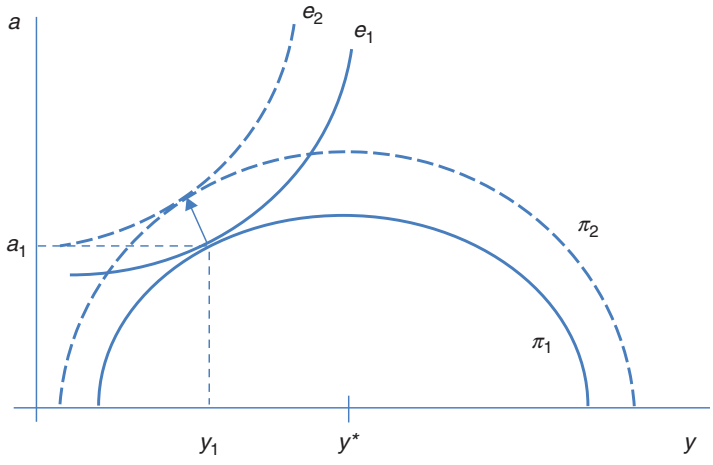
Profits are $\pi = py - c(w, y, a)$. The firm maximises profits subject to an emissions constraint

$$e(y, a) \leq e_1. \tag{3}$$

Figure 2 illustrates the resulting tangency in (y, a) space. The horizontal axis shows output (y) and the vertical axis shows pollution abatement equipment (a). The line labelled e_1 is an iso-emission



Marginal Abatement Costs, Fig. 1 Marginal abatement cost curve



Marginal Abatement Costs, Fig. 2 *Solid lines*: tangency between iso-emissions line for fixed emissions level e_1 and iso-profit line for fixed profit level π_1, showing optimal abatement and output levels denoted (a_1, y_1) respectively. *Dashed lines*: same for π_2 and e_2

line, showing combinations of y and a that yield a constant emissions level. The line labeled π_1 is an iso-profit line, showing combinations of y and a that yield a constant profit level. Profits go up by moving off an iso-profit line towards the horizontal axis at the point y^*, which is the optimal output level in the absence of emission regulations. So the firm seeks the lowest possible iso-profit line that still touches the emissions constraint line, which occurs at the tangency point (y_1, a_1).

Since emissions increase by moving off the iso-emissions line in an upward direction, a tightening of the emission standard is represented as a shift in the line e_1 back to e_2. The firm now moves to a lower profit level associated with the iso-profit line π_2, the tangency point for which implies more use of abatement equipment and less output. Hence the firm adjusts both output and abatement equipment levels in response to a changed emission constraint.

The MAC relates the change in profits ($\pi_1 - \pi_2$) to the change in emissions ($e_1 - e_2$). We can rearrange (1) into the form $a = a(y, e)$, showing the amount of the abating input needed at output level y to achieve emissions level e, and substitute this into the profit function to yield

$$\pi(p, y, e) = py - c(w, y, a(y, e)). \tag{4}$$

Assuming p is constant, the derivative of Eq. (4) with respect to e is

$$\frac{d\pi}{de} = -\frac{\partial c}{\partial a}\frac{\partial a(y, e)}{\partial e}. \tag{5}$$

This is the marginal abatement cost curve. In Fig. 2, a reduction in the allowed emissions level causes the firm to reduce output and use more abatement equipment. The cost to the firm is the change in profits $d\pi \equiv \pi_1 - \pi_2$.

When reading Fig. 1 from right to left, for instance from $\bar{e}$ to e_1, the area under the MAC denotes the total abatement costs (TAC) associated with the reduction in emissions. In Fig. 2 it would correspond to the difference between the unregulated profits associated with output y^* and the profit level π_1. The height of the MAC in Fig. 1 corresponds to the marginal cost of one more unit of emission reductions. Reading the same graph from left to right, the height of the graph corresponds to the marginal profits associated with one more unit of allowed emissions (Eq. (5)), and the area under the curve over an interval shows the total benefit to the firm of being allowed to increase emissions by that increment.

Relation to Policy Setting

For convenience, we can refer to the function relating emissions and profits, namely Eq. (4), as $\pi(e)$, noting that levels of output and abatement equipment adjust optimally in the background as e changes. Then the MAC (Eq. 5) can be denoted

π_e. If, instead of an emissions constraint of the form in Eq. (3), the firm were charged a tax per unit of emissions, its profit maximising problem would become

$$\max\{w.r.t.\ e\}\ \ \pi(e) - \tau e$$

where τ is the emissions tax rate. The solution is

$$\pi_e = \tau. \tag{6}$$

In other words, the firm chooses an emissions level at which MAC equals the tax rate. In Fig. 1, if the tax rate is m_1, the resulting emissions level would be e_1.

In response to a tradable permits policy, if the competitive price of permits is m_1; the resulting emissions level is e_1, the same as in the tax case. Consequently the MAC corresponds to a firm's demand curve for tradable emission permits. Joskow et al. (1998) used data from the US sulphur dioxide trading market to plot bid–offer curves, which show the number of permits sought at each price level. Since these show the industry's marginal willingness to pay for each additional unit of allowed emissions, they correspond to the MACs of the industry subject to the tradable permits regulation.

The MAC in Eq. (5) is derived by assuming a simple emissions constraint in the form of Eq. (3). If the emissions constraint takes another form, the MAC will also change. In general, the less direct the form of the regulatory constraint, the higher the MAC will be at every emissions level. When the desired policy target is an emissions level, then a single constraint in the form of Eq. (3) yields the minimum MAC. If, for example, the constraint is instead expressed in the form of emissions intensity, or emissions per unit of output:

$$\frac{e(y,a)}{y} \leq z_1 \tag{7}$$

then for the same emissions levels, the MAC must be higher compared to the one associated with Eq. (5) (McKitrick 2010, Chap. 6; Helfand 1991).

The Equimarginal Criterion

For the industry as a whole, operating on the lowest MAC requires that the distribution of emission reduction requirements yields equal marginal abatement cost levels for all individual polluters. Suppose each firm $i = 1, \ldots, n$ faces a constraint in the form of Eq. (3). Then the total profits associated with emissions across all firms is given by the summation $\sum_{i=1}^{n} \pi^i(e_i)$. Minimising the cost of emission reductions is equivalent to maximising this term, subject to a cap on total emissions $E = \sum_{i=1}^{n} e_i$. To solve this we form the Lagrangian function

$$L = \sum_{i=1}^{n} \pi^i(e_i) - \lambda\left(\sum_{i=1}^{n} e_i - E\right) \tag{8}$$

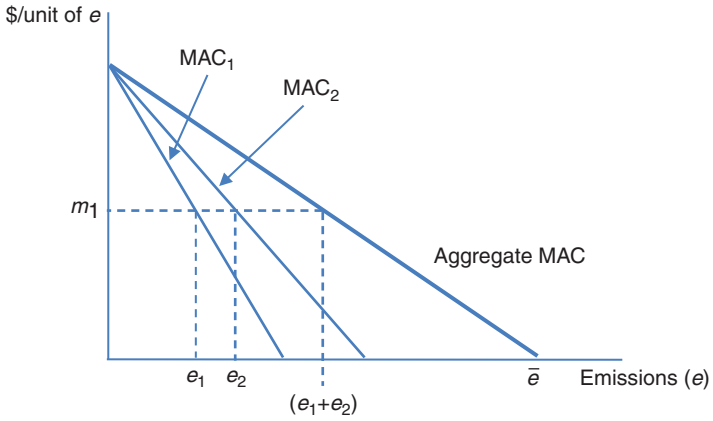
where λ is the Lagrange multiplier. The first-order conditions imply

$$\pi_e^i = \pi_e^j\ \forall\ i \neq j. \tag{9}$$

This is called the equimarginal criterion and states that marginal abatement cost levels must be equal for any arbitrary pair of polluters, and thus across all polluters, in order to yield a cost-minimising distribution of pollution abatement requirements. Since it is typically not the case that regulators have sufficient information to impose firm-specific standards in such a way that Eq. (9) will hold, an alternative is to use a pricing instrument such as an emissions tax τ. Equation (6) applies to all firms, so if all firms face the same tax rate then Eq. (9) must hold.

Aggregation

If the equimarginal criterion holds, then at every price level m_1 the aggregate MAC shows the corresponding total emissions. Figure 1 can be augmented to the two-firm case to illustrate this. As shown in Fig. 3, the aggregate MAC is the horizontal sum of MAC_1 and MAC_2, analogous to the horizontal summation of individual demand curves into a market demand curve.



Marginal Abatement Costs, Fig. 3 Aggregate marginal abatement cost curve

If the equimarginal criterion does not hold, the aggregate MAC is not uniquely defined, since the marginal cost of another unit of emission reductions will depend on which firm or firms abate, and in which order.

Implied Price and Scarcity Rents

Even when quantity is the regulator's target variable, the existence of the MAC implies that there is always a price, or willingness to pay, associated with each level of emissions. Economic instruments such as emission taxes and tradable permits reveal this price, which provides information for a regulator that can be used to refine the implementation towards the optimal level. The price is analogous to (and in case of emission charges, takes the form of) a tax, and like all taxes it generates a marginal excess burden and also exacerbates excess burdens in connected markets. This is called the tax interaction effect, and can be offset in part or in whole by capturing the rents created by the emissions control policy and using them to fund tax reductions elsewhere (Parry 1995).

The interaction effect is still present even when an emissions control policy constrains the quantity rather than imposing a price. Quantity restrictions create scarcity rents that are not captured by the regulator, and therefore are unavailable to fund offsetting reductions in other taxes. Therefore the macroeconomic cost of non revenue-raising policies is higher than revenue-neutral emission pricing policies. This leads to a discontinuity where the MAC meets the emissions axis such that the first unit of emissions reduction is no longer infinitesimally small (Parry et al. 1999).

It is important to note that when emission control policies take the form of constraints on the quantity of emissions, it is incorrect to say that, since there is no emissions tax, economic agents are not 'paying the cost' of their emissions. While they are not remitting an emissions tax to the government, they are paying the cost in the form of higher goods prices and, in some cases, rents that accrue to industries that benefit from quantity restrictions created by the emissions control policy.

Empirical Estimation

A difficulty in estimating the MAC in the form of Eq. (5) is that neither units of abating inputs nor their costs are typically observed, making it infeasible to include them in a cost function framework. Where such data are available, the estimation can be undertaken upon assumption of a specific functional form: for an example, see Yiridoe and Weersink (1998). An alternative approach has been to use output distance functions, which do not require specific data on abatement equipment, instead interpreting input-normalised variations in output as an indicator of overall efficiency, which can indicate costs of

abatement activity. For an example see Kwon and Yun (1999).

Finally, the case of carbon dioxide (CO_2) has received considerable attention, in part because of the connection to the topic of global warming, but also because in almost all cases there are no effective scrubbers or other types of abatement equipment options for reducing CO_2 emissions, which simplifies the empirical problem considerably. Estimation can proceed through direct econometric methods or through the use of computable general equilibrium or other macroeconomic models. For examples see Morris et al. (2012) and the survey in Kuik et al. (2009).

Marginal and Average Cost Pricing

William Vickrey

Abstract

Under perfect competition, marginal cost and average cost of a product are equal to each other and to its price, an arrangement that is Pareto-optimal in the absence of neighbourhood effects. Technical progress is making it possible to vary the prices of some products (such as telephony and electricity) from moment to moment in accordance with marginal cost. Such responsive pricing would help guarantee essential services and reduce the cost of providing reserve capacity. Where there are economies of scale, prices set at marginal cost will fail to cover total costs, thus requiring a subsidy.

In a pure and simple static world of perfect competition, where production units purchase or rent all their inputs in competitive markets and each sells a single homogeneous product competitively, production takes place at a point of constant returns to scale where the marginal cost and average cost of the product are equal to each other and to its price. If in addition there are no neighbourhood effects or externalities operating outside the market, the result will be Pareto efficient, meaning that there is no feasible alternative arrangement that would be better for someone and no worse for anyone.

Difficulties with the Concept of Average Cost

As soon as production takes place with durable capital facilities that must be adapted to the needs of an individual firm there may no longer be an effective market for these facilities and a cost of their use during any particular period must be determined by other means. In the rather extreme case of the 'one-horse-shay' asset that in a static environment yields a stream of identical services over a known lifetime, a constant periodic rental cost can be derived by the use of a 'sinking fund' method of depreciation in which the rent is the sum of an increasing depreciation charge and a decreasing interest charge on the net value. But where the value of the service varies over time, whether because of physical deterioration, an increasing cost of maintenance needed to keep the item in 'as new' condition, or shifts in demand, this would in principle cause depreciation charges to vary; in practice this is done in one of a number of arbitrary ways by using 'straight-line' or various forms of 'accelerated' depreciation. If these charges are used as a basis for pricing, where competition is imperfect enough to give some leeway, the results can be correspondingly arbitrary.

More serious problems arise in the increasingly widespread cases of joint production of several distinguishable products or services. Where competitive markets exist, the market conditions dictate the allocation of joint costs among the various products, as when a meat-packing establishment produces steaks, hides, glue and offals. There is no way in which one can determine a meaningful average cost of hides by considering only the production process. Where the products, though economically widely different, are physically similar, it is tempting to cut the Gordian knot and average over the entire output, often at the cost of serious impairment of economic efficiency. Even when elaborate rationales are concocted by cost accountants, unless demand conditions as well as production conditions are taken into account the results are essentially arbitrary.

One can do a little better with marginal cost, at least if one is seeking a short-run marginal social cost (hereafter SRMSC), which is the concept that would be relevant for efficiency-promoting pricing decisions. Unless a consumer is presented with a price that correctly represents the marginal social cost associated with the various alternatives open to him, he is likely to make inefficient decisions.

The Importance of Emphasizing the Short Run

One often finds in the literature proposals to use a 'long-run marginal cost' as a basis for setting rates. The trouble is that in an operation producing a multitude of products with interrelated costs it is not possible even to define in any precise way what could be meant by a 'long-run marginal cost', any more than one could define a relevant long-run marginal cost for the hides and steak that are derived from the same carcass in the face of fluctuations over time in relative demand.

The attempt to use a long-run concept seems to be motivated in part by the notion that in some sense the long-run concept is more inclusive in that it allows for variation in capital investment and would include a return on such investment, whereas short-run marginal costs would fail to cover the costs of capital investment. In the single-product steady-state case, however, which is the only case for which the long-run marginal cost can be clearly defined, if the investment in plant is at the optimal level, i.e. the level which

will result in the given output being produced at the lowest total cost, short- and long-run average cost curves will be tangent to each other at the given output, and short- and long-term marginal costs will beequal. Short run marginal-cost prices will therefore cover just as much of the total cost as will prices based on 'long-run marginal cost'. If short-run marginal cost is below the long-run marginal cost, this would indicate that the installed plant is larger than optimum, and conversely if plant is below optimum size, short-run marginal cost will be above long-run marginal cost.

Flexible Versus Stable Prices

A long-run approach is sometimes advocated on the ground that it results in more stable prices. Price rigidity, however, exacts a high toll in terms of reduced efficiency. It is sometimes argued that stable prices are required for intelligent planning for installations that commit the investor to the use of a given volume of service. There is nothing in a SRMSC pricing policy, however, that precludes providing the consumer with estimates of the probable course of prices in the longer term, or even entering into long-term contracts to purchase specified quantities of service. If they are not to interfere with efficiency, however, such contracts should allow for the possibility of purchasing additional amounts at the eventual going rates, or of selling back some of the contracted-for output if this should prove profitable for the consumer.

Lack of flexibility in pricing has, indeed, been a major source of inefficiency in the use of utility services, whether arising as a result of the cumbersomeness of the regulatory procedures in privately owned utilities, or of bureaucratic inertia in publicly owned ones. At times it has even appeared that it takes longer to carry out the bureaucratic procedures involved in altering a price than to install additional capacity, whereas in terms of the underlying capabilities prices can and should be altered on shorter notice than the time taken to adjust fixed capital installations.

Optimal Decision-Making Sequence

The efficient pattern of decision-making consists of first establishing a pricing policy to be followed in the future (as distinct from the application of that policy to produce a specific set of prices), then planning adjustments to fixed capital installations according to a cost-benefit analysis based on predicted demand patterns and predicted application of the pricing policy, subject to whatever financial constraints may be applicable, and then eventually determining prices on a day-to-day or month-to-month basis in terms of conditions as they actually develop.

Too often a rigid adherence to inappropriate financial constraints results in a pattern of pricing over time that leads to gross inefficiency in the utilization of facilities that are added in large increments. In the setting of tolls on bridges, for example, a high fixed toll is often imposed from the start in an attempt to minimize early shortfalls of revenues below interest and amortization charges. When the indebtedness incurred to finance the facility is finally paid off, tolls are often eliminated, sometimes just at the time that they should be increased in order to check the growth of traffic and congestion and defer the necessity for the construction of additional facilities.

The Forward-Looking Character of Marginal Cost

Since changes in present usage cannot affect costs incurred or irrevocably committed to in the past, it is only present and future costs that are of concern in the determination of marginal cost. Past recorded costs are relevant only as predictors of what current and future costs will turn out to be. The marginal cost of ten gallons of gasoline pumped into a car is not determined by what the service station paid for that gasoline, but by the cost expected to be incurred to replace that gasoline at the next delivery. The substantial time-lag that often exists between a change in price at the raw material level and its reflection at the retail level is one of the pervasive failings that

contributes to the inefficiency of the economic system.

Another more important case in which future impacts are of vital importance in the calculation of marginal cost is where congestion accumulates a backlog of demand that has to be worked off over a period of time. A particularly striking case of this occurs when traffic regularly accumulates in a queue during rush hours at a bottleneck such as a toll bridge. The consequence of adding a car to the traffic stream is that there will be one more car waiting in the queue from the time the car joins the queue until the queue is eventually worked off, assuming that the flow through the bottleneck will be unaffected by the lengthening of the queue.

The marginal cost of a vehicle trip will be measured in terms of a number of vehicle hours of delay equal to the interval from the time the car would have arrived at the choke point if there had been no delay, to the time the queue is finally worked off. This is not measured by the length of the queue at the moment, but will be determined by the subsequent arrival of traffic over an extended period. A car arriving at the queue after it began to accumulate at 7:30 may get through the bottleneck at 8:00, after being delayed by only 15 minutes, but if the bottleneck will not be worked off until 10:00 the marginal cost will be 21/4 vehicle hours of which only 1/4 hour is borne by the added caritself. The remaining two hours, if evaluated at $5 per vehicle hour, would indicate that under these conditions the toll that would represent this externality would be $10. Marginal cost cannot be determined exclusively from conditions at the moment, but may well depend, often to an important extent, on predictions as to what the impact of current consumption will be on conditions some distance into the future.

Marginal Cost of Heterogeneous Sets of Uses

It will often happen, for various reasons, that the same price will have to be applied to a non-homogeneous set of uses. To set such a price properly, the marginal costs of the various uses within the set covered must be combined in some way to get a marginal cost relevant to this decision. It would be wrong, however, merely to average the marginal costs of all the uses for which this price is to be charged.

Rather, the decision as to whether a decrease in a given price is desirable must consider the cost of the increments or decrements in the various outputs that will be bought as a result of the price change. In averaging the marginal costs of the various usage categories, the weighting will have to be in proportion to the responsiveness of each usage category to the change in price.

For example, if a price is to be set for electricity consumption on summer weekday afternoons, in a system where air-conditioning is an important load, consumption and marginal cost may be higher on hot days than on warm days, but it may be considered too difficult to differentiate in price between the two categories of days. An increase in the price for this entire set of periods may induce some customers to adjust the thermostat setting. But during hot days the equipment may work full tilt without reducing the temperature to the thermostat setting, whereas on warm days there will be a reduction in power consumption. The marginal cost relevant to the setting of the common price would then be determined predominantly by the lower marginal cost of the warm-day consumption, and relatively little, if at all, by the higher marginal cost hot-day consumption.

Anticipatory Marginal Cost

In many cases a customer will make his effective decision to consume an item some time in advance, and it will be the expected price as perceived by him at that time that determines his decision. If, as in services subject to reservation, a firm price must be quoted the time the reservation is made, it is the expected marginal cost as of that moment that should govern the price charged. In the case of a service where the demand is highly variable and to a considerable extent unpredictable, such an expected marginal cost would be an average of marginal costs that might arise under alternative possible

developments, possibly ranging from a very low value, if there turns out to be unused capacity, to the possibly quite high value if another latecomer must be turned away. The respective probabilities of these outcomes, as estimated at a given time, will vary with the proportion of the total supply already sold, the time remaining to the delivery of the service, and the pricing policy to be followed in the interim.

At one extreme, for long-haul airline reservations where the unit of sale is large, one might find it worth while to have a fairly elaborate pricing scheme in which the price quoted would vary according to the proportion of seats on a given flight already sold and the time remaining to departure, in simulation of what an ideal speculators' market might produce, the price at any time being an estimate of the price which, if maintained thereafter, would result in all the remaining seats being just sold out at departure time. This would correspond to marginal cost in that the sale of a seat at any given time would slightly raise the price during the remaining period to decrease demand by one unit, at a price that would be expected to be on the average equal to the price at which the seat was sold, indicating that the price was equal to the value of the seat to the alternative passenger.

Quality-Volume Interrelationships

In principle, in the absence of barriers to entry, competition would induce the supply of just sufficient seats on the various routes to cause revenues produced by such pricing to just cover costs. Even this, however, would be optimal only on those routes where traffic is so heavy that even with planes of a size producing the lowest cost per seat, further increases in service frequency would be of negligible value. On most routes there will remain economies of scale in that either providing more seats at the same frequency of service with larger planes would reduce costs per seat, or providing more seats with the same size of planes would provide an increased frequency of service that would be of value to others than the additional riders. In the latter case the marginal cost of providing for the additional passengers would be calculated by deducting the increase in the value of the service by reason of increased frequency from the cost of providing the added seats.

If it were possible to adjust plane size and frequency in a continuous fashion, then if the situation is optimal the two marginal costs would be equal. In practice both plane size and service frequency can be varied only in discrete jumps, so that this relation would be only approximate. Optimal price would be above a downward marginal cost calculated on the basis of a reduction in service, and below an upward marginal cost calculated on the basis of an increase in service. The decreases and increases might involve a combination of frequency and plane size changes. To preserve the formulation that price should equal marginal cost it may be useful to define marginal cost in such cases as consisting of the range between these upward and downward values rather than as a single point.

In practice, between the existence of economies of scale and the imperfect cross-elasticity of demand between flights at various times and with different amenities, removal of regulation tends to result in an emphasis on non-price competition, attempts to subdivide the market by various devices and restrictions to permit discriminatory pricing, and a bunching of service schedules at salient times and places that provides a lower overall level of convenience than would be possible were the given number of seat miles distributed more efficiently.

Where the unit of sale is small it may not be worth while to incur the transaction costs of varying price in strict conformity with SRMSC. One could, in theory, apply the same principle to the sale of newspapers at a given outlet. The price of a newspaper would vary according to the number of unsold papers remaining and the time of day. This would result in less disappointment of customers having an urgent desire for a paper late in the day and encountering a sold-out condition, and fewer unsold papers returned. But unless some ingenious device can be found for executing such a programme at low transaction costs, it probably would not be considered worth while, even by the most sanguine advocate of marginal cost pricing.

Wear and Tear, Depreciation and Marginal Cost

Even in the absence of lumpiness or technological change, existing methods of charging for capital use often fail to give a proper evaluation of marginal cost. This is especially true where the useful life of a unit of equipment is determined more by amount of use than by lapse of time. In the extreme case of equipment that must be retired at the end of a given number of miles or hours of active service, or after the production of so many kwh of energy, and which, in one-horse-shay fashion, gives a uniform quality of service over its lifetime without requiring increasing levels of maintenance, the marginal cost of use at a given time will be the consequent advancing of the time of retirement of the equipment. The marginal cost of using the newest units will be the lowest, and will advance over time at a rate equal to the rate of interest as the equipment ages and the advancement of replacement consequent upon use becomes less and less remote.

In a service subject to daily and weekly peaks, the newest equipment will be allocated to the heaviest service, operating during both peak and off-peak hours. Equipment will be relegated to less and less intense service as it ages. The marginal cost of service at a particular moment will be that for the oldest unit that has to be pressed into service at that instant. The rental charge for the use of the unit will vary gradually over the entire range of demands, rather than dropping off to zero whenever the full complement of equipment is not required. At the other end, in this extreme case, the service provided would not necessarily be held constant by price variation over an extended peak period: under the conditions postulated it would be possible to provide for needle peaks by planning for the stretching out over time of the final service units of the oldest equipment. In this way the required peak capacity can be provided at a cost much lower than that which would be calculated by loading all the capital charges for the added equipment on this brief period of use.

Another way of looking at the matter is to appeal to the proposition that perfect competition under conditions of perfect foresight will produce optimal results. To this end one can suppose a situation in which vehicles are rented by the hour from a large number of lessors operating in a competitive market. For simplicity, initially, one can assume all vehicles to be of the one-horse-shay variety, being equivalent to bundles of hours of active service, with the quality of service being independent of age up to a final 'bubble-burst' collapse. Also, for simplicity, assume a steady state in which vehicles are scrapped and replaced at a constant rate over time, so that at any given moment vehicles are evenly distributed by age.

A common market rental price for all vehicles at any given time of the week will emerge, being higher as the number of vehicles in service at the time is greater. During any given week, each renter will have a reservation price for his vehicle, such that he will rent his vehicle during those hours for which the market rental is above this reservation price and never when the market rate is lower. This reservation price will increase over time for any given vehicle at the market rate of interest, since a renter will rent his vehicle if and only if the net present value of the rental discounted back to the time of purchase exceeds some fixed amount. The owner would not want to rent his vehicle for a net present value less than he could have got by selling one of this stock of service units at some other time at or just below his reservation price. New buses will have the lowest reservation price and will be assigned to the schedules calling for the most hours of service per week, while old buses will be held idle during slack hours and used only for peak service. As each bus ages it will be assigned to less and less heavy service along the load-duration curve.

This pattern of usage can be regarded as resulting from a desire to recover the capital tied up in the usage units of each bus as rapidly as possible. It is related to the practice in electric utilities of using the newest units for peak service, in that case motivated in part by the tendency for the newer units to be more efficient in thermal terms. To be sure, occasionally new units are designed specifically for peaking service, with a correspondingly low capital cost, though this is a relatively recent phenomenon related to a

slowing-down of secular increases in potential thermal efficiency.

In any case, where wear-and-tear is a factor, one cannot properly allocate depreciation charges primarily to peak service, however defined, nor should they be spread evenly over all service, much less spread evenly over hours of the week so that vehicle hours in off-peak periods would get higher charges than during the peak. Rather the depreciation charge per vehicle hour will vary gradually and in a positive direction with the intensity of use of the equipment at any given hour.

The analysis becomes a little complicated when equipment life is dependent on mileage or loading or intensity of use as well as hours of active service, so that different rentals would properly be chargeable according to the nature of the service for which the unit is being rented. Also further analysis is required if equipment is laid up between runs at isolated terminals rather than at a central depot where a market could be postulated, or if the fleet contains vehicles varying in size or other characteristics. It would even be theoretically appropriate to charge different fares for the same trip at the same time if made on vehicles with different origins or destinations. (In Hong Kong, indeed, the practice is to charge a flat fare on each route, but to differentiate the fare fairly elaborately as among routes. On segments where routes converge, this has the unfortunate result of unduly concentrating riding on buses with the lower fares, even where the higher fare buses have empty seats and are making stops in any case for other passengers.)

Costs of major overhauls that are performed at relatively long intervals would also complicate the picture. There are also problems associated with gradual or sudden changes in overall demand levels, or special events that can be anticipated sufficiently to present an opportunity for reacting in terms of a change in price. The picture can be further complicated if, as was discussed above, there are changes in available technologies or other changes in quality or cost. But the same method of analysis in terms of a hypothetical competitive market can be used to obtain appropriate results.

For the sake of simplicity the above analysis has been couched mainly in terms of a bus service, but the analysis is applicable wherever the useful life of equipment is in part a function of the intensity with which it is used.

Responsive Pricing

In some cases, notably in telephone and electric power services, the technical possibility exists for conveying information as to the current price to customers at the instant of consumption, and for customers to respond to such information in a worthwhile manner at modest cost. In the case of telephone service the information as to the level of charges for local calls can be substituted for the dial tone, with information on rates for long distance calls provided to users who wait for it before dialing the final digits. If the charge exceeds what the customer is willing to pay the call can be aborted with little occupancy of equipment or inconvenience to the user. Prices can be varied from moment to moment in accordance with marginal cost, as estimated from the degree of busyness of the relevant sets of equipment.

In the case of electric power, the costs of providing for a variation of the price according to the conditions of the moment would be somewhat greater. But if the facilities take the form of remote meter reading, either by carrier current over the power lines or by a separate communications channel, much of the cost would be covered by the avoidance of costs involved in manual meter reading. A signal of rate changes can then be provided to the customer as a by-product of the signal required to initiate a new rate period. The customer can then respond either manually or by installing automatic equipment which will adjust the operation of such items as air-conditioning and refrigeration compressors, water heaters and the like, according to the level of rates in a manner determined by the customer himself. Retrofitting of existing meters by attaching a pulse-generating device such as a mirror and photo-electric cell to the rotor shaft of the existing meter and feeding the pulses to electronic counters and registers should be possible at relatively low cost.

Such responsive pricing would be especially valuable in dealing with emergencies, providing greater assurance of the maintenance of essential services than is possible with existing techniques, and making it possible to reduce substantially the cost of providing reserve capacity. In the case of floods, conflagrations, breakdowns in transit, or other emergencies that under present conditions tend to result in the overloading of telephone facilities and difficulties in completing calls of a vital nature, rates can be charged that are high enough to inhibit a sufficient number of less important calls so that the ability of the system to handle vital calls promptly is preserved. This is difficult to do with present techniques, for while it is relatively easy to give priority to calls originating at such points as police stations, hospitals, and the like, most emergency calls are calls to rather than from these points and it is much more difficult to distinguish such calls close to the point of origin. And there are always a certain number of vital calls not distinguishable in terms of either origin or destination.

Again, in the case of unscheduled power cuts, it would be possible to cause an almost instantaneous shedding of substantial water-heating and refrigeration loads, followed, in the case of an extended cut, by partial shedding of elevator, transit and batch process loads for which it is more inconvenient to respond quite so promptly, after which a sufficient refrigeration load can be picked up as needed to avoid food spoilage. Many of the serious consequences of major power blackouts could have been avoided had such a system been in place at the time. Reserve capacity might well be cut back to provision for scheduled maintenance, leaving the load-shedding capability of responsive pricing to function as a reserve. In many cases the speed of response possible with responsive pricing would be faster than the reaction time within which reserve capacity can pick up load, leading to better voltage regulation and a higher quality of service to customers remaining on the line. And if, in spite of everything, areas must be cut off completely, responsive pricing would also be of considerable help in facilitating a smooth recovery from an outage: instead of having a whole army of motors trying to start up at once upon the restoration of power, with consequent load surges, voltage fluctuations, and malfunction of equipment, load could be picked up smoothly and gradually as the price is lowered from the inhibiting level.

Preserving Incentives with Escrowfunds

With privately owned utilities the regulatory process is too slow to permit prices established directly by regulation to be constantly adjusted to changing current conditions, unless indeed the regulators were to assume a large part of what are normally the responsibilities of management. The problem thus arises of how to allow the prices to be paid by customers to be varied by the utility management without giving rise to incentives for behaviour contrary to the public interest. Even if a formula could be devised that would require the utility to adjust prices to track short-run marginal cost, if the utility were allowed to keep the revenues thus generated without restriction, this would set up undesirable incentives for the utility to skimp on the provision of capacity in order to drive up the marginal cost, price, revenues, and profits.

A resolution of this dilemma can be achieved by separating the revenue to be retained by the utility from the amounts to be paid by customers. We can have the 'responsive' prices paid by customers vary according to short-run marginal social cost, while the revenues to be retained by the utility are determined by a 'standard' price schedule fixed by regulation in the normal manner, the difference being paid into or out of an escrow fund. Failure of the utility to expand capacity adequately would drive marginal cost up, and with it the responsive price, causing revenues to flow into the escrow fund, but the only way the utility could draw on these funds would be to expand capacity sufficiently to drive marginal cost down, causing the responsive rate to fall below the standard rate on the average, entitling the utility to make up the difference from the escrow fund as long as it lasts. Excessive expansion would result in the escrow fund being exhausted, with a corresponding constraint on

the revenues obtainable by the utility from the unaugmented low responsive rates.

The setting of the responsive rates would have to be to a large extent at the discretion of the operating utility, though the regulatory commission could monitor the process and even attempt to establish guidelines according to which the responsive price should be set. The utility would normally have no incentive to set the responsive rate below marginal cost, since this would merely increase sales and hence costs by more than any possible long-run increase in revenues to the utility. To be sure, in the short run it might be able to draw on the escrow fund to the extent of the excess, if any, of the standard rate over the responsive rate, but since from a long-run perspective there will normally be other more advantageous ways of drawing on this fund this will not be attractive.

When marginal cost is below the standard price, which would tend to be the usual situation, the utility would in general have an incentive to set the price between the marginal cost and the standard price, since each additional sale produced by the lower price will yield an immediate net revenue equal to the difference between marginal cost and the standard price, offset only by the drawing down of the escrow fund by the difference between the responsive and the standard price. When marginal cost is above the standard price, which with a properly designed standard rate schedule with time-of-day variation should happen relatively rarely, the utility would have an incentive to set the price at least at the marginal cost level, since to set it lower would tend to increase output at a cost in excess of anything the utility could ever recover. How much higher than marginal cost the price might be set would in theory be limited by the condition that the price could not be high enough to curtail demand sufficiently to drive marginal cost below the standard price. If the standard price has an adequate time-of-day variation, this constraint, loose as it may seem, may be sufficient. Additional guidelines could of course be imposed by the regulatory commission for those rare occasions where this constraint might seem insufficient to keep prices within bounds.

Actual Steps Towards Responsive Pricing

Some actual practices of utility companies are steps in the direction of responsive pricing. Contracts for ‘interruptible’ power provide for load shedding at the discretion of the utility subject to some overall limits. As these are fairly long-term contracts that usually require ad hoc communication between the utility and the customer, their applicability is limited and there is no assurance that the necessary shedding will be done in the most economical manner. Many customers are reluctant to submit to load shedding that is not under their control at least to some extent, and that might be imposed under awkward circumstances. Where reserves are ample and interruption is highly unlikely, such contracts have been challenged as being a form of concealed discriminatory concession. On the other hand customers entering into such contracts in the expectation of not being interrupted may feel aggrieved if interruption actually takes place.

Another experimental provision applied by a company with a heavy summer air-conditioning load is for a special surcharge to be applied to the usage of larger customers on days when the temperature at some standard location exceeds a critical level. And another company bases its demand charge on the individual customer’s demand recorded at the time that turns out to have been the monthly system peak load, supplying the customers with information as to moment-to-moment variations in the system load. This leads to interesting game-playing on the part of customers as they attempt to keep their own consumption down at times that look as though they might become the monthly peak, with the result that this action may itself shift the peak to another time.

Economies of Scale, Subsidy and Second Best Pricing

Where there are economies of scale, prices set at marginal cost will fail to cover total costs, thus requiring a subsidy. One reason for wanting to avoid such a subsidy is that if an agency is

considered eligible for a subsidy much of the pressure on management to operate efficiently will be lost and management effort will be diverted from controlling costs to pleading for an enhancement of the subsidy. This effect can be minimized by establishing the base for the subsidy in a manner as little susceptible as possible to untoward pressure from management. But it is unlikely that this can be as effective in preserving incentives for cost containment as a requirement that the operation be financially self-sustaining. To achieve this, prices must be raised above marginal cost, and in a multi-product operation the question arises as to how these margins should vary from one price to another within the agency.

Another objection to subsidy is that it raises hard questions of who should bear the burden of the subsidy. More fundamentally the taxes imposed to provide the subsidy will often have distorting effects of their own, and minimizing the overall distortion would again require prices to be raised above marginal cost. One can, indeed, regard these excesses of price over marginal cost as excise taxes comparable to other excise taxes that might be levied to raise a specified amount of revenue.

The answer given to the problem of how to allocate excise taxes and other margins of price above marginal cost so as to minimize the overall loss of economic efficiency given by Frank Ramsey in 1927 can be expressed for the case of independent demands as the inverse elasticity rule, which says that the margin of price over marginal cost as a percentage of the price shall be inversely proportional to the elasticity of demand. A more general formulation is one that states that prices shall be such that consumption of the various services would be decreased by a uniform percentage from that which would have been consumed if price had been set at marginal cost and demand had been a linear extrapolation from the neighbourhood of the 'second-best' point.

A more transparent formulation, devised by Bernard Sobin in work for the US Postal Service, is the requirement of a uniform 'leakage ratio', leakage being the difference between the net revenue actually derivable from a small increment in a particular price and the hypothetical revenue that would have been obtained had there been no change in consumption as a result of this increment. Leakage is the algebraic sum of the products of the changes in consumption of the various related products induced by the small change in a given price, and the respective margins between their prices and marginal costs. Leakage is a measure of the loss of efficiency resulting from the change in the particular price, and the leakage ratio is the ratio of this loss of efficiency to the hypothetical gain in gross revenue if there had been no change in consumption. If one leakage ratio should be greater than another, the same net revenue could be obtained at greater economic efficiency by getting more revenue from the price with the smaller leakage ratio and less from the other. The second-best solution accordingly requires that all leakage ratios be equal.

This analysis can be extended to the case where the agency is being subsidized by taxes which involve an adverse impact on the economy, in terms of marginal distorting effects, compliance costs, and collection costs, which can be expressed as the 'marginal cost of public funds' (MCPF). For a net decrease in the subsidy derived by increasing a price, which can be considered to be equivalent to imposing a tax equal to the difference between the marginal cost and the price, $\mathrm{MCPF} = \mathrm{LR}/(1 - \mathrm{LR})$, where LR is the leakage ratio. A second-best optimum is then one where the MCPF's are equalized over both external and internal taxes.

Special Sources of Subsidy: Land Rents and Congestion Charges

In the case of goods and services with economies of scale that are provided primarily to consumers within a particular urbanized area, methods of financing may be available that involve no marginal cost of public funds or even result in an enhancement of efficiency. The existence of large cities, indeed, is to a predominant extent due to the availability in the city of goods and services produced under conditions of economies of scale: if there were no economies of scale,

activity could be scattered about the landscape in hamlets, with great reduction in the high transportation costs involved in movement about a large city. If prices of these services are reduced to marginal cost, the increased attractiveness of the city as a consequence would tend to drive up land rents within the city, and it appears quite appropriate that a levy on such rents should be used to finance the required subsidies. And while there are practical and conceptual difficulties in defining exactly how land rents or land values should be specified for purposes of levying a tax, it is generally considered that a tax on land values, properly defined, has negligible adverse impacts on the efficient allocation of resources.

Indeed, there is a theorem of spatial economics which states that in a system of perfect competition among cities, the availability in the city of services and products subject to economies of scale, priced at their respective marginal social costs, will generate land rents just sufficient to supply the subsidies required to permit prices to be lowered to marginal cost. Among the more important of these services are utility services such as electric power, telephone, cable communications, water supply, mail collection and delivery, sewers and waste disposal, and local transit. It is not clear just how broad the conditions are under which this theorem would hold, and there are difficulties in capturing all land rents for subsidy purposes, but steps in this direction are clearly desirable.

On a more intuitive level, one can note that a person who occupies or uses land that is provided with services such as the availability of transit, electricity, telephone, mail delivery and the like will be requiring that these services be carried past his property to serve others whether or not he himself uses them. The user of tennis courts located conveniently in a built-up area should no more be excused from contributing to the costs of carrying these services past the courts, even though no direct use is made of electric power, telephone, mail, or other services, than he should expect his auto dealer to cut the price of an automobile by the cost of the headlights and windshield wipers merely because he asserts that he will never drive at night or in bad weather. Tennis players will indeed pay a rent enhanced by the presence of these services and the consequent greater demand for the land for other purposes, but the rent will go to the landlord, not to the purveyor of the services, and the price of the services to those who do use them will be too high for efficiency, unless indeed they are subsidized by other taxes that have their own distorting effects.

It is a corollary of this theorem that it would be to the advantage of the landlords in the area, *faute de mieux*, to agree collectively to pay a tax based on their land values, in order to subsidize the various utility services to enable the prices to be set closer to marginal social cost. They could expect in the long run that this action would increase their rents by as much or more than the taxes. To be sure, they might do better by getting someone else to pull their chestnuts out of the fire, but they can do this only at considerable damage to the overall efficiency of the economy of the city, to say nothing of the inequity of such a parasitic relationship.

In addition to land rents in the conventional sense, there is the land used for city streets for the use of which no adequate rental is generally charged. Charging on the basis of SRMSC for the use of congested city streets would in most cases yield a revenue far in excess of the cost of maintaining such facilities, which could appropriately be used for the subsidy of other urban facilities. Properly adjusted, such charges would increase efficiency by bringing home to the users the costs that their use directly imposes on others.

Formerly it would have been considered impractical to attempt to charge for the use of city streets according to the amount of congestion caused: the collection of tolls by manual methods at a multitude of points within the city might well create more congestion than it averted. Advances in technology have, however, made it possible to do this at minimal interference with traffic flow and at modest cost. One method, proposed as long ago as 1959 and recently carried to the point, is to require all vehicles using the congested facilities to be equipped with electronic response units which will permit individual vehicles to be identified as they pass scanning stations suitably

distributed within and around the congested area so that the records thus generated can be processed by computer and appropriate bills sent to the registered owners at convenient intervals. If properly done, this would greatly improve traffic conditions so that the net cost of the revenue to the road users would be far less than the amount collected as revenue. A pilot installation has recently been tested in Hong Kong with satisfactory results, but full implementation appears to have been deferred, because of the political situation associated with the impending transfer of sovereignty.

Indeed, one can define 'hypercongestion' as a condition where so many cars are attempting to move in a given area that fewer vehicle miles of travel are being accomplished than could be if fewer vehicles were in the area but could move more rapidly; for example if 1000 vehicles in an area move at 8 mph and produce 8000 vehicle miles of travel per hour, reducing the number of cars in the area at a given time to 800 might raise speed to 11 mph producing 8800 vehicle miles of travel per hour. By restricting the flow of traffic in the period leading up to the hypercongestion period, road pricing could prevent hypercongestion from occurring, except possibly sporadically, and in any case so improve conditions that more movement would be accomplished during the peak period at faster speeds. The improvement during peak periods might even be such that total movement throughout the day would be increased, and where conditions are now severe users could find that they are better off than before, even inclusive of the payment of the congestion charge.

If there are bridges, tunnels, or other special facilities for which a toll is already being charged, and which regularly back up a queue during the morning rush-hour, substantial revenues can be obtained at no overall net cost to the users by adding a surcharge to the toll during the period where queueing regularly threatens, rising gradually from zero to a maximum and down again in such a way that by gradual adjustment regular queueing is substantially eliminated. The toll surcharge will then be taking the place of the queue in influencing decisions as to when to travel, and in general those who plan their trips in terms of time of arrival at their destination will be able to leave as many minutes later as they formerly wasted in the queue, pass the bottleneck at the same time as before, and arrive at their destinations at the same time as before. The extra toll will be roughly the equivalent of the value of the extra time enjoyed at the origin point, and the revenue will in effect be obtained at no net burden on the users. In practice the results may be even better than this as a result of the added encouragement to car-pooling, the reduction of obstruction to cross-traffic, and the expediting of emergency or other trips where the delay had been a particularly serious matter.

Gains in the evening may be not quite so dramatic. The situation is not symmetrical, as typically the timing of the trip will be determined in terms of time of departure, which is separated by the queue from the time at the bottleneck. On the other hand the risk of conditions approaching gridlock is greater, since the accumulation of queues inside circumferential bottlenecks is more likely to create congestion, and there is less of a physical barrier to the simultaneous emergence of large quantities of traffic from parking lots into the downtown streets than there is in the morning to the convergence on the congested area of traffic arriving from the outside.

Congestion charges should be imposed, at least notionally, without exception on all forms of traffic. Such charges would be a necessary element in the cost-benefit analysis by which decisions are made as to the level and pattern of bus service to be provided, even though they would not be directly relevant to the determination of the price structure to be applied to that service.

Paradoxes in the Behaviour of Marginal Social Cost

A strict calculation of marginal social cost in particular circumstances may produce what may appear to be quite paradoxical results. For example, in many circumstances it will be optimal, and even essential, to maintain at least a minimum frequency of service in off-peak hours with buses of a standard size, resulting in there being practically always a large number of empty seats

in each bus. Under these circumstances the cost of carrying additional passengers is predominantly the cost of boarding and alighting, including the time of the driver and the other passengers on the bus who are delayed in the process. This cost will be relatively higher if the bus is half full than if it is nearly empty. The result is likely to be that the cost of a trip from a point near one end of the run to a point near the other end, at both of which points the bus is likely to be lightly loaded, may be smaller than for a shorter trip between points near the middle of the run where the bus is likely to be more heavily loaded. This is not a trivial matter: if it were there would be no sense to the refusal of express buses with empty seats to pick up local passengers. It is highly unlikely, however, that fares based on such a seemingly perverse behaviour of cost would meet with popular approval. Indeed, the original US interstate commerce legislation contained prohibitions against higher rates being charged shorter hauls than for any longer hauls within which they might be included.

Another paradoxical example can occur in mixed hydrothermal electric power systems: an increase in fuel prices could result in the marginal cost of power at particular times being reduced rather than increased. If hydro dams are spilling water at certain seasons of the year, increased fuel costs may make it economical to increase the installed generating capacity to make use of the spilling water, even for a briefer period of time over the year than was previously worth while. If during the wet season installed hydro generating capacity is more than sufficient to meet trough demand, marginal cost during such periods will be substantially zero, or at most limited to a small element of wear and tear on equipment pressed into service.

Installing more turbo-generators would expand the period during which this low marginal cost is effective, so that while increased fuel costs cause marginal cost to rise during the peak, the result could also be to lower marginal cost in these intervals into which the period of exclusive hydro supply expands.

In the case of long distance telephone service, the drastic reductions in the cost of bulk line-haul transmission have created a situation where distance, especially beyond the range where separate wire transmission is economical, is relatively unimportant as a cost factor, and where satellite transmission is involved, ground distance is indeed irrelevant. What remains important is the number of successive circuits, with their associated termination and switching equipment, involved in the making of a call. Thus a call between two small communities over a moderate distance, for which the volume of calling is insufficient to warrant the provision of a separate circuit, will generally cost substantially more than a call between important centres over a much longer distance, since the latter will involve only a single long-haul circuit, while the former will require patching through two or more long-haul circuits.

Another anomaly occurs when an innovation promising substantial reductions in costs appears on the horizon, such as has happened repeatedly in telecommunications. Any further installation of the old technology in the interim before the new technology is actually available will involve an investment which will have its capital value diminished over a brief period to that determined by its competition with the new technology. High depreciation or obsolescence charges are in order, and the prospect of the new lower costs results in higher current prices which would serve to hold back current demand and lessen the amount of old technology required to be installed.

Marginal cost pricing is thus not a matter of merely lowering the general level of prices with the aid of a subsidy; with or without subsidy it calls for drastic restructuring of pricing practices, with opportunities for very substantial improvements in efficiency at critical points.

Marginal Efficiency of Capital

John Eatwell

The variety of attempts to generate neoclassical results in a 'Keynesian' framework, and 'Keynesian' results in a neoclassical framework, together point to important failings in the *General Theory*. I will argue that the key failures are the inadequacy of Keynes's critique of the neoclassical theory of output and the important ambiguities introduced into the analysis by his marginalist treatment of the labour market and by his portrayal of the marginal efficiency of capital as an elastic demand schedule for investment. Garegnani (1978, 1979) has argued that these failings may be remedied by application of the results of the debate on the neoclassical theory of capital derived from Sraffa's *Production of Commodities*. I will illustrate this point by reference to the implications of the debate for Fisher's analysis of investment and the rate of interest which Keynes identified with his own analysis.

Keynes defined the marginal efficiency of capital as follows:

> If there is an increased investment in any given type of capital during any period of time, the marginal efficiency of that type of capital will diminish as the investment in it is increased, partly because the prospective yield will fall as the supply of that type of capital is increased, and partly because, as a rule, pressure on the facilities for producing that type of capital will cause its supply price to increase; the second of these factors being usually the more important in producing equilibrium in the short run, but the longer the period in view the more does the first factor takes its place. Thus, for each type of capital we can build up a schedule, showing by how much investment in it will have to increase within the period, in order that its marginal efficiency should fall to any given figure. We can then aggregate these schedules for all the types of capital, so as to provide a schedule relating the rate of aggregate investment to the corresponding marginal efficiency of capital in general which that rate of investment will establish. We shall call this the investment demand-schedule; or, alternatively, the schedule of the marginal efficiency of capital (Keynes 1936, p. 136).

Keynes's argument is more complicated than may at first appear, involving as it does assumptions on both the supply and demand conditions for individual capital goods in both short and long run and, finally, at both individual and aggregate levels – the ultimate objective being the derivation of the relationship between the 'rate of aggregate investment' and 'the corresponding marginal efficiency of capital in general', or, to put it another way, the general rate of return.

Taking first the short-period aspect of the argument, Keynes's assumption that increased investment in a given type of capital good will lead to higher cost of production – rising supply price – is quite unfounded. Any short-period situation, and particularly a short period in which capital capacity is widely underutilized, will be characterised by *excess* stocks of materials and machines in some (maybe all) sectors, with (perhaps) shortages in a few sectors too. In such a situation no definite hypothesis may be made as to the likely effect of increased output on cost, though in

conditions of widespread excess capacity it seems reasonable to suppose that costs will tend to *fall* as fixed costs are averaged over higher output. 'Pressure on the facilities' for producing a given capital good will only tend to become significant as full employment is approached, and even then the consequences for the cost of production of an increase in supply of any one capital good cannot be predicted with confidence.

The short-run influence of the demands for capital goods on 'prospective yield' to be derived from further investment are likewise unpredictable, and as to the aggregate effect of all this – nothing can be said at all. Indeed, there is no short-run 'marginal efficiency of capital *in general*' to say anything about! The relationship which Keynes sought must be a long-run relationship, in the sense that it is sufficiently unambiguous and persistent to allow definite conclusions to be drawn concerning the influence of a given volume of investment on the rate of return.

Now, in the longer run Keynes himself suggested that increased output will not result in any increase in cost. Any diminution in return must, therefore, derive from the fall in prospective yield as more capital goods compete to sell their services. What then is the relationship between the volume of investment and the rate of return in the longer run, that is in a situation in which the cost minimising combination of factors is chosen? At the partial level Keynes first considers, the answer seems clear: if all other prices in the economy are taken as given, then *ceteris paribus* it may be argued that there is an inverse relationship between the rate of return and the quantity of capital invested in the production of a given output. But Keynes's argument is on very shaky ground when he attempts to define the relationship for the economy as a whole by simple aggregation of these partial effects, for he can no longer use the *ceteris paribus* condition to keep at bay some fundamental problems.

These fundamental difficulties in Keynes's characterization of the marginal efficiency of capital may be clarified by returning to Fisher's analysis of the incremental rate of return on investment which Keynes tells us is 'identical with my definition' (Keynes 1936, p. 140).

Fisher's analysis is based on the substitution of capital for labour in a full-employment equilibrium, and throughout his discussion of the theory of saving, investment and interest, he imposes a major limitation on his argument – he assumes that all prices, wages and rents are fixed, and do not vary with variations in the rate of interest (Fisher 1930, p. 131n). This 'fixedprice' assumption allows Fisher to express all magnitudes in terms of 'money', and to move between discussion of individual behaviour and that of the economy as a whole without considering the inter-relationship between the rate of interest and prices.

An attempt to generalize Fisher's analysis to a many-commodity model, and hence to relate the determination of prices to the determination of the rate of interest, has been made by Solow (1963, 1967). I have analysed Solow's model and the debate it provoked elsewhere (Eatwell 1976); for our purposes we need only summarize my main conclusions.

It is assumed by Solow that the economy is in a stationary state, producing a consumption good, corn, by means of many reproducible inputs and labour. To enable the definition of limits we may further assume that the technical possibilities of the economy are characterised by a wage-profit frontier which is an envelope to an infinity of wage-profit curves, such that techniques are arrayed continuously along the frontier. Furthermore, consumption and value of capital per head associated with the variation in technique may be described by differentiable functions.

Since the techniques used in the production of corn require inputs of commodities other than corn, the wage-profit line for each technique may assume any negatively sloped curvature. But consumption good output per capita, c, (ie net output per head) and the value of produced inputs per capita, k, are continuous differentiable functions of the rate of interest (rate of profit), r, even though the technique in use varies continuously with r:

$$c = z(r) \quad k = \frac{\text{net output} - \text{wages}}{\text{rate of profit}} = [z(r) - g(r)]/r \tag{1}$$

where $g(r) = w$ is the equation of the wage-profit frontier.

The rate of return over cost of a transition between the technique in use at r and the 'adjacent' technique at $r + h$ is the ratio of the value of the difference in the perpetual consumption streams to the value of the difference in the capital stocks (i.e. the sacrifice required to effect the transition):

$$[z(r+h) - z(r)] / \left[\frac{z(r+h) - g(r+h)}{r+h} - \frac{z(r) - g(r)}{r}\right] \quad (2)$$

'In the limit, as the number of techniques grows denser', $h \to 0$ and expression (2) becomes:

$$z'(r)\frac{r^2}{r[z'(r) - g'(r)] - z(r) + g(r)} \neq r; \quad (3)$$

the marginal rate of return over cost is not equal to the rate of profit. The equality would hold iff:

$$z(r) = g(r) - rg'(r) \quad (4)$$

This would be the case of an economy having the properties of Samuelson's (1962) surrogate production function, and would indicate that, to all intents and purposes, the economy under consideration was set in a one-commodity world. The inequality does not depend on the presence of reswitching or even perversity. So long as the economy contains more than one produced input the rate of profit is not equal to the rate of return over cost. Or, more generally, no demand schedule for investment as a function of the rate of interest may be constructed.

The lack of any logical foundation for the construction of an elastic demand schedule for investment as a function of the rate of interest is simultaneously a critique of the neoclassical theory of output and of Keynes's concept of the marginal efficiency of capital – which was itself derived from the neoclassical schedule. Moreover, the fact that the neoclassical theory of output is synonymous with the neoclassical theory of value means that an effective critique of the latter necessarily constitutes an effective critique of the former. There is no logically consistent foundation to the idea that variation in relative prices, or in the rate of interest, or in money wages, will cause the system to tend to a full-employment level of output. Keynes's utilisation of the notion of a demand schedule for investment may perhaps be explained by the pioneering nature of the *General Theory*, in which the main propositions of a new theory of output are combined with vestiges of the old theory; by the need to present an apparently 'complete' theory; and by the pragmatic ambiguity with which many neoclassical propositions were presented in the then dominant Marshallian formulation.

However, once the corrosive influence of the presence of a marginal efficiency of capital schedule is removed, not only is the neoclassical synthesis seen to be without logical foundation (as in any other version of pseudo-Keynesian theory, such as that of Leijonhufvud (1968) or Malinvaud (1977), which assumes a monotonic inverse relationship between the rate of interest and the volume of investment), but also Keynes's positive contribution, the principle of effective demand, is thrown into more dramatic relief.

Marginal Productivity Theory

R. Dorfman

JEL Classifications
D2

Marginal productivity theory is an approach to explaining the rewards received by the various factors or resources that cooperate in production. Broadly stated, it holds that the wage or other payment for the services of a unit of a factor is equal to the decrease in the value of commodities produced that would result if any unit of that factor were withdrawn from the productive process, the amounts of all other factors remaining the same.

The basic justification of this assertion is highly intuitive. It rests on three assumptions: that the product is sold and the factor services are purchased in competitive markets; that the firms in those markets operate so as to maximize their profits; and that the products sold are produced by technologies that satisfy the 'law of variable proportions', which holds that successive equal increments of one factor of production, the amounts of all other factors remaining unchanged, will yield successively smaller increments of physical output. It follows immediately from these assumptions that if the wage of any factor exceeds the value of the output that would be lost if a unit less of that factor were employed, then a unit less of that factor will be employed, and successive units will be released until the inequality is annihilated. Similarly, if the wage of any factor is less than the value of the output that an additional unit could produce, successive units of that factor will be employed until the inequality vanishes.

The motivating concept in the foregoing argument was the effect on the value of output of small changes in the quantities used of different factors of production. This idea is so important that a special vocabulary has developed in order to discuss it with precision. The marginal product of a factor of production is the ratio of the greatest change in the output of some product that can be obtained by a small change in the use of the factor to the change in the use of the factor. The marginal product multiplied by the price of the product is the value of the marginal product. Marginal productivity theory holds that the payment for any factor of production tends to be about equal to the value of its marginal product, where, in a multiproduct firm, the product used in the calculation is the one for which the value of marginal product is greatest.

Clearly, the marginal product and its value may depend on the size of the 'small' change in the amount of the factor that is used in the calculation. To avoid being ambiguous when the amount of the factor is a continuous variable, the concept of marginal productivity is used: the marginal productivity of a factor is the limit that its marginal product approaches as the change in the quantity of the factor approaches zero. The result of multiplying the marginal productivity by the price of the product is called, somewhat inaccurately, the value of the marginal product; confusion rarely results.

Two of the assumptions made above to justify the marginal productivity doctrine can be relaxed. First, if the assumption that the firm produces for a competitive market is dropped, the conclusions of

the theorem has to be weakened slightly. If a firm produces for a market that is not perfectly competitive, it will recognize that it cannot change the quantity of any of the commodities it sells without simultaneously changing the price. Consequently, it will take account of the fact that if it changes the amount used of any factor, the resulting change in sales revenue will not equal the value of the factor's marginal product, but that value adjusted for the induced change in price. The ratio of the change in sales revenue to the change in the employment of a factor, for 'small' changes, is called the factor's marginal revenue product. Then the reasoning used to deduce the marginal productivity doctrine leads to the conclusion that the firm will employ each factor at the level where its marginal revenue product equals its rate of pay, whether or not the firm sells in a competitive market. In competitive markets, the marginal revenue product of a factor equals the value of its marginal product, but not necessarily in other market types.

The assumption that firms operate so as to maximize their profits can also be weakened for some purposes. If the firm operates only so as to produce its outputs at the lowest possible total cost, the same line of argument shows that the rates of pay for any two factors used by the firm will be proportional to the marginal revenue products of the factors. This is a weaker conclusion than was found for profit- maximizing firms, and does not imply any particular relationship between a factor's rate of pay and its marginal revenue product or the value of its marginal product.

Development of the Concept

Simple as it may appear, the marginal productivity principle was seen clearly only after a long, slow evolution. It was first presented in essentially its modern form around 1890, by J.B. Clark and Alfred Marshall, who apparently arrived at it independently. Their formulation built on the work of numerous predecessors, each of whom saw an important aspect of the principle but did not perceive its full generality.

The problem that gave rise to the marginal productivity principle – to explain the distribution of the national income among the great social classes and, especially to explain the shares claimed by the owners of capital and land – was at the top of the agenda of 19th-century economics. Thus, originally, only three very broad factors of production were considered: land, labour and capital, corresponding to the three social classes.

The first application of the principle occurred in the Malthus–Ricardo theory of rent, in particular in the concept of the intensive margin, which held that doses of labour and capital (in unspecified proportions) would be applied to each parcel of land until the value of the increase in product equalled the cost of the dose. The separate rewards to labour and capital were explained on other grounds.

In 1833, Longfield argued that the rate of interest was governed by the earnings of the least productive unit of capital, using a marginal argument. But he did not extend the reasoning to wages. At around the same time, von Thünen applied the principle to both wages and interest but did not publish his findings until much later, and then so obscurely that they had no influence. Jevons, in 1871, accounted for the rate of interest by a marginal argument, but explained wages as a residual after rent and interest were paid. Indeed, Jevons's theory is remarkably similar to Longfield's.

The ingredient that all these applications of the marginal principle missed was that the equality of marginal product and factor reward applied to all factors. Walras in 1874 (and, indeed, J.-B. Say three-quarters of a century before) insisted on treating the various factors of production symmetrically, but he did not derive any of the factor shares by a marginal argument until the later editions of the *Elements*, and then only awkwardly. Thus the marginal insight was not applied symmetrically to all factors until Clark published the papers that led to his *The Distribution of Wealth* (1899), and Marshall published his *Principles of Economics* (1890), thereby introducing a unified theory of income distribution.

The achievement of the unified theory raised a puzzling question: if each unit of every factor was

paid the value of that factor's marginal product, would the total value produced be neither more nor less than just sufficient to make all the factor payments? In 1894 Philip Wicksteed showed that the answer is affirmative for production processes with constant returns to scale, thus establishing the internal consistency of the marginal productivity principle. (Clark had believed it all along, but on inadequate grounds.) Wicksteed's proof amounted to an independent rediscovery of part of Euler's Theorem for Homogeneous Functions.

Beginning with the late 1880s, when the various partial glimpses of the doctrine congealed, marginal productivity theory became an essential part of the accepted explanation of the general level of wages and of the rate of interest, with important implications for practical economic issues. For example, it is often held that unions are powerless to raise the average level of wages because wages are governed by the marginal productivity of the labour force, which union activity cannot affect.

Although the marginal productivity concept was originally applied to explain the rewards of the broad social classes – the workers, landowners and entrepreneur–capitalists – beginning with Walras it became absorbed into the general theory of production and value. In that context it is used to explain the payments for the services of all the classes of factors that enter into production, and the definitions of these classes can be chosen freely to fit the problem under study. The tripartite classification continues to be used frequently, however.

Qualifications

The marginal productivity doctrine does not purport to be a complete explanation, even in principle, of the payments received by factors of production. As the simple, basic argument indicated, it explains only the amount of each factor that an enterprise will employ at different rates of payment for its services and in the presence of given quantities of the other factors used; that is, the demand curves for the factors. Supply curves also are needed to complete the explanation of the equilibrium level of use and rate of payment for the factors.

Furthermore, especially in the version that deals with numerous factors, rather than just two, a high degree of simultaneity arises. The demand curve for each factor depends on the amounts used of the other factors, but those amounts, depend on the amount used of the first factor, so, in the end, the rates of payment and the quantities used of all the factors are determined simultaneously. Consequently, the rates of payment for the various factors cannot be explained except in the context of a full-fledged general equilibrium model. Still, in such a model it often turns out that the payment received by each factor corresponds to its marginal productivity in each productive process in which it is used and in which marginal productivity is a well- defined concept. These complications will be clarified by considering a more formal and rigorous derivation and statement of the principle.

Formal Derivation of the Marginal Productivity Thesis

The theory is based on the behaviour of a profit-maximizing firm in a competitive industry. To describe that behaviour, imagine a firm that produces m products by the use of n factors or inputs. Suppose that the price of the ith product is p_i and that the quantity produced (per year) is y_i. Then the gross revenues per year will be $R = \sum p_i y_i$. Similarly, let w_j be the price per unit of the jth factor used. If the jth factor is a kind of labour or a purchased input w_j is simply its price or wage, but if it is a kind of fixed capital, then w_j should be regarded as its rental cost, normally interest on its purchase or construction cost plus a depreciation allowance. The amount of the jth factor used will be denoted by x_j. Then the total cost incurred per year will be $C = \sum w_j x_j$. The profit that the firm seeks to maximize is $R - C$.

The quantities (per year) of output, y_i and input x_j, cannot be chosen freely. This basic presentation will be limited to the simplest situation, in which the choices are constrained only by an explicit, differentiable production function, which will be

written $g(y1, \ldots, ym, x1, \ldots, xn) = c$. The implicit constraint that none of the arguments of $g(.,.,.. .)$ can be negative has important consequences that will be noted below.

In this set-up, invoking the assumptions mentioned in the second paragraph of this entry, the necessary conditions for a choice of y and x to maximize the firm's profits are the familiar marginal equalities. Specifically:

1. Marginal rates of substitution. The marginal rate of substitution between two factors, say the jth and the kth is the rate at which small amounts of the jth factor can be substituted for the kth with no effect on the rates of output in accordance with the production function constraint. Denote it by $\delta xj = \delta xk$: Mathematically, it is the ratio of the partial derivatives of the production function, or $\delta x_j = \delta x_k = -(\partial g/\partial)/(\partial g/\partial x_k)$ Economically, when the firm's profits are being maximized $\delta x_j/\delta x_k = w_k/w_j$. The intuitive content is clearest when the maximizing condition is written as $w_j\delta x_j = w_k\delta x_k$, which requires that when profits are being maximized the amounts of factors that can be substituted for each other in accordance with the production function must have equal monetary value.
2. Marginal rates of transformation. There is a similar relationship among the rates at which the outputs can be 'transformed' into one another in accordance with the production function constraint. Let $\delta y_i/\delta y_k$ denote the ratio at which production of the ith output can replace production of the kth. Mathematically, $\delta y_i/\delta y_k = (\partial g/\partial y_k)/(\partial g \partial y_i)$. Economically, when profits are being maximized $\delta y_i = \delta y_k = p_k/p_i$. Again, this result asserts that when profits are being maximized a small quantity of one of the outputs can be replaced by a quantity of equal value of any of the other outputs.
3. Marginal productivity of a factor. The final necessary marginal equality relates small changes in the quantity of an input, say x_j, to the resulting changes in the quantity of any of the outputs, say yi, in accordance with the production function. Mathematically, $\delta y_i/\delta x_j = (\partial g/\partial x_j/\partial g/\partial y_i)$. When profits are being maximized $\delta y_i/\delta x_j = w_j/p_i$. Economically, this is seen to require that if any output is increased by a small amount, the use of some factor must be increased by an amount of equal value.

This third differential equality, of course, is the marginal productivity doctrine, which is seen to be one of the consequences of the theory of profit maximization under competitive conditions. It is often written in the form $\text{VMP}_j = p_i(\delta y_i/\delta x_j) = w_j$ for all values of i. This formula defines the value of the marginal product of the jth factor to be the increase in the value produced of any product for which that factor is used, per unit increase in the use of the factor, and holds that the price per unit of that factor's services will be equal to the VMP when profits are being maximized.

Evaluation

At present the marginal productivity principle is used to explain the demand for factors of production in both a two-factor version using aggregate capital and aggregate labour as the factors, and an n-factor version, where n is the number of distinguishable factors used in the production process.

To use the two-factor version it is necessary to establish quantitative measures of the aggregates of dissimilar objects that are given the names 'capital' and 'labour', a task that has never been performed to anyone's satisfaction. For a long time, until the publication of J. Robinson's disturbing paper, 'The production function and the theory of capital' (1953), the lack of satisfactory measures of the aggregates was regarded as a technicality that did not affect the essential insight. But that paper drove home the realization that in the absence of those measures the marginal productivities, i.e. $\partial g/\partial K$ and $\partial g/\partial L$, were essentially undefined. From that time forth, analyses that use the two-factor version have been regarded as simplified 'parables', useful for making an intuitive point, but not to be taken literally.

Clarifying the meaning of 'capital' and 'labour' regarded as homogeneous factors of production continues to be one of the main problems of capital theory.

The *n*-factor version avoids the impossible task of aggregating apples and bulldozers, but has problems of its own. The formulation considered in this article is too simple to fit most industrial or commercial situations. It presumes that the constraints on choices can be described reasonably well by a single well-behaved, differentiable production function. This is generally not the case. Extreme examples are production functions in which factors are used or outputs are produced in fixed proportions. Any cooking recipe provides an example. More usual are cases in which the choices of input and output quantities are constrained by several functional relationships. The typical example is a firm or industry in which several different machines are each used in the production of several different products. Then there will be a functional relationship for each type of machine, to express the capacity of that type required for each combination of quantities of the different products. This is the sort of problem that has given rise to the use of linear programming in production planning and economic planning generally.

Where there are several constraints, the formulation used above does not apply because, essentially, the amounts of the inputs and outputs cannot be varied two at a time if they are connected by more than a single constraint. Marginal productivity is still a well-defined concept, but it no longer satisfies simple formulas like $\mathrm{MP}j = p_j(\delta y_i/\delta x_j)$ for any value of i. Instead, the marginal productivities, as defined above, are identified with the shadow prices in the solution to a mathematical programming problem, which is a considerably less intuitive concept.

Very frequently, if the problem of finding the combination of factor inputs that maximizes profits is solved straightforwardly, some of the input levels in the solution turn out to be negative – which is nonsense. Then, again, resort must be had to mathematical programming types of formulation and interpretation. The essential perceptions of marginal productivity theory still apply, but they can no longer be expressed by equalities between price ratios and ratios of marginal changes.

Marginal Revolution

Roger E. Backhouse

Abstract

The marginal revolution saw the introduction of the idea of marginal utility into economics in the early 1870s by Jevons, Walras and Menger. This change in economic theory was a slower process than the word 'revolution' suggests, and, to understand the changes associated with it, it is necessary to explore the scientific, social and political context in which they occurred.

The marginal revolution (sometimes called the marginal utility revolution) refers to the introduction into economics, in 1870–1, of the concept of marginal utility by William Stanley Jevons, Léon Walras and Carl Menger and which has widely been seen as involving a revolutionary break with the 'classical' economics of David Ricardo, John Stuart Mill and many of their contemporaries (see Blaug 1996, ch. 8). The value of a commodity was no longer explained in terms of its cost of production (possibly reducible to the labour required to produce it) but in terms of its value to the consumer. The concept of utility was used to explain consumer choices, marginal utility being seen by some (though not all) authors as replacing cost of production as the foundation on which the theory of value rested. In the 1890s marginal techniques were then applied systematically to the problem of income distribution. This change, it is argued, revolutionized economics, laying the foundations on which modern economic theory is built. Its many dimensions – viewing behaviour as optimization, using utility to describe individual behaviour, focusing on individual agents, the use of mathematics – attest to its importance (Hutchison 1978, provides a longer list; Maas 2005, ch. 1, sketches more recent attempts to choose between them). There is disagreement over the extent to which the change should be described as a revolutionary or as an evolutionary change going back many decades, and over its exact significance; but the marginal revolution is firmly established in histories of economic thought. However, while it describes certain developments in economic theory, to understand the changes that took place in economics around this time one should place it in a broader historical context.

Varieties of Marginalism

The most important qualification to the idea of a marginal revolution is the heterogeneity of economics during this period. Classical ideas were dominant in Britain, but even within classical economics there was great variety, and it has even been argued that marginalist ideas can be traced back as far as Steuart (see ▶ English School of Political Economy). At some time, virtually every element in the classical system outlined above had been challenged, many of these challenges leaving their mark. Much of this variety was captured within Mill's *Principles of Political Economy,* which went through seven editions between 1848 and 1873, and was undoubtedly the leading treatment of the subject: he worked with a very broad supply and demand theory of value and had accommodated many modifications to the Ricardian theory of income distribution. From Mill, the jump to marginalist theories was much easier than from Ricardo. Indeed, Alfred Marshall, though unfairly praising Ricardo at the expense of Mill (see O'Brien 1990), derived his theory of value by translating Mill into mathematics during the 1860s; when he encountered Jevons's work, it was a simple matter to graft marginal utility on to a mathematical treatment of supply and demand (Whitaker 1975).

There was also great variety across countries. In Ireland, it has been argued that an independent tradition of subjective value theory had been established at Trinity College Dublin, by successive holders of the Whately Chair (Black 1945). Ireland also produced two leading exponents of a

historical approach to economics, T.E. Cliffe Leslie and John Kells Ingram. Leslie's assault on deductive theorizing was a significant factor in the shaking of confidence in classical economics in Britain in the 1870s (see Hutchison 1953). In Germany, supply and demand theories had a long history, a supply and demand diagram having been used in a textbook as early as 1843 by Heinrich Rau (see Streissler 1990). In France, Smithian political economy had been mediated not through Ricardo but through Jean-Baptiste Say. The work of Augustin Cournot and the engineers of the École des ponts et chaussées, whose analysis rested on the concept of a demand curve, created an intellectual background very different from that prevailing in Britain.

These differences, together with profound differences in their personal backgrounds, meant that the work of Jevons, Walras and Menger, though often bracketed together, was far from homogeneous (see Jaffe 1975). Though Jevons and Walras both advocated the importance of mathematical argument, their emphases differed. Walras, closer to French rationalism, saw his general equilibrium equations as an abstract system that could solve the same problem that was solved in the real world by other means. Jevons focused on mechanical analogies and the notion that the same methods could be applied to physical and social sciences (Maas 2005). The contrast was even more marked in their applied work, where Jevons was a pioneer in the use of statistics but Walras was not. Menger, in contrast with both of them, rejected the use of mathematics, seeing the use of simultaneous equations as incompatible with identifying the causal relations between human needs and the value of commodities.

The varieties of marginalism increase further when later marginalists are brought into the account. Jevons, Walras and Menger did have disciples, most of them took their analysis in new directions and many are in many ways originals, the best examples being Marshall, Joseph Alois Schumpeter (Austrian, geographically and intellectually, yet an admirer of Walras), Knut Wicksell (whose Swedish synthesis of Austrian and Walrasian ideas bore little resemblance to Schumpeter's) and John Bates Clark (who constructed a non-mathematical American version of marginalism). Given this variety, it is not surprising that the marginal revolution can also be portrayed as a very slow process. Even in the 1880s and 1890s, some economists were still writing textbooks organized on classical lines, marginalist ways of thinking co-existing with other lines of enquiry.

The Wider Context

While scholars might, at one time, have been content to explain the advent of marginalist ideas in terms of economists coming to see the truth about consumers and value, historians are no longer satisfied with such explanations, arguing that economic ideas have to be explained in terms of the context out of which they arose. One context is that of 19th-century science. The most widely discussed explanation has been Mirowski's (1984, 1989) argument that marginalist economics reflects developments in physics (see De Marchi 1993). The 1860s saw the rise of energetics – the attempt to reduce all physical phenomena to energy. If physical phenomena could be reduced to energy, then so should social phenomena. More than that, adopting the methods of physical scientists and the mathematics of maximization and energy conservation offered economists the possibility of acquiring the status of physicists, adopting similar standards of rigour. Mirowski directed historians' attention to the many passages where Jevons, Walras and others stated explicitly that this was what they were doing. Though Mirowski drew normative conclusions about which many historians have been sceptical, and though his interpretation clearly does not fit some of the most important marginalists (notably Menger and Marshall), historians have taken up the idea that a major dimension to the marginal revolution was seeing economics as amenable to the methods of the physical sciences rather than as something radically different (see Maas 2005; Schabas 2005).

Moreover, at this period, physics was not the only prestigious natural science: controversies over evolution were at their height, following the publication of Charles Darwin's *Origin of Species* and

the application of evolutionary arguments to human society by Herbert Spencer. This cannot explain the advent of marginalism, but it represents an important additional connection between economics and contemporary science and helps explain why economics looked very different at the end of the 19th century from the way it looked in the 1860s. Raffaelli (2003) has pointed out that Marshall, perhaps the most significant figure in late-19th century marginalist economics, based his economics, not on the Benthamite utilitarianism used by Jevons, but on evolutionary psychology. Human nature was moulded by experience. Evolutionary ideas thus reinforced the notion that human beings had to be seen as different from one another and that they could be changed. This way of thinking could lead into eugenics, a widely entertained body of ideas that developed towards the end of the century (see Peart and Levy 2005). But such ideas also served to undermine the Malthusian bogey that had provided an argument against much social reform throughout the century (Stedman Jones 1984). Marshall, for example, though he used the static, mechanical apparatus of supply and demand, used it to discuss dynamic processes. He saw industries evolving as biological species, and human character changing in response to human activities, a process that was too complicated to be represented mathematically, and as a result never worked with formal dynamic models: they would have been too mechanical. Against such arguments that evolution became influential at that time, Schabas (2005), though stressing that neoclassical economists were very interested in psychology, has recently questioned whether Darwin has as much influence as has been claimed.

The significance of evolutionary ideas points to another aspect of the context against which the advent of marginalist ideas needs to be set: the political climate. The late 19th century has been called the liberal age, when Europe moved towards freer trade and the franchise became more democratic. The progress of liberal ideas and policies varied greatly from country to country, but everywhere there was debate over the merits of liberalism and collectivism, with the latter taking many forms, ranging from Fabian 'municipal socialism' to Marxian socialism. In Britain, the mid-century radicals, amongst whom Mill was pre-eminent, were liberals who wanted to reform the institutions of society in ways consistent with their liberalism. But, by the end of the century, following the extension of the franchise to much of the working class in 1867 and 1884, radicalism became increasingly collectivist. Against Social Darwinist arguments for individualism were ranged ethical arguments for reform, from the American Social Gospel movement to the variety of movements for social reform inspired in Britain by the Oxford philosopher T.H. Green (see Richter 1964). In the same way that the Great Depression motivated many who came into economics in the 1930s and 1940s, the problem of poverty affected this earlier generation. Economists' attitudes towards policy changed (see Hutchison 1978), as did the way they developed their theories, the most noticeable example being the development of welfare economics by the Cambridge School, J.A. Hobson, and others.

Though it was again a process the speed of which varied greatly from country to country, a further element of the context in which the marginal revolution took place was the professionalization of economics. By the middle of the 19th century, economics was being developed by a mixture of academics and members of a broader educated elite; those recognized as economists might be politicians or businessmen. Specialist journals existed in some countries, but original work in the subject was also published in journals read by non-specialists. By the end of the century economics, like many other disciplines, had changed, becoming an academic discipline in which the main communication was between specialists. This made possible a different type of discourse, more technical and addressing issues that might seem more tenuously related to issues of concern to lay people.

Conclusions

The marginal revolution, like other revolutions in economics, is associated with changes in economic theory that undoubtedly altered the way economics was conceived. However, picking out

a single theoretical or methodological innovation that explains why the marginal revolution was apparently so important has proved difficult. The reason may be that, as in the case of the Keynesian Revolution, though economics changed profoundly in the closing decades of the 19th century, these changes owed as much, if not more, to deeper changes in the social, political and intellectual context in which economists were working as to any specific innovation in economic theory.

Marginal Utility of Money

Eugene Silberberg

Abstract

Alfred Marshall identified the area to the left of a demand curve as consumer surplus, but he added that his discussion was valid only under the assumption of 'constant marginal utility of money'. For much of the 20th century economists debated the meaning of that phrase and its relevance to consumer surplus. The analysis became clear only after the development of duality theory, particularly the properties of the expenditure function. Marshall's caution becomes unnecessary with a proper definition of consumer surplus.

Interest in the marginal utility of money probably dates from Alfred Marshall's identification of consumer surplus as the area under the demand curve. Marshall went on to add a qualification to his analysis:

> In the same way if we were to neglect for the moment the fact that the same sum of money represents a different amount of pleasure to different people, we might measure the surplus satisfaction which the sale of tea affords, say, in the London market, by the aggregate of the sums by which the prices shown in a complete list of demand prices of tea exceeds its selling price. (Marshall 1920, p. 106)

In the mathematical appendix (Note VI), Marshall identifies the 'total utility of the commodity' with the area under the demand curve, defined by an integral, but then qualifies that analysis by saying 'we assume that the marginal utility of money to the individual purchaser is the same throughout'. The meaning of these phrases is anything but clear. The text phrase seems to indicate that interpersonal comparisons of utility are a necessary prerequisite for the use of consumer's surplus; in the appendix, Marshall's concern is that, as more of a commodity is purchased, money will yield less satisfaction to the consumer, destroying any linear relationship between money and utility.

Later interpretation of 'constant marginal utility of money' was further complicated by the use of the word 'money' in two different contexts. To Marshall, money provided no direct utility to the consumer; it was a device solely for lowering the transactions cost of exchange. The concurrently developed general equilibrium theory of Walras, however, treated money as that one good which happened to have the additional property of serving as the medium of exchange, a numéraire commodity whose price was unity.

We now analyse the connection between the marginal utility of money and consumer's surplus. The consumer is assumed to maximize $U = U(x_1, \ldots, x_n)$ subject to $\sum p_i x_i = M$. We derive the Marshallian (money income held constant) demand functions $x_i = x_i^M(p_1, \ldots, p_n, M)$ along with $\lambda^M(p_1, \ldots, p_n, M)$ using the Lagrangian $L = U + \lambda(M - \sum p_i x_i)$.

The indirect utility function $U^*(p_1, \ldots, p_n, M) = U(x_1^M, \ldots, x_n^M)$ indicates the maximum utility for given prices and money income. Using the envelope theorem, $\partial U^*/\partial M = \lambda^M$, the marginal utility of money income. Also, $\partial U^*/\partial p_i = -\lambda^M x_i^M$ (Roy's identity). The Hicksian (utility held constant) or 'compensated' demand functions $x_i^U(p_1, \ldots, p_n, U)$ are derived from minimizing $M = \sum p_i x_i$ subject to $U(x_1, \ldots, x_n) = U_0$. The expenditure function $M^*(p_1, \ldots, p_n, U^0) = \sum p_i x_i^u$ indicates the minimum cost of maintaining utility level U^0 for arbitrary prices $p_1, \ldots, p_n$ the envelope theorem, the Hicksian demands are the first partials of the expenditure function: $x_i^U = \partial M^*/\partial p_i$. (See ▶ Hicksian and Marshallian Demands.)

The area to the left of a consumer's demand curve between two prices (where the initial price is higher than the final price), is $-\int x_i \partial p_i$. The units of this integral are that of money income, being price times quantity. Suppose this area equals some value A. The issue is: what question does A answer, and what is the relation between that answer and the marginal utility of money? Since a Hicksian demand function is the first partial of the expenditure function, the area to the left of this demand curve is simply a change in the expenditure function:

$$-\int x_i^U \mathrm{d}p_i = -\int (\partial M^*/\partial p_i)\mathrm{d}p_i = M^*(p^0, U^0) - M^*(p^1, U^0)$$

where p^0 and p^1 are the initial and final price vectors over which the integral is taken. The area to the left of Hicksian demand function therefore represents a change in expenditure with utility held constant; this area indicates the amount a consumer would be willing to pay (or have to be paid) to willingly accept some change in the purchase price of some good. Moreover, there is no need to invoke any assumption at all about the marginal utility of money.

The area to the left of the Marshallian demand function, however, has no such easy interpretation, because unlike the Hicksian demands, the Marshallian demand functions are *not* in general the partial derivatives of some integral function; therefore the integrals of the Marshallian demands are not expressible in terms of changes in some well-defined function of the initial and final prices and income levels. From Roy's equality, the Marshallian demands are the first partials of the indirect utility function *divided by the marginal utility of income*. Thus

$$-\int x_i^M \mathrm{d}p_i = -\int \left(1/\lambda^M\right)\left(\lambda^M x_i^M\right)\mathrm{d}p_i = \int \left(1/\lambda^M\right)\left(\partial U^*/\partial p_i\right)\mathrm{d}p_i.$$

However, if the marginal utility of money term is 'constant', that is, independent of prices, it can be moved in front of the integral sign; only then can this expression be integrated to yield a function of the endpoint prices (and money income):

$$-\int x_i^M \mathrm{d}p_i = \left(1/\lambda^M\right)\int \left(\partial U^*/\partial p_i\right)\mathrm{d}p_i = \left(1/\lambda^M\right)\left[U\left(p^1\right) - U\left(p^0\right)\right].$$

Thus, in this case, the area to the left of the Marshallian demand function would equal a change in utility divided by the marginal utility of money, thus converting that change in utility into units of money. Marshall's claim that the area to the left of a demand curve may be interpreted as a change in utility under the assumption of constant marginal utility of money would thus be technically correct for the demand functions derived from utility maximization, though how much of the above discussion he had in mind can easily be debated.

The problem with this analysis is that λ^M cannot literally be a 'constant,' as shown by Samuelson (1942). Since $\lambda^M = U_i/P_i$ a proportionate change (for example, doubling) of prices and income leaves the amount of the goods consumed unchanged (since the Marshallian demand functions are homogeneous of degree zero in prices and income), and thus the numerator of this expression unchanged. However, the denominator has doubled, meaning λ^M has halved. Thus $\lambda^M = (p_1, \ldots, p_n, M)$ must be homogeneous of degree –1; it can be independent of at most n of its arguments. It can, for example, be independent of all prices, but not income also, or it can be independent of $n - 1$ prices and income.

Since $\partial U^*/\partial p_i = -\lambda^M x_i^M$ and $\partial U^*/\partial M = \lambda^M$, Young's theorem on invariance of partial derivatives to the order of differentiation yields (omitting superscripts)

$$M^*_{p_i M} = -[\lambda \partial x_i/\partial M + x_i \partial\lambda/\partial M] = \partial\lambda/\partial p_i = M^*_{M p_i}.$$

Suppose

$$\partial\lambda^M/\partial p_i = 0, i = 1, \ldots, n.$$

Then

$$(M/x_i)(\partial x_i/\partial M) = -(M/\lambda)(\partial\lambda/\partial M) \text{ for } i = 1, \ldots, n.$$

That is, the income elasticities are all equal (necessarily to unity, from the budget constraint); thus the utility function must be homothetic. Denoting the Marshallian area CS, we have

$$CS = \left(1/\lambda^M\right)\left[U^*\left(p^1, M\right) - U^*\left(p^0, M\right)\right].$$

Thus for homothetic utility functions, where the indifference curves are all radial blow-ups of each other, the Marshallian area represents the unique monetary equivalent of a change in utility; the coefficient which converts 'utiles' to money income is invariant over the price change.

Suppose now that λ^M is a function of one price only, say p_n. Then from the above equation, $\partial x_i^M / \partial M = 0, i = 1, \ldots, n-1$. Since there is no income effect for goods 1 to $n - 1$, the Marshallian demand functions for those goods coincide with the Hicksian demands. This is the famous case of 'vertically parallel' indifference curves. Therefore the interpretation of the area to the left of any of these Marshallian demand curves is identical to the case of the Hicksian demands, that is, the willingness to pay to face the lower price.

Marginalist Economics

Antonietta Campus

Unsystematic ideas about use value and demand and supply as determinants of the exchange value of commodities, which were developed parallel with, and in opposition to, classical theory, found a systematic treatment at the beginning of the 1870s in W.S. Jevons's *Theory of Political Economy*, C. Menger's *Grundsätze der Volkswirtschaftslehre* (both published in 1871), and Walras's *Eléments d'economie politique pure* (published in two parts in 1874 and 1877). It is usual to mark the beginning of marginalist economics with the appearance of these works, in which the long-sought relationship between use value and exchange value was established for the first time. Earlier works on use value (i.e. utility – reinterpreted in subjective terms) had now led after various elaborations to the principle of decreasing marginal utility (see Dmitriev 1902; Stigler 1950).

What is so new in the works of the 1870s, and of such fundamental importance as to be considered that which 'constitutes the very foundation of the whole edifice of economics' (Walras 1900, p. 44) is the condition of proportionality between prices and marginal utilities for each consumer after exchange, i.e. the condition of maximum utility. This condition (which implies the hypothesis of substitution between goods for each consumer when prices vary) gave an analytical basis to downward sloping demand curves for goods, and, with them, to the idea that, *given* the quantities produced, relative prices are exclusively determined by marginal utilities, independently of the costs of production of commodities.

The 'general relations of demand and supply' as determinants of the normal prices and the value of the component parts of the cost of production, i.e. distribution, were advanced by Walras in 1877 in the second part of his *Eléments*. But Walras's work was not, at that time, widely read because of its mathematical difficulty. Jevons's *Theory* and Menger's *Grundsätze* contained no systematic alternative to the undoubtedly confused classical theory of distribution, in the then dominant form found in J.S. Mill's *Principles*.

The lack of a sufficiently well worked out theory of distribution which could be coordinated with the new theory of value, was reflected in the lack of coordination between costs and prices. Yet there remained the apparent fact that in a competitive economy in the long run, prices tend to be equal to costs. When Marshall reviewed Jevons's *Theory* in 1872, he pointed out these deficiencies. However, he did not apparently have a solution in view at the time, for in 1909 he wrote to Cannan:

> There remained great lacunae in my theory till about '85; when on my return to Cambridge, I resolved to try to find out what I really did think about Distribution and I gradually developed . . . the doctrine of substitution between prima facie non-competitive industrial groups, of quasi-rents, etc. (see Pigou 1925, p. 405).

The eagerness to fill this void must have been considerable. With the publication in 1867 of Volume I of Marx's *Capital*, Ricardo's theory of value and distribution had reappeared, not in the conciliatory form of J.S. Mill's *Principles*, but in the dangerous form which had been typical of the theory in the decade following Ricardo's death. According to Böhm-Bawerk, this theory constituted for the Germany of 1884 'the focal point about which attack and defence rally in the war in which the issue is the system under which human society shall be organized' (Böhm-Bawerk 1884, p. 241).

It was in this context that an attack on Marx's theory of value was launched simultaneously in 1884 by Wicksteed in Britain and by Böhm-Bawerk in Austria. Both beginners as economists at this time, they became in a few years two of the

great makers of the marginalist theory of distribution, following the line laid down in the works of Jevons and Menger. They conducted their criticism of Marx's theory of value along essentially similar lines, which clearly reflect the impasse in the marginalist theory of *distribution* at the time. The chosen line of criticism, which perhaps they were obliged to follow, was of an 'esoteric' nature, i.e. that of simply contrasting the utility theory with the labour theory of value. Böhm-Bawerk's critique, for instance, basically maintained that in Marx's theory, no less than in Ricardo's, labour rather than utility could be singled out as the source of value because the analysis was artificially restricted to reproduceable goods alone. When this restriction was removed, and the wider category of 'economic goods' – whether reproduceable or not – was considered, it would be apparent that utility, not labour, is the common source, and determining element, of exchange value.

The most obvious objection to this line of argument is that, even allowing that marginal utility theory could explain the price of *non-reproducible* goods, it was quite unable at this stage to explain the prices of *reproducible* goods – that is, of those goods the price of which is subject to the constraint of cost. After all, it was Böhm-Bawerk's opinion that to understand the connection between price and cost 'is to understand a good half of economics' (Böhm-Bawerk 1889, p. 249). If we leave aside the publication in 1877 of the second part of Walras's *Eléments* (on account of its total lack of impact at the time), the 'good half of economics' (on which the other half ultimately depended) in 1884 had not been developed yet by marginalists: hence the 'esoteric' nature of their critique of Marx's theory of value.

On the other hand, the economists who opposed marginalist theory, because of the crucial role they assigned to the cost of production, did not make their case well. This was because the notion of cost itself, which, vague enough in J.S. Mill's *Principles* (not least because of the eclectic nature of that work), had become, in Cairnes's *Some Leading Principles* (1874), what Whitaker defined as 'an appalling jumble of ideas' (1904, p. 10). And it was to become even worse in the 1880s, following the abandonment – after Walker's attack in 1875 and 1876 – of the Wages Fund theory, and the spread, during the 1880s, of what Cannan defines as 'the produce-less-deduction' theories of distribution (Cannan 1929, pp. 356–8). This explains why the discussion of economic theory took on a form peculiar to this period of interregnum: that of a frontal opposition between cost theory and utility theory.

Marshall's *Principles* (published in 1890) at last provided a widely comprehensible solution to the problem of the cost–price relationship that the marginalists had been seeking for twenty years. Marshall established the relationship by simultaneously determining by the same principle, prices as determined by the principle of decreasing marginal utility, and the value of the component parts of the cost of production as determined by the analogous principle of decreasing marginal productivity (which had been discovered later than marginal utility and had certainly been prompted by it, as Wicksteed clearly indicated: 1894, pp. 7–10).

The solution to the problem of the cost–price relationship within marginalist theory is obviously not a 'reconciliation' between classical and marginal theory within a more complete theoretical paradigm. The idea of a reconciliation is, rather, the version of the facts that Marshall ably put forward and soon caused to prevail, favoured in this by the then state of confusion of traditional cost theory, and by the peculiar context in which discussions were necessarily conducted at that time (that of frontal opposition between cost theory and utility theory).

In fact, what Marshall pointed out in his *Principles* through his 'doctrines of substitution' between goods and methods, was a new unifying principle of simultaneous determination of the prices and the value of the component parts of the costs of production: the principle of supply and demand. In Marshall's own words:

> The 'cost of production principle' and the 'final utility' principle … are component parts of the one all-ruling law of supply and demand' insofar as 'marginal uses and costs do not govern value but are governed together with value by the general relations of demand and supply (Marshall 1890, p. 280; p. 410).

This solution, which had already been presented by Walras should have been particularly congenial to Marshall, considering that, already in his review of Jevons's *Theory* in 1872, he had pointed out as a basic limit of Jevons's work a 'successivistic' approach, so to speak, to value and distribution, rather than one of simultaneous determination of prices, distribution and quantities produced.

It is of particular importance to note Marshall's statement in a letter to J.B. Clark in 1908: 'My whole life has been and will be given to presenting in realistic form as much as I can of my Note xxi' (see Pigou 1925, p. 417). Note xxi of his *Principles* is – except for the treatment of capital – substantially Walras's general equilibrium system, generalized for variable coefficients. The *Principles* – the work of Marshall's entire life – is thus essentially a presentation 'in realistic form' of the general equilibrium system which we find in Note xxi. An essential premise, in this 'realistic form' of presentation, is the demonstration of the analytical bases of the 'general conditions of demand and supply', i.e., the 'doctrines of substitution' (following on from the principles of decreasing marginal utility and productivity on which the general equilibrium system in Note xxi rests).

The illustration of the analytical bases of demand and supply was perhaps the most important element which, by making it comprehensible, quickly brought acceptance to a theory which, as presented in Walras's *Eléments*, was far from comprehensible at the time and therefore not amenable to practical application. The possibility of practical application of the 'general conditions of demand and supply', i.e. of general equilibrium, was pursued by Marshall fundamentally through his peculiar method of 'partial equilibrium' (Robbins 1932, p. xv and fn3) later to become one of the most debated aspects of Marshall's *Principles* (see Sraffa 1925, 1926; Robertson, Shove and Sraffa 1930; Newman 1960). Whatever the demerits of the 'partial equilibrium' method, it was thanks to this 'realistic form' of presentation that marginalist economics gained its first general acceptance through the pervasive ascendancy of Marshall's *Principles* in Britain and, directly or indirectly, the United States, Sweden and a large part of Europe (see Shove 1942, pp. 313–16).

But, as Robbins puts it, Marshall's 'peculiar blend of realistic knowledge and theoretical insight … was not necessarily conducive to clear presentation of abstract theoretic issues' (Robbins 1934, p. 10). In fact, Marshall's often explicit propensity to evade precisely defined economic notions, with the justification that, in concrete realities, everything 'shades into the other by imperceptible gradations' facilitated, together with the domination of Marshall's version of marginalist economics, that blurring of difficulties which beset the theory from its beginnings and which were amply debated in the period in which the first six editions of the *Principles* were published (1890–1910).

These difficulties can be illustrated in the simple terms in which they first appeared. The discovery of the principle of decreasing marginal productivity (at which, on the analogy of the earlier principle of decreasing marginal utility, Edgeworth, Marshall, J.B. Clark, Wicksteed, Wicksell and Walras himself arrived simultaneously, between the end of 1880s and the beginning of the 1890s) suggested a method, long sought by the opponents of classical economics, through which the product of each agent of production 'may be disentangled from the product of cooperating agents and separately identified' (Clark 1899, p. viii). However, this possibility of 'disentanglement' proved problematical when the attempt was made to 'identify' the product of that peculiar agent of production which is capital. And on the notion of capital to which one must have recourse to determine distribution, on the basis of the marginalist principles of supply and demand, the greatest exponents of the marginalist theory of distribution, from Böhm-Bawerk and J.B. Clark to Walras and Marshall, openly declared themselves to be at variance with each other. In Böhm-Bawerk's words: 'It is an almost tragicomic circumstance that the champions of the different definitions of capital charge each other with the same error, the irrelevance of the recommended concept' (Böhm-Bawerk 1889, 3rd edn, 1909, Bk. I, ch. III, fn96).

While the divergences as to the way of dealing with capital obviously involved differences in the determination of the rate of profit, in fact they implied more pervasive difficulties. Böhm-Bawerk himself rightly observed that: 'when divergence is as wide as it is on this point of capital, we are forced to the conclusion that there must be something quite unusual about this specific apple of discord.' And he added that Knies appraised the implications of the controversy over capital 'quite accurately', when he said that 'there is more involved here than in the ordinary case of a conflict over a felicitous versus an awkward definition, or even a right versus a wrong *definition*' (Böhm-Bawerk 1909, p. 31). In fact, on account of the necessary relationship between the rates of profit, wages, and rent (Wicksteed 1894), the disagreement over the treatment of capital and therefore over the determination of the rate of profit implied difficulties for the whole theory of distribution and thus for the determination of costs, and normal prices. It was to this state of things that Ashley must have been referring in his 1907 Presidential address to Section F of the British Association, when he said: 'There is hardly a single point in the whole theory of distribution on which there is as yet any approach to unanimity.' And – assuredly having Marshall's attitude to controversy in mind – he remarked: 'Doubtless all the differences could be construed as differences of emphasis; but this is hardly reassuring, for the emphasis may differ so much as to give totally opposite impressions'. (Ashley 1907, pp. 477–8).

Given the almost total domination that marginalist economics has enjoyed for about a century, it would seem natural to think that

> from these 'clashes of thought' between marginalist theoreticians 'the spark of an ultimate truth had at length been struck' (Sraffa 1926, p. 535).

However, things did not really go this way. What happened was rather that 'Clark's value concept of capital . . . gained a considerable and constantly increasing number of adherents' (Böhm-Bawerk 1909, p. 57). Alfred Marshall was perhaps the most important of its 'adherents'. With this adhesion, 'considerations of capital theory proper . . . simply disappeared from the picture' in the English-speaking world (Robbins 1934, p. xiv), at least until the 1930s.

The unresolved question – lying at the very foundation of marginalist theory – as to that 'something quite unusual' which 'there must be' about capital, has, however, been brought to full light in 1960, with the publication of Sraffa's *Production of Commodities by Means of Commodities*. One of the important things proved in this work is that, when commodities are produced by means of 'capital' as well as labour and land, there will in general be 'reversals in the direction of the movement of relative prices' when distribution varies (Sraffa 1960, p. 38). This implies that there is no reason why the 'laws of substitution' between goods and methods, which lie at the basis of the demand curves for goods and factors, should go in the direction required to define downward sloping demand curves for factors. With this, the marginalist theory of distribution seems to land in an untenable position – even in the version presented by Walras – and, with it, the connected theory of the cost of production and normal prices – unless we disregard produced means of production and consider some 'model of pure exchange' as acceptable for the explanation of value. This would be tantamount to accepting, after a century of theoretical 'refinements', what was patently unacceptable in marginalist economics between 1870 and 1890: the lack of coordination between price and cost.

Marital Institutions

Scott Drewianka

Abstract

Marital institutions are rules governing marriages and divorces. Most work to date has focused on unilateral and no-fault divorce reforms. Theoretical discussions generally

hinge on the applicability of the Coase theorem. Empirical evidence is mixed, but generally indicates that those reforms played only a modest or temporary role in generating trends in marriage, divorce and fertility. There is more consistent evidence of substantial effects on intrahousehold allocation and other distributional outcomes, especially in conjunction with rules on post-divorce division of property. Several new institutions that have emerged in recent years present promising opportunities for future research.

Marital institutions are laws and customs governing relationships between spouses or domestic partners. Examples include rules defining who may marry, the benefits and responsibilities associated with various family arrangements, the circumstances under which a partnership may end, and the division of property and child custody in that event.

Although researchers have studied many such institutions, the oldest and most developed branch of the literature investigates a wave of divorce reforms enacted during the 1960s and 1970s in most US states and several countries. Two common changes involved dropping the requirement that one spouse be guilty of violating terms of the marital contract ('no-fault divorce') and allowing one spouse to obtain a divorce without the other's consent ('unilateral divorce'). Researchers' interest was largely motivated by contemporaneous changes in family structure. The US divorce rate more than doubled and marriage and fertility rates declined during the reform period, leading some to suspect a causal relationship. However, many economists remained sceptical because divorce rates rose steadily before the reform period, increased during the reform period even in places that did not enact reforms, and fell sharply in subsequent decades.

Theory provides additional reason for doubt. Following the logic of the Coase theorem, Becker (1981) argues that if intrahousehold transfers can be negotiated costlessly, divorce occurs only when a marriage no longer generates a surplus. In that view, reforms that reassign bargaining power between spouses would not affect the incidence of divorce. However, Becker's reasoning would break down if negotiation costs were important or if reforms changed the cost of separating. Reforms could also affect the gains from marriage by altering incentives for match-specific investment (Stevenson 2007; Wickelgren 2009).

Numerous papers have attempted to resolve these claims empirically. The main complication is that reforms may be correlated with existing levels or trends in divorce rates, so failing to account for that correlation would lead to biased estimation. For example, the first known empirical study found that no-fault divorce was more common in states with a greater pre-existing demand for divorce (Broel-Plateris 1961).

Such correlations played a central role in early studies using cross-sectional data. Despite using similar data and methods, Peters (1986, 1992) and Allen (1992) reached opposite conclusions about the effect of divorce reforms on US divorce rates. Their dispute revolved around the appropriateness of specifications with regional dummies and controls for pre-reform divorce rates. Peters argued that those variables were necessary to account for the non-random incidence of divorce reforms, but Allen claimed that they unnecessarily removed variation useful for identifying the reforms' effect.

That debate was eventually resolved using panel data. Friedberg (1998) showed that the estimated effect of unilateral divorce on divorce rates was large when state fixed effects were excluded, but statistically insignificant when they were included. She then advanced the issue by showing that reforms were also negatively correlated with trends in divorce. When she added state-specific time-trends to her specification, her results indicated that unilateral divorce laws encouraged divorce.

However, subsequent work by Wolfers (2006) extended Friedberg's model by allowing the law's effect to vary dynamically. His results confirmed that reforms raised divorce rates, but the effect dissipated after about eight years. According to Rasul (2006), the effect is only temporary because the reform alters the optimal sorting of spouses, and divorce rates rose for couples married before the change but not for those married under the new regime.

A related question is whether the reforms affected incentives to start families in the first place. The evidence on marriage is mixed, with some papers claiming a positive effect and others a negative effect. However, none of the estimates is large, and published papers find little evidence of a statistically significant effect.

In contrast, there is more consistent evidence that unilateral divorce slightly reduces overall fertility, slightly increases marital fertility, and reduces nonmarital fertility more substantially. The latter two effects may reflect individuals' increased willingness to marry in the event of a premarital pregnancy if a potential divorce would be easier to obtain (Gruber 2004; Stevenson 2007; Drewianka 2008). Similarly, Ekert-Jaffe and Grossbard (2008) show that a greater share of births are within-marriage in countries with 'community property' laws, which typically grant a greater share of a divorcing couple's assets to the lower-earning spouse.

In sum, while not entirely consistent with the purely Coasian view, most estimates indicate that divorce reforms had only modest or temporary effects on marriage, fertility and divorce rates.

A second branch of the literature investigates distributional outcomes. Even in a Coasian framework, reforms could still alter outcomes related to spouses' relative bargaining power. Indeed, some marital institutions appear specifically intended to affect bargaining power, such as rules governing post-divorce division of assets. However, a critical difficulty in assessing such effects lies in knowing which spouse benefits from the reform. Even when the change clearly benefits the spouse who is more eager to end the relationship (as in the case of unilateral divorce), researchers often cannot be sure which spouse that is.

This challenge may explain conflicting evidence on domestic violence. Dee (2003) finds that wives are more likely to murder their husbands (but not conversely) under unilateral divorce, especially when rules governing property division tend to favour husbands. His interpretation is that wives respond violently to their heightened risk of economic hardship. In contrast, Stevenson and Wolfers (2006) find that unilateral divorce substantially reduces domestic violence, particularly against women. They argue that it provides both an immediate escape to abused spouses and increased bargaining power that may pre-empt abuse.

Research consistently finds that rules on division of property have increased wives' labour supply, however. Intuitively, those laws tend to favour people with work experience, and thus they particularly encourage market work among married women because that group has a relatively low labour force participation rate (Parkman 1992; Gray 1998).

Although the literature on marital institutions has heretofore emphasized divorce law, a promising topic for future research is new marital institutions. Since the mid-1990s, several states and many European nations have created new legal institutions for domestic partners. These institutions are often available to both heterosexual and homosexual couples, and in some places gays can now marry formally. Another new institution is 'covenant marriage', which is much like standard marriage but with more limited grounds for divorce. Three US states currently offer a covenant marriage option, and it has been considered in many others.

Because these institutions are new, little has been written about them. One interesting empirical finding is that couples choosing covenant marriage would appear to be at high risk of divorce – many are young, heterogamous, and from high-divorce communities (Felkey forthcoming). A theoretical model by Drewianka (2004) indicates that new institutions typically could either encourage or discourage marital commitment by any particular couple, depending on whether the individuals are more likely to enter that institution with their current partner or a

potential future partner. This suggests that theoretical predictions are inherently ambiguous, so empirical evidence will be essential in this context.

Market Competition and Selection

Lawrence Blume and David Easley

Abstract

There is a long history in economics of using market selection arguments in defence of rationality hypotheses. According to these arguments, rational investors drive irrational investors out of asset markets and profit maximizing firms drive non-maximizing firms out of goods markets. In this article we present the history of these arguments and discuss the literature that examines whether these arguments for market selection, and its impact on efficiency, are correct.

Keywords

Rationality; Market selection; Kelly rule; Incomplete markets

JEL Classifications

C78; L1; G1; C73

Realized positive profits, not *maximum* profits, are the mark of success and viability. It does not matter through what process of reasoning or motivation such success was achieved. The fact of its accomplishment is sufficient. This is the criterion by which the economic system selects survivors:

> those who realize *positive profits* are the survivors; those who suffer losses disappear. (Alchian 1950, p. 213)

Most economic models make use of extreme rationality hypotheses: firms maximize profits with full knowledge of their technology and prices, and investors are subjective expected utility maximizers whose beliefs are correct. Surely some firms and some investors do not always behave as these models hypothesize, but does this matter for predictions of market outcomes? It could be that the aggregation that takes place in supply and demand results in prices and market quantities that agree with the predictions of models using extreme versions of rationality. It could be that, over time, firms and investors learn to behave as these models predict and so market outcomes converge to those predicted by the models. Finally, it could be that markets select for firms and investors who behave 'as if' they are rational. This last defence of the use of rationality is the essence of the quote from Alchian (1950).

There is a long history in economics of using market selection arguments in defence of rationality hypotheses. The early literature focused on selection for profit maximizing firms. Among its best-known proponents is Friedman (1953, p. 22): 'The process of natural selection thus helps to validate the hypothesis (of profit maximization) or, rather, given natural selection, acceptance of the hypothesis can be based largely on the judgment that it summarizes appropriately the conditions for survival.' Of course, even if the selection reasoning is correct, selection can only work over those types of behaviours that are present in the economy. If no firm maximizes profits, then no profit-maximizing firm can be selected. Alchian was acutely aware of this:

> The pertinent requirement – positive profits through relative efficiency – is weaker than 'maximized profits,' with which, unfortunately, it has been confused. Positive profits accrue to those who are better than their actual competitors, even if the participants are ignorant, intelligent, skilful, etc. The crucial element is one's aggregate position relative to actual competitors, not some hypothetically perfect competitors. As in a race, the award goes to the relatively fastest, even if all the competitors loaf. (Alchian 1950, p. 213)

Enke (1951) argued that, at least in competitive industries, the relatively fastest will in fact be profit maximizers, and so in this case selection will lead to the survival only of profit maximizing firms:

> In the long run, however, if firms are in active competition with one another rather than constituting a number of isolated monopolies, natural selection will tend to permit the survival of only those firms that either through good luck or great skill have managed, almost or completely, to optimize their position and earn the normal profits necessary for survival. In these instances the economist can make aggregate predictions *as if* each and every firm knew how to secure maximum long-run profits. (Enke 1951, p. 567)

Similar market selection arguments have been proposed to justify strong rationality hypotheses on the part of investors. Fama argues that:

> dependency in the noise generating process would tend to produce 'bubbles' in the price series . . . If there are many sophisticated traders in the market, however, they may cause these 'bubbles' to burst before they have a chance to really get underway. (Fama 1965, p. 38)

According to Fama, 'A superior analyst is one whose gains over many periods of time are *consistently* greater than those of the market'. This is at least indirectly an argument for market selection and its affect on the efficiency of prices. Cootner was an early, clear proponent of this argument:

> Given the uncertainty of the real world, the many actual and virtual traders will have many, perhaps equally many, forecasts . . . If any group of traders was consistently better than average in forecasting stock prices, they would accumulate wealth and give their forecasts greater and greater weight. In this process, they would bring the present price closer to the true value. (Cootner 1967, p. 80)

In this article we examine the more recent analyses of whether these arguments for market selection, and its impact on efficiency, are correct. We consider in turn, selection over firms and selection over investors.

Selection over Firms

Alchain, Friedman and Enke argue that a profit dynamic will select for firms that, for whatever

reason, maximize profits. Correspondingly, according to this argument, those that do not act as profit maximizers will be driven out of the market. But how is it that non-maximizers are driven out? The implicit idea is that, in the presence of maximizers, the non-maximizers experience losses that deplete their financial capital, which forces them out of the market. The literature has explored two avenues by which losses of financial capital could have this effect. One is that if the firm's operations are financed from retained earnings, then firms that consistently experience losses would eventually exhaust their retained earnings, causing them to vanish. A second argument is that unsuccessful firms will not be able to raise capital in the financial markets, and may not even be able to retain their initial capital. Thus, so this argument goes, the markets will punish unsuccessful firms, which will eventually vanish.

Winter (1964, 1971) and Nelson and Winter (1982) analyse a retained earnings dynamic. They argue that the retained earnings of profit maximizers will grow fastest, and thus these firms will eventually dominate the market. These authors construct a partial equilibrium model in which the 'as if' hypothesis of profit maximization describes the long-run steady state behaviour of firms. In their analysis, prices are fixed and all firms have access to the same technology. This structure leads to the existence of a uniformly most-fit firm, which is selected for by a retained earnings-based investment dynamic.

The early work on market selection was greatly concerned with the meaning of profit maximization when profits are random. Dutta and Radner (1999) directly take up the question of whether markets select for firms that maximize expected profits. Their answer is 'no': the decision rules that maximize the long probability of survival are not those that maximize expected profits. Dutta and Radner's firms are owned by investors who choose how much of the firm's earnings to reinvest in the firms and how much to withdraw as dividends. An expected profit maximizing firm is one that maximizes the expectation of present discounted value of dividends paid to its owners. This policy results in an upper bound on the retained earnings left in the firm, and from this level of retained earnings any firm can experience a string of losses that results in bankruptcy.

There are two parts to the argument for market selection of profit maximizers. First, there is the issue of whether the market selects for profit maximizers. Second, there is the issue of whether in the long run the economy behaves as if only profit mazimizing firms exist. The Dutta and Radner analysis casts doubt about a positive answer to the first question in stochastic settings. Koopmans (1957) cast doubts about a positive answer to the second question even in a deterministic setting. According to his analysis, appealing to an external dynamic process to defend the profit maximization assumption is not a satisfactory way to proceed. Instead, he believed that the dynamic process itself should be modelled. Nelson and Winter (1982, p. 58) were also aware that the co-evolution of firm behaviour and the economic environment resulting from a complete model of the dynamic process could pose problems for the evolutionary defence of profit maximization. They observed that among the 'less obvious snags for evolutionary arguments that aim to provide a prop for orthodoxy' is 'that the relative profitability ranking of decision rules may not be invariant with respect to market conditions'. They do not, however, go on to provide a general equilibrium analysis of the consequences of replacing static profit maximization with a selection dynamic.

Blume and Easley (2002) showed that Koopman's concern about the market selection dynamic in a general equilibrium setting is correct. They show that although only profit maximizers persist in any steady state of the retained earnings dynamic, the long run of the economy need not be well described by assuming that only profit maximizing firms exist. The difficulty arises because of the endogeneity of prices, which causes the relative profitability of firms to depend on the allocation of capital across the firms. As a result, the retained earnings dynamic need not settle down, and efficient firms can be driven out of the market by inefficient firms.

In addition to raising working capital through retained earnings, firms also enter the capital markets. Whether these markets reinforce the market selection hypothesis, as Friedman argues, or

undermine it, depends on how well these markets function. If markets are complete (without the securities created by non-maximizing firms) and investors are expected utility maximizers with rational expectations, then investors would not allocate capital to non-maximizing firms. Such firms would never produce, and the selection hypothesis would be trivially, and instantly, correct. Alternatively, if some investors have incorrect expectations, then they could invest in non-maximizing firms. The fate of these firms depends on the fate of their investors. So, in this case, the question of selection for profit maximizing firms reduces to the question of selection for investors who act as expected utility maximizers with rational expectations.

Selection over Investors

Friedman et al. argue that asset markets will select for rational investors, and that because of this selection, assets will eventually be priced efficiently. Two interesting approaches have been taken to the selection for rational investors question. First, suppose traders use a variety of portfolio rules. Is it the case that traders whose rules are not rational will lose their money to those who do act as if they are rational? Second, suppose that all traders are subjective expected utility maximizers. Is it the case that markets select for those whose expectations are correct, or most nearly correct?

In order to pose these questions precisely rationality has to be defined (see rationality). The selection literature has asked about selection for a very strong form of rationality – expected utility maximization with correct expectations about the payoffs to assets. This is the interesting question because in economies populated by subjective expected utility maximizers whose beliefs are not tied down by a rational expectations hypothesis we have little to say about asset prices. The mere assumption that investors are subjective expected utility maximizers (in the sense of Savage 1951) places no restrictions on the stochastic process of Arrow security prices (Blume and Easley 2005).

Selection over Rules

Consider an intertemporal general equilibrium economy with a collection of Arrow securities and one physical good available at each date. Suppose traders are characterized by their stochastic processes of endowments of the good and by portfolio and savings rules. A savings rule describes the fraction of wealth the trader saves and invests at each date given any partial history of states. Similarly, a portfolio rule describes the fraction of savings the trader allocates to each Arrow security. The savings and portfolio rules that rational traders could choose form one such class of rules; but other, non-rationally motivated rules are also possible.

Three questions arise about the dynamics of wealth selection in this economy. First, is there any kind of selection at all? Second, is it possible to characterize the rules which win? Third, if selection does take place, does every trader using a rational rule survive, and in the presence of such a trader do all non-rational traders vanish?

In repeated betting, with exogenous odds, the betting rule that maximizes the expected growth rate of wealth is known as the Kelly rule (Kelly 1956). The use of this formula in betting with fixed, but favourable odds was further explored by Breiman (1961). In asset markets the 'odds' are not fixed; instead they are determined by equilibrium asset prices, which in turn depend on traders' portfolio and savings rules. Nonetheless, the market selects over rules according to the expected growth rate of wealth share they induce. Blume and Easley (1992) show that if there is a unique trader using a rule that is globally maximal with respect to this criterion, then this trader eventually controls all the wealth in the economy, and prices are set as if he is the only trader in the economy. A trader whose savings rate is maximal and whose portfolio rule is, in each partial history, the conditional probability of states for tomorrow has a maximal expected growth rate of wealth share. This rule is consistent with the trader having logarithmic utility for consumption, rational expectations and a discount factor that is as large as any trader's savings rate. Thus, if this trader exists, he is selected for. However, rationality alone does not guarantee a maximal expected growth rate of

wealth share. There are rational portfolio rules that do not maximize fitness (even controlling for savings rates), and traders who use these rules can be driven out of the market by traders who use rules that are inconsistent with rationality.

Amir et al. (2005) and Evstigneev et al. (2006) take an alternative approach to selection over rules in asset markets. They consider general one-period assets and ask if there are simple portfolio rules that are selected for, or are evolutionarily stable, when the market is populated by other simple (not explicitly price dependent) portfolio rules. In this research, either all winnings are invested, or equivalently, all investors are assumed to invest an equal fraction of their winnings. So selection operates only over portfolio rules. Amir et al. (2005) find that an investor who apportions his wealth across assets according to their conditional expected relative payoffs drives out all other investors as long as none of the other investors end up holding the market. This result is consistent with Blume and Easley (1992) as the log optimal portfolio rule agrees with the conditional expected relative payoff rule when only these two rules exist in the market. Hence, both these rules hold the market in the limit. Evstigneev et al. (2006) use notions of stability from evolutionary game theory to show that the expected relative payoffs rule is evolutionarily stable.

Selection Among Subjective Expected Utility Maximizers

DeLong et al. (1990, 1991) analyse selection over traders who are subjective expected utility maximizers with differing beliefs. In an overlapping generations model they show (1990) that traders with incorrect beliefs can earn higher expected returns, because they take on extra risk. But as survival is not determined by expected returns, this result does not answer the selection question. DeLong et al. (1991) argue that traders whose beliefs reflect irrational overconfidence can eventually dominate an asset market in which prices are set exogenously. This result appears to contradict Alchian's and Friedman's intuitions. But, as prices are exogenous, these traders are not really trading with each other; if they were, then were traders with incorrect beliefs to dominate the market, prices would reflect their beliefs and rational traders might be able to take advantage of them.

In an economy with complete markets and traders who have a common discount factor, Alchian and Friedman's intuition is correct. Sandroni (2000) shows, in a Lucas trees economy with some rational-expectations traders, that if traders have a common discount factor, then all traders who survive have rational expectations. Blume and Easley (2006) show that this result holds in any Pareto optimal allocation in any bounded classical economy and thus for any complete markets equilibrium. To see why the market selection hypothesis is true for these economies suppose that states are iid and that traders have differing, fixed iid beliefs. Then each trader assigns zero probability to almost all the infinite sample paths that any other trader believes to be possible. Each trader would be willing to give up all his endowment on the sample paths he believes to be impossible in order to obtain more consumption on those he believes to be possible. Since markets are complete, these trades are effectively possible. But, if only one trader has correct beliefs, then only one trader puts positive probability on the infinite sample paths that actually occur. So only this trader will have positive consumption, and thus positive wealth, in the limit.

For bounded complete market economies there is a survival index that determines which traders survive and which vanish. This index depends only on discount factors, the actual stochastic process of states, and, traders' beliefs about this stochastic process. Most importantly, for these economies, attitudes towards risk do not matter for survival. The literature also provides various results demonstrating how the market selects among learning rules. The market selects for traders who learn the true process over those who do not learn the truth, for Bayesians with the truth in the support of their prior over comparable non-Bayesians, and among Bayesians according to the dimension of the support of their prior (assuming that the truth is in the support).

In economies with incomplete markets, the market selection hypothesis can fail to be true. Blume and Easley (2006) show that if markets are incomplete, then rational traders may choose either savings rates or portfolio rules that are dominated by those selected by traders with incorrect beliefs. If some traders are irrationally optimistic about the payoff to assets, then the price of those assets may be high enough for rational traders to choose to consume more now, and less in the future. Their low savings rates are optimal, but as a result of their low savings rates the rational traders do not survive.

An alternative version of the market selection hypothesis is that asset markets select for traders with superior information. The research discussed above asks about selection over traders with different, but exogenously given, beliefs. Alternatively, if traders begin with a common prior and receive differential information they will have differing beliefs, but now they will care about each others' beliefs. In this case, the selection question is difficult because the information that traders have will be reflected in prices. If the economy is in a fully revealing rational expectations equilibrium, then there is no advantage to having superior information; see Grossman and Stiglitz (1980). So the question only makes sense in the more natural, but far more complex, case in which information is not fully revealed by market statistics. Figlewski (1978) shows that traders with information which is not correctly reflected in prices have an advantage in terms of expected wealth gain over those whose information is fully impounded in prices. But as expected wealth gain does not determine fitness this result does not fully answer the question. Mailath and Sandroni (2003) consider a Lucas trees economy with log utility traders and noise traders. They show that the quality of information affects survival, but so does the level of noise in the economy. Scuibba (2005) considers a Grossman and Stiglitz (1980) economy in which informed traders pay for information and shows that in this case uninformed traders do not vanish.

Conclusion

The modern literature has shown that the market selection hypothesis needs to be qualified. For some economies it acts much as the earlier writers conjectured; in others it does not select for profit maximizers or rational traders. Much work remains to be done, however. Blume and Easley (2006) and Sandroni (2000) mostly discuss selection in complete markets. Sandroni, though, points out that even when markets are incomplete, traders with log utility and rational expectations are favoured, while Blume and Easley construct some examples to show that the outcome of market selection can depend on market completeness. The connection between market structure and market selection is not well understood. The implications of market selection for asset pricing are known only for complete markets in the long run and some examples. Most economists' intuition about market behaviour and asset pricing comes from the study of market models that allow little or no agent heterogeneity. Taking heterogeneity seriously and chasing down its implications for market performance promises to be a rich area for future research.

Market Failure

John O. Ledyard

Abstract

Market failure occurs when there are too few markets, non-competitive behaviour, or non-existence, leading to inefficient allocations. Many suggested solutions for market failure, such as tax-subsidy schemes, property rights assignments, and special pricing arrangements, are simply devices for the creation of more markets. This remedy can be beneficial but, if the addition of markets creates either non-convexities or thin participation, then adding markets will simply lead to market failure from monopolistic behaviour. Examples are natural monopolies and informational monopolies. To achieve a more efficient allocation of resources in the presence of such fundamental failures one must explore non-market alternatives.

The best way to understand market failure is first to understand market success, the ability of a collection of idealized competitive markets to achieve an equilibrium allocation of resources that is Pareto optimal. This characteristic of markets, which was loosely conjectured by Adam Smith, has received its clearest expression in the theorems of modern welfare economics. For our

purposes, the first of these, named the first fundamental theorem of welfare economics, is of most interest. Simply stated it reads: (1) if there are enough markets, (2) if all consumers and producers behave competitively, and (3) if an equilibrium exists, then the allocation of resources in that equilibrium will be Pareto optimal (see Arrow 1951; Debreu 1959). Market failure is said to occur when the conclusion of this theorem is false; that is, when the allocations achieved with markets are not efficient.

Market failure is often the justification for political intervention in the marketplace (for one view, see Bator 1958, section V). The standard argument is that if market allocations are inefficient, everyone can and should be made better off. To understand the feasibility and desirability of such Pareto-improving interventions, we must achieve a deeper understanding of the sources of market failure. Since each must be due to the failure of at least one of the three conditions of the first theorem, we will consider those conditions one at a time.

The first condition requires there to be enough markets. Although there are no definitive guidelines as to what constitutes 'enough', the general principle is that if any actor in the economy cares about something that also involves an interaction with at least one other actor, then there should be a market for that something; it should have a price (Arrow 1969). This is true whether the something is consumption of bread, consumption of the smoke from a factory, or the amount of national defence. The first of these examples is a standard private good, the second is an externality, and the third is a public good. All need to be priced if we are to achieve a Pareto-optimal allocation of resources; without these markets, actors may be unable to inform others about mutually beneficial trades which can leave both better off.

The informational role of markets is clearly highlighted by a classic example of market failure analysed by Scitovsky (1954). In this example, a steel industry, which must decide now whether to operate, will be profitable if and only if a railway industry begins operations within five years. The railway industry will be profitable if and only if the steel industry is operating when the railway industry begins its own operations. Clearly each cares about the other and it is efficient for each to operate; the steel industry begins today and the railway industry begins later. Nevertheless, if there are only spot markets for steel, the railway industry cannot easily inform the steel industry of its interests through the marketplace. This inability to communicate desirable interactions and to coordinate timing is an example of market failure and has been used as a justification for public involvement in development efforts; a justification for national planning. However, if we correctly recognize that there are simply too few markets, we can easily find another solution by creating a futures market for steel. If the railway industry is able to pay today for delivery of steel at some specified date in the future then both steel and railway industries are able to make the other aware of their interests through the marketplace. It is easy to show that as long as agents behave competitively and equilibrium exists, the addition of futures markets will solve this type of market failure.

A completely different example of the informational role of markets arises when actors in the marketplace are asymmetrically informed about the true state of an uncertain world. The classic example involves securities markets where insiders may know something that outsiders do not. Even if it is important and potentially profitable for the uninformed actor to know the information held by the informed actor, there may not be enough markets to generate an efficient allocation of resources. To see this most clearly, suppose there are only two possible states of the world. Further, suppose there are two consumers, one of whom knows the true state and one of whom thinks each state is equally likely. If the only markets that exist are markets for physical commodities, then the equilibrium allocation will not in general be Pareto optimal. One solution is to create a contingent claims market. An 'insurance' contract can be created in which delivery and acceptance of a specified amount of the commodity is contingent on the true state of the world. Assuming both parties can, *ex post*, mutually verify which is indeed the true state of the world, if both behave competitively and an equilibrium

allocation exists, it will be Pareto optimal, given the information structure. A more general and precise version of this theorem can be found in Radner (1968).

Analysing this example further we note that in equilibrium the prices of commodities in the state that is not true will be close to or equal to zero, since at positive prices the informed actor will always be willing to supply an infinite amount contingent on the false state, knowing delivery will be unnecessary. If the uninformed actor is clever and realizes that prices will behave this way in equilibrium then he can become informed simply by observing which contingency prices are zero. If he then uses this information, which has been freely provided by the market, the equilibrium will be Pareto optimal under full information. In a very simple form, this is the idea behind rational expectations (see Muth 1961). With clever competitive actors, it may not be necessary to create all markets in order to achieve a Pareto-efficient equilibrium allocation.

Completing markets seems to be an easy technique to correct market failure. The suggestions that taxes and subsidies (Pigou 1932) or property rights reassignments (Coase 1960) can cure market failure follow directly from this observation. However, an unintended consequence can sometimes occur after the creation of these markets. In some cases, adding more markets may cause conditions (2) and (3) of the first theorem to be false. Curing one form of market failure can lead to another. To understand how this happens and how the second condition requiring competitive behaviour can be affected, consider the informed consumer in our previous example. If he realizes that the uninformed consumer is going to make inferences based indirectly on his actions then he should not behave competitively because he could do better by pretending to be uninformed. He can, by strategically limiting the supply of information of which he is the monopoly holder, do better than if he behaved competitively. It is only his willingness to supply infinite amounts of the commodity in the false state that gives away his knowledge. Supplying only a little commodity contingent on that (false) state in return for a small payment today would not allow the uninformed agent to infer anything and would allow the informed agent to make a profit from his monopoly position. This is not very different from the standard example of a violation of condition (2), monopoly supply of a commodity.

A different example of this phenomenon of unintended outcomes arises when markets are created to allocate public goods. It is now well known that the introduction of personal, Lindahl prices to price individual demands for a public good does indeed lead to Pareto-optimal allocations if consumers behave competitively (see Foley 1970). However, under this scheme, each agent becomes a monopsonist in one of the created markets and, therefore, has an incentive to understate demand and not to take prices as given. This is the phenomenon of 'free riding', often alluded to as the reason why the creation of markets may not be a viable solution to market failure. To understand why, let us now examine the second condition of the first theorem in more detail.

The second condition of the first theorem about market success is that all actors in the marketplace behave competitively. This means that each must act as if they cannot affect prices and, given prices, as if they follow optimizing behaviour. Consumers maximize preferences subject to budget constraints and producers maximize profits, each taking prices as fixed parameters. This condition will be violated when actors can affect the values that equilibrium prices take and in so doing be better off. The standard example of market failure due to a violation of this condition is monopoly, in which one actor is the sole supplier of an output. By artificially restricting supply, this actor can cause higher prices and make himself or herself better off even though the resulting equilibrium allocation will be inefficient.

Can we correct market failure due to non-competitive behaviour? To find an answer let us first isolate those conditions under which agents find it in their interests to follow competitive behaviour. The work of Roberts and Postlewaite (1976) has established that if each agent holds only a small amount of resources relative to the aggregate available, then they will usually be unable to manipulate prices in any significant way and will act as price takers. It is the depth of

the market that is important. This is also true when the commodity is information. If each agent is informationally small, in the sense that he either knows very little or what he does know is of little importance to others, then he loses little by behaving competitively (see Postlewaite and Schmeidler 1986). On the other hand, if he is informationally important, as in the earlier example, he may have an incentive to behave non-competitively. The key is the size of the agent's resources, both real and informational, relative to the market.

The solution to market failure from non-competitive behaviour then seems to be to ensure that all agents are both resource and informationally small. Of course this must be accomplished through direct intervention as in the antitrust laws and the securities market regulations of the United States and may not be feasible. For example, it may not be possible to correct this type of market failure by simply telling agents to behave competitively. In such an attempt, one would try to enforce a public policy that all firms must charge prices equal to the marginal cost of output. But, unless the costs and production technology of the firm can be directly monitored, a monopolist can easily act as if he were setting price equal to marginal cost while using a false cost curve. It would be impossible for an outside observer to distinguish this non-competitive behaviour from competitive behaviour without directly monitoring the cost curve. If the monopolist were a consumer whose preferences were unobservable, then even monitoring would not help. In general, market failure from non-competitive behaviour is difficult to correct while still retaining markets. We will hint at some alternatives below.

Expansion of the number of markets can also lead to violations of the third condition of the first theorem. For illustration we consider three examples. The first and simplest of these is the case of increasing returns to scale in production. The classic case is a product that requires a fixed set-up cost and a constant marginal cost to produce. (More generally we could consider non-convex production possibilities sets.) If the firm acts competitively in this industry and if the price is above marginal cost the firm will supply an infinite amount. If the price is at or below marginal cost the firm will produce nothing. If the consumers' quantity demand is positive and finite at a price equal to marginal cost, then there is no price such that supply equals demand. Equilibrium does not exist. The real implication of this situation is not that markets do not equilibrate or that trade does not take place, it is that a natural monopoly exists. There is room for at most one efficient firm in this industry. Again it is the assumption of competitive behaviour that is ultimately violated.

The next example, due to Starrett (1972), involves an external diseconomy. Suppose there is an upstream firm that pollutes the water and a downstream firm that requires clean water as an input into its production process. It is easy to show that if such a diseconomy exists and if the downstream firm always has the option of inaction (that is, it can use no inputs to produce no outputs at zero cost), then the aggregate production possibilities set of the economy when expanded to allow enough markets cannot be convex (see Ledyard 1976 for a formal proof). If the production possibilities set of the economy is non-convex, then, as in the last example, it is possible that a competitive equilibrium will not exist. Expansion of the number of markets to solve the inefficiencies due to external diseconomies can lead to a situation in which there is no competitive equilibrium.

The last example, first observed by Green (1977) and Kreps (1977), arises in situations of asymmetric information. Recall the earlier example in which one agent was fully informed about the state of the world while the other thought each state was equally likely. Suppose preferences and endowments in each state are such that if both know the state then the equilibrium prices in each state are the same. Further, suppose that if the uninformed agent makes no inferences about the state from the other's behaviour then there will be different prices in each state. Then no (rational expectations) equilibrium will exist. If the informed agent tries to make inferences the prices will not inform him, and if the uninformed agent does not try to make inferences the prices will inform him. Further, it is fairly easy to show that if a market for information could be created (ignoring incentives to hide information) the

resulting possibilities set is in general non-convex. In either case there is no equilibrium.

Most examples of non-existence of equilibrium seem to lead inevitably to non- competitive behaviour. In our example of non-existence due to informational asymmetries, it is natural for the informed agent to behave as a monopolist with respect to that information. In the example of the diseconomy, if a market is created between the upstream and the downstream firm, each becomes a monopoly. If there is a single polluter and many pollutees, the polluter holds a position similar to a monopsony. The non-existence problem due to the fundamental non-convexity caused by the use of markets to eliminate external diseconomies is simply finessed by one or more of the participants assuming non-competitive behaviour. An outcome occurs but it is not competitive and, therefore, not efficient.

Market failure, the inefficient allocation of resources with markets, can occur if there are too few markets, non-competitive behaviour, or non-existence problems. Many suggested solutions for market failure, such as tax-subsidy schemes, property rights assignments, and special pricing arrangements, are simply devices for the creation of more markets. If this can be done in a way that avoids non-convexities and ensures depth of participation, then the remedy can be beneficial and the new allocation should be efficient. On the other hand, if the addition of markets creates either non-convexities or shallow participation, then attempts to cure market failure from too few markets will simply lead to market failure from monopolistic behaviour. Market failure in this latter situation is fundamental. Examples are natural monopolies, external diseconomies, public goods and informational monopolies. If one wants to achieve efficient allocations of resources in the presence of such fundamental failures one must accept self-interested behaviour and explore non-market alternatives. A literature using this approach, sometimes called implementation theory and sometimes called mechanism design theory, was initiated by Hurwicz (1972) and is surveyed in Groves and Ledyard (1986). More recent results can be found at mechanism design and mechanism design (new developments).

Market Institutions

John McMillan

Abstract

Market-supporting institutions ensure that property rights are respected, that people can be trusted to live up to their promises, that externalities are held in check, that competition is fostered, and that information flows smoothly. Evidence is reviewed here on some market institutions: property rights and contracting with and without the law, and mechanisms to sustain information flow in markets.

In order to work as they should, markets need institutions. Defining the rules of the game, institutions consist of the constraints, formal and informal, on economic and political actors (North 1991). Market institutions serve to limit transaction costs: the time and money spent locating trading partners, comparing their prices, evaluating the quality of the goods for sale, negotiating agreements, monitoring performance and settling disputes (McMillan 2002).

The notion that institutions matter is as old as the study of economics. For markets to create gains from trade, as Adam Smith recognized, the state must define property rights and enforce contracts.

That institutions matter is also one of the chief insights from modern economics. In the presence of informational asymmetries, markets can falter. If buyer and seller have different information about the item to be exchanged, a 'lemons market' may arise. Unable to distinguish high-quality goods, buyers may be unwilling to pay a price that elicits supply of anything other than low-quality items. Potential gains from trade go unrealized (Akerlof 1970). When information is distributed unevenly – as is ubiquitous in the real world of economics, even if most of the textbooks have yet to bring it on board – prices do not incorporate all relevant information, and so non-price information is needed (Spence 1973; Rothschild and Stiglitz 1976). Limiting the inefficiencies from informational asymmetries requires mechanisms for signalling and screening: devices like reputation, warranties and credentials, as well as in some cases government-set rules and regulations. A more nuanced view of market processes is called for than the institution-free textbook account of price equilibration via supply and demand.

Evidence on the role of market-supporting institutions is accumulating. Much of the evidence comes from developing countries and countries in transition from communist central planning. Where markets work smoothly, in affluent countries, the market-supporting institutions are almost invisible. It is hard to find evidence of lemons markets in a country like the United States, because institutional solutions have evolved. By contrast, where markets work badly, in poor countries, the absence of institutions is conspicuous (Klitgaard 1991). A few examples are given in what follows.

Property Rights and Contracting

Institutional innovation sometimes occurs even in affluent countries. An experiment in property rights has arisen in fisheries. Worldwide, fisheries are in crisis. Overfishing results from an externality: the costs of any one fisher's taking too many fish are mostly borne by others. Applying the idea of Ronald Coase (1960) of defining property rights to solve an externality, the New Zealand government has created, essentially, property rights in the fish. Fishers are assigned quotas that define, by species, their allowable fish catch. The quotas are tradable, so they end up with those fishers with the highest willingness to pay, which probably leads to an efficient allocation. Property rights in fish do not come for free, however, but require extensive, costly government monitoring (Grafton et al. 2000). Military aircraft patrol the oceans. Each step of every single fish's journey from landing to final sale is documented, with catch reports, buyers' receipts, cold-storage records and export invoices being collated. Fishery inspectors police breaches. The costs of overseeing the quotas have yielded a return, as fish stocks have been successfully conserved.

Another property-rights experiment has occurred in residential land. In cities in every developing country there are squatters, poor people living on land to which they hold no legal rights. Ad hoc property rights exist even in the absence of formal legal protections, as neighbourhood associations and the squatters themselves guard the land. However, the inability to appeal to the law brings some inefficiencies. Hernando de Soto (2000) argued that, if the impoverished squatters held land titles, they would acquire access to capital markets, because they would then have collateral to offer. In Peru, following de Soto's advocacy, over a million squatter households were granted title to the land they occupied. The effects of this huge inauguration of property rights showed up, unexpectedly, not in the capital market but in the labour market. Householders' borrowing increased little, but hours worked outside the home by adult household members increased and hours worked by their children decreased (Field 2003; Field and Torero 2004). Without land titles, householders stayed at home to watch over their property, sending their children out to work. Holding land titles, they felt secure enough to enter the workforce. Establishing the market institution brought instant welfare gains. However, the gains came in an unforeseen form, illustrating the difficulty in general of anticipating the effects of institutional reform (McMillan 2004).

With contracting, as with property rights, informal substitutes operate in the absence of formal institutions. Small firms make deals with each other and get finance, using personal networks and ongoing relationships to substitute for missing laws of contract and using retained earnings and trade credit to make up for a lack of access to financial markets (Fafchamps 2004; McMillan and Woodruff 2002). Large firms also can prosper without institutions, coping instead by cultivating favours from politicians. Where the lack of institutions shows up is for small firms wishing to grow. Needing to make large, discrete investments, they can no longer rely on retained earnings and trade credit, so they may be unable to grow if the financial market is underdeveloped. Needing to deal with increasing numbers of trading partners, they cannot continue to rely on personal connections but must start to use the law of contract. The firm-size distribution in a typical developing country shows a missing middle, with a lot of employment in tiny firms and quite a lot in large firms, but not much in mid-sized firms (Snodgrass and Biggs 1996). The missing middle is a symptom of weak legal and regulatory institutions.

Information Transmission

An archetypical lemons market existed in India in the 1970s (Klitgaard 1991). Quality fresh milk was hard to find because vendors routinely watered it down. Buyers could not assess the milk's butterfat content, and so the low-quality milk drove out the high-quality milk. Launching a campaign against adulterated milk, the National Dairy Development Board provided inexpensive machines to measure butterfat content as the milk

moved from farmer to wholesaler to vendor. It also set up payment schemes making the price of milk reflect its measured quality and created brand names to give buyers trust in what they were getting. As a result of this coordinated initiative, quality improved and consumption rose.

The loan market is impeded by information asymmetries: both adverse selection (a lender may find it hard to distinguish whether any given loan applicant is a good credit risk) and moral hazard (a borrower, having received a loan, may have an incentive to default). Since these transaction costs are proportionately larger for small than for large loans, small lenders often pay exorbitant interest rates or are frozen out of the loan market. In Bangladesh's Grameen Bank and other microcredit banks, tiny loans are made to poor people via groups of borrowers. Each group member is held responsible for any other member's loan. Being neighbours, the group members know each other's business better than any banker, can monitor each other's use of the loans and can invoke social sanctions to discipline defaulters. Group lending is an elegant solution to the loan market's informational asymmetries.

The equity market relies heavily on institutions. For shareholders, who lack information about the firm's affairs, evaluating managers is difficult, and so a lemons market may arise. In many countries, lax oversights allow controlling shareholders to expropriate minority shareholders (Johnson et al. 2000). If the rules governing the financial markets are inadequate, investors are reluctant to buy stocks because they are unwilling to trust managers, and so firms do not get the finance they need. A well-functioning equity market relies on a complex set of interrelated institutions, formal and informal, to foster information flow (Black 2001). First, reputations for honest dealings must be built up by auditors, law firms, investment banks and the business press. Second, there are self-regulating private-sector bodies such as industry associations as well as the stock exchange, with its rules on listing firms' financial reporting and its sanction of delisting. Third, the equity market rests on state-provided mechanisms: not only laws requiring that investors receive accurate data, but also an activist regulator. The law's transaction costs (Glaeser and Shleifer 2003) mean that a regulator supplements the courts in setting and enforcing the rules of the game.

Conclusion

Market-supporting institutions ensure that property rights are respected, that people can be trusted to live up to their promises, that externalities are held in check, that competition is fostered and that information flows smoothly (McMillan 2002). Without institutions, the promise of efficient markets goes unrealized.

Market Microstructure

Maureen O'Hara

Abstract

Market microstructure research uses the rules and trading protocols of markets to analyse price formation in asset markets. Microstructure research shows how markets provide liquidity and price discovery, and how prices come to reflect information. Of particular importance to this process is how market participants learn from market data. Microstructure researchers often consider issues related to market structure, in particular how changing features of the market affect the price process. Empirical microstructure research uses high-frequency data-sets, and develops statistical approaches to deal with such data.

Market microstructure studies the behaviour and formation of prices in asset markets. Whereas economic analyses of price formation generally abstract from any particular price-setting mechanisms, market microstructure relies on the specific rules and protocols of markets to analyse how prices are determined. This focus on the microstructure of the market provides insights into how the design of markets affects the price process, detailing both how individual prices are determined and how those prices evolve over time. Such insights are useful for a wide range of issues in asset pricing, as well as for guiding econometric investigations of high frequency data. In addition, microstructure research analyses structural issues in securities trading, such as the role and function of exchanges, the optimal design of trading systems, and the optimal regulation of securities markets.

Fundamental to microstructure research is the realization that asset prices are set in actual markets, and not by fictional auctioneers. Thus, while the forces of supply and demand ultimately underlie all asset prices, the specific formation and evolution of prices is much more complex. Buyers and sellers, for example, need not arrive synchronously, making the determination of a market-clearing price at a point in time problematic. When traders do arrive at markets, they may also face a range of market frictions such as transactions costs, search costs and the like (see Stoll 2001). Furthermore, the value of assets may change over time, with some traders potentially knowing more about future values than other traders. Markets facilitate the trading of assets by providing liquidity and price discovery, and how they do so depends on the rules and structure of the market (see O'Hara 2003).

Canonical Models in Microstructure

Early microstructure models focused on the specific market structure found in organized stock markets. In such markets, a designated market-maker or specialist quotes prices to buy or sell units of the asset. By serving as counter-party to buyers and sellers, the market-maker solves the asynchronicity problem noted above by standing ready to provide liquidity on either side of the market. The market-maker earns the 'spread', or the difference between the price at which he buys shares (the bid) and the price at which he will sell shares (the ask). In return, however, the market-maker has to bear inventory risk, essentially going long when traders wish to sell, and short when traders wish to buy.

There is an extensive literature analysing the market-maker's pricing problem in the presence of inventory risk (for a review of models, see O'Hara 1995). In general, such models assume risk-averse market-makers facing exogenous holding costs in a setting in which all agents are symmetrically informed and 'true' asset prices are assumed fixed or, at least, stationary processes. An important feature of the equilibrium is that there is no single price: the price the market-maker sets depends upon whether the trader wishes to buy or sell, and on how much he wishes to trade. Prices change over time in response to the specialist's inventory position, his market power and parameters relating to the supply and demand for the asset. Such inventory models have been extended to a wide variety of market settings such as foreign exchange, bond markets, and options and futures markets. Empirical analyses find substantial support for the predictions of inventory models.

An alternative class of microstructure models considers price-setting when some agents have better information about the asset's true value than do other agents. The impetus for such models was an early paper by Treynor (1971), who noted that traders arriving at the market included those who needed to trade for liquidity reasons, those with better information about the asset's true value, and those who thought they had better information but were in fact incorrect. Treynor conjectured that the market-maker's prices were a balancing act offsetting his losses to the informed traders with his gains from the liquidity and noise traders. Viewed from this perspective, a spread arises naturally in security markets, independent of any inventory or transactions costs explanations. Fisher Black (1986) expanded on this notion to highlight the important role played by noise or liquidity traders in allowing markets to become efficient.

An intriguing implication of this research is that, if some traders do have better information about the asset's true value, then the nature of the order flow can be informative as to future asset values. Consequently, the market-maker's price-setting problem evolves from being a simple balancing of expected gains and losses to that of learning how to extract information from the order flow. With the market-maker drawing inferences from the order flow, this sets the stage for traders to consider the impact of their trades as well, particularly if they are attempting to profit on private information.

There are two general approaches to modelling price-setting in the presence of asymmetric information, sequential trade models and Kyle (1985) models. Glosten and Milgrom (1985) consider a risk-neutral market-maker facing known populations of informed and uninformed traders, where traders arrive sequentially to the market. The market-maker knows these population parameters, but does not know the identity of any individual trader. The market-maker does know, however, that traders informed of good news will all want to buy, while those informed of bad news will all want to sell. Consequently, the market-maker's conditional expectation of the asset's value also differs with trade direction, and it is these conditional expectations that become his bid and ask prices. Based on the trade that actually occurs, the market-maker updates his beliefs regarding the asset's value using Bayes' rule. The continued one-sided trading of the informed traders eventually forces prices to the true equilibrium level.

Sequential trade models provide an elegant means to characterize the relation between trades and prices on a tick-by-tick basis. Because the market-maker learns from trades, the evolution of prices depends on the order flow, as does the size and movement of the spread. More complex

analyses demonstrate a role for other market information in affecting price behaviour. Trade size, for example, may be informative as informed traders prefer to trade larger rather than smaller amounts (Easley and O'Hara, 1987). The time between trades may also have information content as a signal of the existence of new information, and this, in turn, can impart information content to volume (Easley and O'Hara 1992). Trade location, trade in correlated assets, and alternative order types can also have information content. Because of their tick-by-tick focus, sequential models are particularly useful for guiding empirical analysis of microstructure data, an issue we will return to shortly.

An alternative modelling approach is a Kyle (1985) model. Kyle models focus on the dual problems facing the market-maker, who must figure out what the informed traders know, and the informed trader, who wishes to exploit his private information for profit. The Kyle model uses a batch-auction framework in which the market-maker sees the aggregated trades of both the informed traders and the noise or liquidity traders, and based on this order flow he sets a single price. The market-maker conjectures a trading strategy for the informed trader that is linear in the asset's true value, while the informed trader conjectures a pricing strategy for the market-maker that is linear in the total order flow. In equilibrium, both conjectures must be correct, a feature typical of rational expectations equilibrium models. As in sequential trade models, the market-maker's price reflects his conditional expected value for the asset, this conditional expectation changes as he learns from the order flow, and prices eventually adjust to true values. Back and Baruch (2004) demonstrate conditions under which the Kyle and Glosten–Milgrom models essentially converge.

An important feature of Kyle models is their ability to characterize the trading strategy of the informed trader. The optimal strategy for the informed trader is essentially to hide his trades in the noise trade, and he varies his trades over time in response to the market-maker's growing precision of his beliefs about the asset's true value. Holden and Subrahmanyam (1992) show that, if there are many informed traders, then their combined trading actions force prices almost instantaneously to true values, a result again reminiscent of rational expectations models. A wide range of research has considered variants of the Kyle model allowing for different types of information structures, for uninformed traders to also act strategically, and for the market-maker to have differential information.

These two asymmetric information-based modelling approaches allow researchers to address a broad range of issues in the trading of financial assets, and are particularly useful in demonstrating how markets perform their price discovery function. Because market-makers are risk neutral and unconstrained as to their inventory holdings, liquidity issues in these models reflect more difficulties induced by the potential information content of trades, rather than the risk-bearing considerations that arise in inventory models. As both effects are likely to be present in actual markets, a wide range of research has investigated empirically how spreads and price changes are influenced by information, inventory, and the fixed costs of making markets.

Research Directions in Microstructure Research

The growth of financial asset markets worldwide, as well as the increasing availability of high frequency microstructure data from a wide array of markets, has allowed microstructure researchers to investigate a broad range of issues, both empirical and theoretical. I highlight here a few areas that are of particular importance.

Econometrics of High-frequency Data

Microstructure data allows researchers to analyse the evolution of prices and market data on a second-by-second basis. Indeed, most microstructure data sets include millions of observations, raising a range of econometric issues. Of particular importance are the periodicity of the data, biases introduced by market structure protocols, optimal statistical models for evaluating the behaviour of prices and spreads, and data sampling issues. Hasbrouck (2006) discusses each of these topics.

Because prices arise only when there are trades, price data is not spaced uniformly throughout the trading day. This introduces a censored sampling problem as prices can be thought of as draws from the true asset value distribution, but where the timing of the draws may not be independent of evolution of the value process itself. Engle and Russell (1998) exploit this insight to develop the auto-conditional duration (ACD) model to analyse the evolution of intra-day volatility. A related problem is sampling across assets, as non-synchronicity of trading may result in price observations that lag true value innovations across stocks. A number of authors have considered the implications of non-synchronous trading for cross-sectional econometric analyses.

A variety of authors also consider the time-series properties of microstructure data, with a particular focus on decomposing price movements into those associated with the value process and those reflecting noise arising from the microstructure such as tick size constraints, bid/ask bounce, price continuity rules, and so on. These econometric issues are particularly important for asset pricing research.

Asset Pricing – Liquidity and Information Risk

Microstructure models analyse the liquidity and price discovery roles markets play in asset pricing. Recent research has focused on whether these two market roles also affect asset returns. Amihud and Mendelson (1986) first suggested that liquidity could influence asset returns by affecting an investor's overall cost of trading.

Numerous empirical researchers have investigated whether spreads, a proxy for these liquidity costs, are related to asset returns, but the empirical evidence has been mixed. More recent research by Pastor and Stambaugh (2004) using lagged volume measures of liquidity provides stronger evidence, and the authors propose a liquidity factor to explain asset returns. One reason why this effect may arise is commonality in liquidity. Chordia et al. (2000) find that liquidity measures appear to vary systematically across stocks, and these effects may be time-varying. Other researchers have found similar commonality effects in bond market liquidity measures.

A second research stream considers the price discovery process, and whether investors require higher returns to hold stocks for which a greater fraction of the available information is private rather than public. Easley et al. (2002) derive measures of information-based trading using a structural microstructure model, and demonstrate that asset returns are explained by these information measures. What generates this effect is the inability to diversify optimally, as uninformed traders always lose to informed traders, who are better able to shift their portfolio weights to reflect true values. Empirical research supports a distinct role for both liquidity and information risk in affecting asset returns.

Electronic Markets and Trading Systems

Microstructure models have typically analysed price-setting on a centralized market with a designated market-maker (or makers). While such a setting corresponds well to an exchange or dealer market, it is less applicable to the wide variety of electronic markets now used to trade many financial assets. Of particular importance are electronic trading systems which rely on the aggregation of limit orders to effectuate trades. Orders to buy and sell at a specific price and quantity are collected in the 'book', with price and time priority rules dictating how such orders are handled. At any point in time, a spread exists between the highest (lowest) price at which someone is willing to buy (sell) the asset. In such systems, trades arise when orders cross, imparting an importance to the order decisions of individual traders.

Traders face complex decision problems in placing orders due to the uncertainty of execution of any order. Of particular concern is that uninformed traders may face an adverse selection problem in that their trades are more likely to execute when there is new information, causing them to buy when there is bad news and sell when there is good news. This difficulty is further compounded by trading protocols that allow limit orders to 'sweep the book' and thereby trigger the execution of many individual orders as the opposite side of a large order. There is a substantial literature looking at the behaviour of such electronic markets, but the complexity of these markets leaves many important issues yet to be resolved.

Market Structure

Microstructure research is traditionally concerned with issues related to the design and structure of markets. The rise of new markets and trading technologies has raised a plethora of market structure issues. Of particular interest to many researchers are questions relating to transparency, or what information is available to traders and when can they see it. Bond markets, for example, were traditionally opaque, but new reporting rules have increased their transparency. Numerous authors have investigated how this has changed the liquidity and efficiency of the bond market. Option markets traditionally faced little competition, but the development of a national options market in the United States, along with the rise of electronic competitors, has changed this market structure. Regulatory changes in the United States and Europe have also dramatically affected market structure in equities, raising questions as to the efficacy of these new rules. Finally, the markets themselves are evolving from member-owned cooperatives to publicly traded firms, raising a host of issues relating to corporate governance and self-regulation. Microstructure research provides a means to evaluate the economic impact of these changes and to suggest alternative structures for the trading of financial assets.

The concept of market period was introduced by Marshall to define markets according to the time period over which they extended. It was thus an additional classification of markets to that of location or space (*Principles*, V.i.6). This distinction became the modern textbook one between the short period and the long, reducing Marshall's more complex three-period classification. As he put it,

> we shall find that if the period is short, the supply is limited to the stores which happen to be at hand; if the period is long, the supply will be influenced, more or less, by the cost of producing the commodity in question; and if the period is very long, this cost will in its turn be influenced, more or less, by the cost of producing the labour and material things required for producing the commodity.

Hence the short run is that period for which stocks are constant, the long run that period where price is determined by the costs of production (but factors are constant) and the very long run that period where all factors vary.

The Marshallian market period was, as Hicks pointed out (1965, chapter 5) one of the ways in which Marshall used his 'static method'. For in the short period, Hicks goes on to say, Marshall could treat the industry as if it were in static equilibrium. Capital, fixed in the short period, is like land in Ricardo, and it earns a rent. In the longer run, the static method breaks down, as capital becomes variable, like labour.

The concept of Marshallian short period has been used extensively in the theory of the firm, in terms of short- and long-run equilibria, and the defining of cost curves according to this classification. Harrod, in 1934, linked this Marshallian concept with the new theory of imperfect competition developed by Joan Robinson (and Chamberlin), to look at the process of imperfect competition and the impact of entry on short- and long-run profit maximization.

The Marshallian short run concept was taken over into macroeconomics by Keynes as one of three components of Marshall's theory which he used to construct the *General Theory* (the others were partial equilibrium and thus exogenous expectations, and the representative firm aggregate which Keynes took over as the economy). However the Keynesian use of market period was not universally adopted in macroeconomics and it is Hicks's much more restrictive concept used in the IS–LM framework which is now much more familiar. The Hicksian 'week' is a market period in which fundamentally it is stocks that are constant, while the Keynesian 'year' allows for an element of 'user cost' whereby the utilization of capital affects the future demand for capital.

The Hicksian week and the concept of temporary equilibrium associated with it were first set out by Hicks in the middle chapters of *Value and Capital* in 1939, and were subsequently revised in an important, somewhat neglected essay entitled 'Methods of Dynamic Analysis' in 1956, reprinted in *Money, Interest and Wages* (1982). These concepts formed part of an attempt to construct a theory of dynamics, going beyond Marshall's static analysis. The alternative extreme hypothesis of allowing all factors to vary is a longer-run theory, and forms the basis of general equilibrium and growth theory. Both the Hicksian and Keynesian theories attempt to construct an intermediary period, and for each the corresponding problems were to decide which factors are to be allowed to vary, which to stay constant and what process of adjustment to vary, which to be employed by firms. But once these theoretical assumptions have been made, the individual periods become discrete rather than continuous (as in the longer-run case). Thus a theory of dynamics based on the Hicksian week requires an additional theory by which to link the discrete periods together to form a continuous model. We need to know how to get from one period to another. Both Keynes and Hicks resorted in one way or another to a link via expectations, though both provided what now appear to be inadequate explanations of their formation.

The modern new classical theory of macroeconomic equilibrium avoids the short and the long run distinction by appealing both to the perfectibility of markets per se, and to a theory of expectations which is itself based on perfect markets. Thus although the rational expectations approach 'solves' the problem of linking market periods, it does so in a way which avoids rather than solves the problems of market period analysis. Perfect

markets do not have dynamics with limited time horizons and rigidities and thus, in the rational expectations perfect foresight model, there is really no need for market period analysis. It is clear however that market imperfections in real variables and expectations do exist, and hence that short-run temporary equilibria cannot easily be linked together.

Market Power and Collusion in Laboratory Markets

Douglas D. Davis

Abstract

Despite the robust tendency of laboratory markets to generate competitive outcomes, some market designs deviate persistently from competitive predictions. This article discusses the primary drivers of supra-competitive prices that have been observed in market experiments.

JEL Classification

C9; L1

The robustness of competitive market predictions stands as one of the most impressive results in experimental economics. Laboratory markets regularly generate competitive outcomes in environments populated by just two or three sellers. However, as in natural contexts, competitive outcomes do not always emerge. This article reviews results of laboratory markets in which price increases are driven by factors such as the exercise of unilateral market power or by collusion.

Before reviewing the main concepts and contributions in this area, I offer two observations. First, laboratory methods represent an important but limited complement to existing empirical tools for investigating market performance. Given the stark simplicity and limited duration of laboratory markets, experimentalists can aspire to say little about specific naturally occurring markets. Experiments can, however, provide important insights into the behavioural relevance of theories upon which antitrust policies are based.

Second, the trading rules defining negotiations and contracting can exert first-order effects on market competitiveness. For example, markets organized under the double auction trading rules used in many financial exchanges, are much more robustly competitive than markets organized under the posted-offer trading rules used in most retail exchanges: duopoly or even monopoly sellers are less able to increase market prices in double-auction than in posted-offer markets (Davis and Holt 1993, chs 3, 4; Holt 1995). Indeed, one of the motivating factors in the emerging field of institutional design was an interest in developing institutional rules that promoted efficient market outcomes.

For specificity I focus here on results from posted-offer markets, primarily because posted-offer markets allow a particularly intuitive illustration of the factors affecting market competitiveness. However, a host of other trading institutions exist, ranging from single and multi-unit auctions, to multi-sided computerized 'smart' markets, and again to institutions that exist primarily as theoretical constructs, such as quantity-setting Cournot mechanisms. The competitive implications of each of these institutions must be evaluated independently.

Posted-Offer Markets and Unilateral Market Power

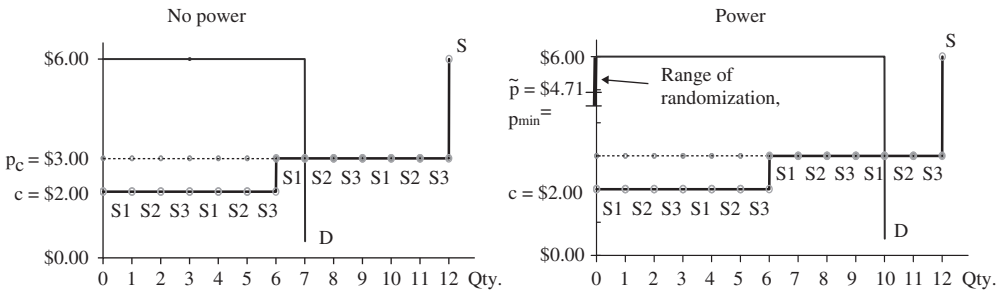
Unilateral market power is perhaps the most frequently observed reason why prices in laboratory markets deviate from competitive predictions. This market power exists when one or more sellers, acting on their own, find it profitable to raise prices above the competitive level. The supply and demand structures shown in the two panels of Fig. 1 illustrate how capacity restrictions can create market power. In each panel, the market consists of three sellers, S1, S2 and S3, each of whom offers four units for sale, under the conditions that two units cost \$2.00 and two units cost \$3.00. A buyer will purchase a fixed number of units (seven in the left panel or ten in the right panel) at prices less than or equal to \$6.00.

Exchange in these markets proceeds in a number of trading periods. At the outset of each period, sellers simultaneously make price decisions. Production is 'to order' in the sense that sellers incur costs only for the units that actually sell. Once all sellers post prices, a simulated fully revealing buyer makes all possible purchases, starting with the least expensive units first. In the case of a tie, the buyer rotates purchases among the tied sellers.

In the market shown in the left panel of Fig. 1 the buyer will purchase at most seven units. Given an aggregate supply of 12 units, sellers in this market have no market power: at any common price above \$3.00, each seller can increase sales from an expected 2.33 units to four units by posting a price just slightly below the common price. For any vector of heterogeneous prices above \$3.00 only the seller posting the lowest price will sell all four units. The seller posting the second highest price will sell three units, while the high-pricing seller will sell nothing. The unique Nash equilibrium for the stage game has each seller posting the competitive price of \$3.00, selling 2.33 units in expectation and earning \$2.00.

Expanding demand to ten units, as shown in the right panel of Fig. 1, limits excess supply, and thus creates market power. Given that the highest price seller is now certain to sell at least two units, the competitive price of \$3.00 is no longer a Nash equilibrium for the stage game. At a common price of \$3.00 each seller sells 3.33 units (in expectation) and earns \$2.00. By posting a price of \$6.00, any seller can sell two units and increase earnings to \$8.00. A common price of \$6.00 is not an equilibrium for the stage game, since any seller would find that deviating from \$6.00 increases sales to four units. Sellers have similar incentives to undercut any common price down to a minimum $p_{min} = \$4.50$, where the profits from selling four units as the lowest pricing seller equals earnings at the limit price. The equilibrium for this game involves mixing over the range from \$4.50 to \$6.00. As shown in the figure, the unique symmetric equilibrium is \$4.71.

An extensive series of experiments show that sellers respond to unilateral market power by raising prices. Further, power drives pricing outcomes more powerfully than do changes in the number of sellers. For example, when they reallocated units among five sellers to create market power, Davis and Holt (1994) observed substantial price



Market Power and Collusion in Laboratory Markets, Fig. 1 Supply and demand arrays for markets without and with unilateral market power

M

increases. However, reducing the number of sellers from five to three in a way that held market power conditions fixed, Davis and Holt observed only modest additional price increases. Market power of the sort illustrated in the right panel of Fig. 1 has wide applications, ranging from distortions in markets for emissions trading (Godby 2000) and for electricity transmission (Rassenti et al. 2003), to price stickiness in the face of aggregate demand shocks (Wilson 1998).

Tacit Collusion

Experimentalists have also observed supra-competitive prices in repeated market games where sellers have no market power. This *tacit collusion* has been observed most frequently in duopolies (for example, Alger 1987; Fouraker and Siegel 1963). However, tacit collusion has also been observed in thicker markets where sellers possess no market power. For example, Cason and Williams (1990) observe persistently high prices in a four-seller design similar to that shown as the left panel of Fig. 1. Experimentalists often measure tacit collusion as the difference between observed prices and prices consistent with the Nash equilibrium for the market analysed as a stage game. Importantly, other than exceeding equilibrium price predictions, tacitly collusive laboratory outcomes typically exhibit no obvious signs of coordinated activity.

Tacit collusion may coexist with market power. For example, prices in the market power sessions reported by Davis and Holt (1994) were significantly above prices consistent with the equilibrium mixing distribution. In this context, the difference between mean observed prices and the mean of the equilibrium mixing distribution may be reasonably taken as a measure of tacit collusion.

Tacit collusion is not yet well understood, and isolating the causes of tacit collusion represents an important project for future experimental work. Price signalling activity at least partially explains tacit collusion (for example, Durham et al. 2004). However, evidence suggests that more than price signals and responses may be at play. Dufwenberg and Gneezy (2000) report an experiment where duopolists deviate from the static Nash (competitive) prediction for a game, even when sellers are rematched into different markets after each decision. In such a context price signalling is not possible.

Explicit Collusion

Given opportunities to explicitly discuss pricing, laboratory sellers quite persistently organize profit-increasing cartels (Isaac et al. 1984). However, a capacity to monitor agreements and prevent secret discounts appears critical to the success of these arrangements (Davis and Holt 1998). Given the illegality of explicit agreements, the more interesting questions regarding explicit collusion concern the capacity of authorities to detect such arrangements through the actions of sellers in the market (Davis and Wilson 2002).

Other Factors Affecting Pricing

A host of experimental studies indicate that standard 'facilitating practices' can contribute to price increases. Experimental studies where supra-competitive prices have been attributed to facilitating practices include 'most favoured nation' and 'meet-or-release' clauses (Grether and Plott 1984), non-binding price signals (Holt and Davis 1990) and multi-market competition (Phillips and Mason 1991).

Buyer behaviour can also affect market outcomes. When buyer decisions are simulated, details of the purchasing rules can have a large effect on prices (Kruse 1993). Powerful human buyers can substantially undermine both market power and tacit collusion (Ruffle 2000). However, the use of real rather than simulated buyers appears to generate more competitive prices even when the human buyers engage in no strategic behaviour (Coursey et al. 1984).

Finally, information conditions and even sellers' expectations can significantly affect pricing outcomes. For example, Huck et al. (2000) report that information regarding underlying supply and demand conditions facilitates the exercise of predicted market power (markets are drawn to static

Nash predictions). However, information on rival sellers' profits made markets more competitive in a market where the high-profit seller has the highest market share, so imitation by others will tend to expand quantity and reduce price. Also, in a Cournot context, Huck et al. (2007) report that seller aspirations for increased profits helped consolidated sellers maintain prices substantially above static Nash levels.

Cantillon, R.; Competition; Market price; Natural price

JEL Classifications

D4

The market price, or market value, is defined as the actual price paid for a commodity during a certain period of time, and may be contrasted with

the natural or normal price, which is determined by the long-term forces and the permanent causes of the value of commodities (see ► Natural Price).

The distinction between market price and the intrinsic value of a good can be traced back to the origins of economic science. Before Adam Smith, Richard Cantillon had already analysed the causes which influence the temporary value of a commodity (Hollander 1973, p. 41).

Many different causes can affect the market price of a commodity and it is difficult to explain the day-to-day changes in its value. However, economic theory has generally singled out the relationship between the demand for a product and its supply on the market as the main force determining the market value. For Smith, the existence of a positive difference between the effectual demand for a commodity and the quantity of it which has been produced and brought to the market leads to a high market price vis-à-vis the natural value, and vice versa. But if there is free competition between producers, market prices cannot be too different from natural prices for a long period of time. Market competition forces lead to the gravitation of market prices around the natural prices. Therefore in classical political economy the two concepts are carefully listed. In particular, the market price is continuously brought towards the natural price.

The concept of market price is an important feature of Adam Smith's description of the competitive mechanism and the way in which it leads to a uniform rate of profit in all sectors of the economy. For instance, when the supply of a commodity falls short of its effectual demand the market price is higher than the natural one, because of the competition between the buyers who are eager to purchase that good (Smith 1776, pp. 73–4). Either one or more of the three component elements of value – wages, profits and rent – is paid at a rate higher than the natural rate. In a freely competitive economy producers compare their rate of profit with profit rates earned in other activities. Thus entrepreneurs invest their capital in the sectors which yield the highest rates or profit. This leads to an increase in the output of the commodities whose market prices are higher than natural ones, and vice versa a decrease when market prices are lower than natural values. Therefore the concept of market price is part of Smith's explanation of the changes in output which occur from one production period to another in each sector.

Given the natural price, and the corresponding level of effectual demand, the increase in output leads to a market situation in which more consumers (willing to pay for the good at its natural price) can be satisfied. There is less competition than before between the consumers, and the market price tends to move towards the natural price. Again, the entrepreneurs compare market prices and profit rates in all sectors of the economy and capital will move if the rate of profit is not uniform. Only when all the demand is matched by an equal supply at a market price level which equals the natural one will competition stop; in this situation the market price is exactly the right amount to pay all the components of price at their natural values. The market price depends on excess demand (or supply) on the market at any moment in time, but cannot be too far away from the natural price for a long period of time, because competition tends to bring it towards this level.

Alfred Marshall's distinction between the market and normal value of commodities is similar to Adam Smith's. Normal value is related to the cost production of commodities, while market prices are mainly influenced by utility and demand (Marshall 1920, pp. 289–90). Marshall also believes that it is difficult to work out a precise theory to determine the market values of commodities; they are affected by too many factors. Marshall argues that there are long and short period forces acting on prices. But he is much more sceptical than Smith about the existence of a precise mechanism, namely competition, which should prevent short-term market prices from moving too far away from the normal price of commodities.

Market Share

William G. Shepherd

The leading element of market structure, the market share of the firm is a simple fact which is central to the study of industrial organization. Because it shows how far the firm's control over the market extends, market share is the direct indicator of each firm's position in the market. Its key role is of ancient tradition, and it reflects a universal recognition in business life that market share is commonly decisive for the firm's degree of success.

Market share's role derives from the fundamental theory of monopoly. A pure monopoly (market share of 100 per cent) controls the entire market, exerting the maximum monopoly power that is possible within the specific conditions of that market. The monopolist's demand is as inelastic as that of the entire market, and so its ability to raise price and influence other market outcomes reflects a full exploitation of that inelasticity.

The inelasticity arises from a lack of near substitutes, from instilled consumer loyalties, and from lags in adjustments. The inelasticity allows the monopolist to use price discrimination so as to maximize profits and to minimize the possibility of new competition from any other firm. The monopolist may engage in a variety of strategic actions, involving the full range of prices and various elements of product quality, marketing, and threats. Also, the monopolist is often able to raise barriers to new competition, by using strategic actions and adjusting the amount and technology of the capital that it installs. These sources of monopoly power are long-established in theory and thoroughly familiar in the mainstreams of actual industrial activity.

All of these factors also operate at lower market shares, though with lower degrees of force. Dominant firms (conventionally, those firms with at least 40 per cent of the market and no close rival) exercise a high degree of monopoly power, though less than pure monopolists. Their use of strategic actions to forestall small rivals or new entrants is often forceful and complex, but the effectiveness shades down directly in line with the dominant firm's market share.

Firms with market shares down in the 20 to 40 per cent range usually have significant market power, but they often face other substantial firms and problems of oligopolistic interdependence. Here market power is usually obtained mainly via collusion with other oligopolists. Below 20 per cent, and particularly below 10 per cent of the market, firms hold little or no monopoly power. This is generally true regardless of the market shares held by other firms.

Market share is therefore the most general, direct single indicator of the firm's ability to exert market power. It is mainly an ordinal indicator: within each market, each firm's market power varies with its market share. Cardinal comparisons of market power among markets do not operate along such a single scale. A 60 per cent share of one market may give much higher monopoly power than the same share in another market. Even so, market dominance usually provides a high degree of market power in every market.

Because market share is so crucial, it is a highly sensitive datum. Firms almost never willingly disclose their shares for fear of giving advantage of some sort to competitors or of inviting unwanted policy actions. Therefore, reliable market shares are scarce. The Census is prohibited from revealing them from the data that it collects. Some market shares emerge from commercial market surveys and from antitrust cases, as well as from occasional painstaking scholarly studies. But market-share data have been far scarcer than concentration ratios, and so those ratios took centre stage in research from the 1930s to the 1970s in the US. Market shares, and the role of individual firm dominance, therefore fell into relative neglect during this period, and oligopoly condtions drew disproportionate attention. Market-share research

has expanded since 1970, but it usually has to rely on rather rough estimates of market shares. Such research clearly has much further to go, in improving data and exploring the causes and effects of market shares.

Even so, the research has already succeeded in affirming market share as the central element in market structure. This has been estimated with regression models including the main structural elements. The most general forms are two. One is

$$\text{Profit Rate} = a + b\text{MS} + c\text{Conc} + d\text{Size} + e\text{AdInt} + f\text{Growth} \quad (1)$$

(where Profit Rate is the rate of return on equity capital or total assets, MS is market share, Conc is 4-firm concentration in the market, Size is a measure of the firm's absolute size, AdInt represents the firm's advertising as a percentage of its sales, and Growth is a filter variable for the firm's growth rate). The other form is

$$\text{Profit Rate} = a + b\text{MS} + c\text{Conc} + d\text{HB} + e\text{MB} + f\text{Growth} \quad (2)$$

(where HB and MB are dummy variables for high and medium entry barriers). In both forms, the *d* and *e* variables represent entry-impeding conditions. These equations are fitted to cross-section data for 100 or more large industrial firms, across a range of industries. The tests also pool up to 10 years' data for various periods since 1960, in order to reflect basic conditions rather than yearly fluctuations.

Various studies report consistent findings. Market share's partial correlation with profit rates is very highly significant, with *t*-ratios commonly above 9.0. The coefficient is usually in the 0.2 to 0.3 range, showing that an added 10 points of market share commonly yield profit rates two to three points higher. The a term represents the competitive rate of return, at the prevailing cost of capital. The analysis therefore shows that a small-share firm might earn a 10 per cent profit rate, while a 60 per cent market-share dominant firm might expect a 20 to 25 per cent profit rate. Such large differences accord with common business experience. The relationship appears to be linear, with market share's yield remaining steady virtually throughout the range of market shares. Tests with Tobin's *Q* ratios in place of profit rates give closely similar results: market share's role is strong.

The other elements (concentration and entry barriers) play much weaker roles, in the tests of general conditions. Market share supplants concentration, on the whole, while entry conditions only affect profit rates by a point or two.

All of these results have been tested for the effects of risk, leverage, and other side factors. Given the amount of error in the profit and structural data, and the variety of company groups, time periods, and the alternative measures that have been tested, the research findings can be regarded as quite strong and consistent.

Two other tests are of interest. Market shares have been related to innovative activity, mainly as shown by patents and by new products. A curved pattern has emerged, with innovative activity peaking at market shares in the vicinity of 20–25 per cent. The influence causing changes in market shares have also been explored. Broadly, high market shares undergo a general process of erosion, usually in the range of one point per year. Dominance therefore dwindles, but rather slowly. High profit rates also encourage a slightly faster decline, as the firm cashes in on its market share rather than retain it by restraining its profitability.

While market share's role has emerged as central, the meaning of that for efficiency has become highly controversial. A high share may reflect a mere seizing of control, by means of mergers, anticompetitive acts, or sheer luck. The resulting monopoly effects may be harmful and without redeeming causes. That is the conventional view. Against it, the neo-Chicago School claim is that dominant firms arise because of economies of scale or some superiority (management, innovations, etc.) which gives them supremacy in the market. The dominance reflects efficient causes, which justify whatever monopoly effects may result.

Both views admit that the origins may include both monopolizing and efficient causes, while various monopoly effects may occur. The clash is over the amounts of these causes and effects. Mainstream experts rate the efficient causes low and the monopoly effects high, while neo-Chicagoans see all causes as efficient and all monopoly effects as trivially small. Chicagoans have provided little empirical basis for their claim, and so the burden of proof is still against them. But the issue is open.

The measurement of market shares begins with the effort to define the relevant market. A market is a group of buyers and sellers exchanging goods which are highly substitutable, perfectly so in the ideal case. The market's edges are set by the zone of choice of the main mass of buyers, as they compare alternative products and suppliers.

Each market exists in two main dimensions: product space and geographical area. One first identifies the products which are highly substitutable and distinct from others, so as to form a distinct market. One also determines the geographic area within which the main mass of customers can choose.

The cross-elasticity of demand is the basic concept for such decisions, in both dimensions. But is is rarely available, and so usually one must turn to other practical signs of substitutability, such as product features, pricing patterns, participants' views, transport costs, and actual shipping patterns. One may also make estimates, by *gedankenexperiment*, of the responsiveness of goods to significant price changes, during reasonable time intervals, as was claimed to be the method used by the US antitrust agencies after 1982. But the definition of markets, which in turn determines the resulting estimated market shares, remains unavoidably a matter of judgement in some degree. No formula or measurement device has yet proven satisfactory in itself.

Actual distributions of market shares in real markets tend to display a strong gradation of market shares, from top to bottom. Usually there is no distinct 'oligopoly group', of a few leading firms with roughly equal shares. Rather, the array of firms usually tapers down from the largest firm to a fringe of small ones. The degree of this asymmetry varies, but in the average case each of the largest handful of firms has about twice the share of the next largest. This has led some analysts to speak of a 'law' of market structure which embodies such a half-share gradation.

There is no official source of individual-firm market share data. Market survey firms do make private estimates for sale, and some of these figures do filter out in stories in the business press. The 'PIMS' data bank contains estimates by many firms about their own products' shares, and the Federal Trade Commission's Line of Business data for 1974–7 include market shares. Yet access to both of these data sets is tightly restricted. This author's estimate's for certain US manufacturing firms in 1961, 1968, 1972 and 1980 are available but approximate.

Despite all the secrecy and measurement problems, the leading cases of high market shares have been known for many decades, especially those in the US economy. From Standard Oil, American Tobacco, and US Steel as of 1910–20, down to ALCOA and United Shoe Machinery in the 1940s, and IBM, Eastman Kodak, General Motors, Procter & Gamble, Gillette, Campbell Soup and many others in the 1960s to the 1980s, the more notable dominant positions have become reliably known through antitrust cases and general trade information.

A relatively few prominent instances have somehow avoided the usual erosion of high market shares, by fair means, or foul, or both. They present a leading problem, both for research and for antitrust consideration. Market shares re-emerged in the 1970s as a leading research frontier in the field of industrial organization. They are likely to continue to be hard to measure, highly sensitive in policy matters, and intensely debated by scholars.

Market Socialism

W. Brus

Market socialism is a theoretical concept (model) of an economic system in which the means of production (capital) are publicly or collectively owned, and the allocation of resources follows the rules of the market (product-, labour-, capital-markets). With regard to existing socialist economies the term is often applied more loosely to cover both systems which tend to approximate it in the strict sense (as the Yugoslav system in the aftermath of the 1965 reform), as well as those which replace commands and physical distribution of producer goods by financial controls and incentives as instruments of central planning ('regulated market', as in the Hungarian 'new economic mechanism' after the 1968 reform).

Introduction

Marx's political economy had for a long time been interpreted to hold that socialism is incompatible with the market. Market relations, even in their simplest form of commodity exchange between two self-employed producers, are presented in *Das Kapital* (Marx 1867) as a nucleus out of which – logically and historically – capitalism emerges. The market forms an indispensable link between economic actors when they are apparently separated from each other (by private ownership), and the social nature of their activity is hidden, revealing itself and being verified only through exchange; the overall outcome is then an ex post resultant of a multitude of spontaneous actions, with the negative consequences becoming the more pronounced the more developed the truly social character (interdependence) of the economic process. Socialism – according to this line of thought – makes the market redundant and overcomes its shortcomings as an allocation mechanism by bringing into the open the social nature of work, assigning it directly ex ante to a particular role in the economic process through the 'visible hand' of planning, which secures full utilization of resources, free of cyclical fluctuations. Above all, socialism removes the absurdity of having, side by side, unsatisfied needs, and excess capital and labour.

After the Russian revolution of 1917, when the shape of socialist economic systems became a practical problem, basic elements of the marketless concept of socialism found their way into programmatic documents of the Communist

parties. Any application of the market mechanism was presented as only a temporary concession, to be justified mainly by the immaturity of the socio-economic conditions that required a longer transition period between capitalism and socialism, especially in underdeveloped countries with dominant peasant agriculture and other types of 'petty commodity production' (Communist International 1929). At the same time, however, the social-democratic wing of Marxism began to recognize the relevance of the market for the operation of a socialist economy (Kautsky 1922).

Theoretical debates on market socialism acquired a new dimension in the interwar period, particularly after republication by F.A. von Hayek (1935) of an article by L. von Mises published originally in 1920, which categorically denied the possibility of rational economic calculation under socialism, because exchange relations between production goods and hence their prices could be established only on the basis of private ownership. Among the many attempts at refutation of this view (Taylor 1929; Dickinson 1933; Landauer 1931; Heimann 1932), probably the best known is that by Oskar Lange (1936–7). Similar ideas had been developed in the same period by Abba Lerner (1934–7), hence the often used designation of 'Lange–Lerner solution'.

Lange not only denied the purely theoretical validity of von Mises' stand (by pointing to Barone's (1908) demonstration of the possibility of dealing with the question through a system of simultaneous equations), but also tried to present a positive solution. This was to consist of a 'trial and error' procedure, in which the Central Planning Board performs the functions of the market where there is no market in the institutional sense of the word (or – it may be added – where market imperfections threaten the parametric function of prices). In this capacity the Board fixes prices, as well as wages and interest rates, so as to balance supply and demand (by appropriate changes in case of disequilibrium), and instructs managers of socialist enterprises (and entire industries) to follow two rules: (1) to minimize average cost of production by using a combination of factors which would equalize marginal productivity of their money unit-worth; (2) to determine the scale of output at a point of equalization of marginal cost and the price set by the Board.

The emphasis in the elaboration of the 'trial and error' procedure was, in the first place, on proving socialism to be capable of allocating resources in a way equivalent to a purely competitive market system. But it acquired much wider significance as an attempt to construct a normative model of market socialism. However, in the latter interpretation – as a normative solution – the model of a socialist market economy becomes more vulnerable to practical tests of validity than would a model of a capitalist market economy. The real behaviour of actors in capitalist markets is by no means determined by the propositions of general equilibrium theory, whereas socialist managers are to be *instructed* to follow the textbook rules, with all the ensuing consequences of iteration processes which may not only operate with considerable time-lags and oscillations, but may not be convergent at all. This explains to some extent the inclusion into the model of a number of features which would distinguish it from a standard 'free market'. In Lange's presentation the main such feature is the determination of the rate of accumulation, not by market processes but directly ('arbitrarily') by the Board, which establishes also the rules of distribution of the social dividend from publicly owned capital and land (with a proviso that this should not affect the choice of occupation).

In addition, the 'trial and error' procedure assumes that actual markets are limited to consumer goods and labour only, while the functions of the market for production goods are performed by the Board itself (market *simulation*). Moreover, in a generalized version, even these assumptions may be dropped. The Board may impose its own scale of preferences on the composition of consumer goods output, even ration goods and assign people to their jobs, but it can still apply the 'trial and error' procedure to derive accounting (shadow) prices of production goods provided that there is no rationing outside the sphere of distribution of consumer goods and labour, i.e. at least a simulated market for production goods must exist. Thus, the market may be understood in Lange's model as a 'computing device of the

pre-electronic age' for solving a system of simultaneous equations, as that author himself emphasized in his last article (Lange 1965), in which the relative merits of the computer and the market are weighed very carefully, with the market in an institutional sense being judged by no means superior on all scores, particularly with regard to long-term dynamic problems.

Market socialism in the above form was to be capable of combining the allocative efficiency of competitive conditions (secured by the Board's rules, which ought to preclude oligopolistic and monopolistic behaviour), with welfare maximizing income distribution (by eliminating inequalities stemming from private ownership of capital and land) and internalization of externalities (by inclusion of all alternatives foregone into comprehensive social cost calculations). An economy operating on the principles of this model was to be open to innovations without generating cyclical fluctuations. The main difficulty considered – the danger of bureaucratization of economic life – was assessed (by Lange) as not greater than that under monopolistic capitalism, and perhaps even more containable under socialism due to democratic control over public functionaries.

This concept of market socialism came under heavy criticism from two opposite sides: from those who disputed the validity of the socialist component in the market system, and those who disputed the market component in the socialist system. The first kind of criticism, mainly following Hayek (1940) has concentrated on the unlikelihood of creating the informational and motivational foundations of market-type managerial behaviour without the background of private ownership which provides the necessary stimuli (expected returns) and constraints (financial responsibility) to innovative decisions involving risk. Schumpeter (1942) denied the relevance of the charge by pointing to the divorce between ownership and management under modern capitalism, but the empirical evidence from communist countries suggests that this is indeed a most serious issue. The second type of criticism, apart from that of general ideological nature, has concentrated on the market-type behaviour postulated in the model and directed toward static efficiency, and the overriding exigency of a dynamic process with full utilization of resources which it is claimed can be satisfied only through direct central planning – otherwise, strong elements of instability would become inherent in the system, along with deviations from the postulated pattern of income distribution (Dobb 1939; Baran 1952). Independently, the rationale of relying on market mechanisms of allocation in the face of large-scale dynamic problems was widely questioned in the Soviet debates in the 1920s (Erlich 1960), as well as in the East European countries and in China after World War II. Lange himself acknowledged the need to re-examine his model from the point of view of long-term economic dynamics, oscillation, and income effects (Lange 1947 and 1965). As for the informational and motivational weaknesses stemming from elimination of private ownership, the problems involved had not attracted much attention in communist countries until the last quarter of the 20th century, when they surfaced quite distinctly in connection with difficulties encountered in the course of various attempts to reform the economic system by increasing the role of actual markets.

The Command System

The history of economic institutions in communist countries could be interpreted as displaying a certain tendency toward broadening the scope of operation of the market; but changes have been slow, and by the mid-1980s most communist countries still adhered to the essentials of the orthodox Soviet system based on commands and physical allocation of producer goods. The command system introduced in the USSR in the early 1930s was transplanted after World War II to all other communist countries (including China and Cuba), which might be taken as evidence that it was regarded as a general model and not as a reflection of Russian conditions peculiar to that time. Prior to that the Soviet Union went through so-called 'war communism' (during the civil war, 1918–20), when circumstances of extreme penury precipitated an attempt to switch to a moneyless economy with resources and products distributed

in natura (it was this system which first prompted von Mises to challenge socialism's capacity for rational economic calculation). Later came the period of 'the new economic policy' (NEP), (1921–28/9), when the market was allowed to function relatively widely, but only as a temporary expedient of transition from capitalism to socialism. The first five-year plan (1928–32) and forced collectivization of agriculture marked the end of this period; the command economic system was installed as corresponding to the stage of socialism (a lower stage of communism).

The principles of the command system as a model do not eliminate the market completely, but they relegate it to the peripheries of the state-owned (or fully state-controlled, as in the case of nominally collective farms and other cooperatives) production sphere. Freedom of choice of consumer goods – outside public consumption – combined with freedom of choice of occupation and jobs means that economic relations between the state and the households have to go through some kind of market with an active role for money. Prices, wages and interest rates on savings and personal loans etc. affect choices made by households as labour suppliers, consumers and savers. Free sales of agricultural produce above the state-quotas, particularly from individual plots cultivated by members of collective farms (as well as by many state employees) constitute another important segment of the market in the command system. In practice, however, all these segments are subject to restrictions, such rationing, forced labour, curbs on labour mobility, constraints on the scale of individual farming etc. During the Stalinist period these restrictions were very severe, at some points overshadowing the elements of the market. However, the general tendency since 1953 has shown a gradual removal of restrictions, which makes the model's assumptions more meaningful.

Within the production sphere of the command system, the market does not function as an allocative mechanism. This role belongs to the Plan, which is meant to decide in a direct way not only major macroeconomic issues of growth, structure of productive capacity and income distribution, but also detailed schedules of current output and input, together with directions of flows between production units and toward the consumption sphere – predominantly in physical terms. Plans in the command system are in fact commands. The supply of production factors and intermediate goods is limited by rationing (allocation orders), and performance is assessed by plan-fulfilment yardsticks. Money is used within the production sphere for aggregation and accounts-control purposes, and the forms of exchange transactions (sales, purchases, prices, credit) between enterprises are used in the same way. However, money remains *passive,* i.e. calculations and transactions in money terms follow the physical flow of resources and intermediate goods decided by the Plan (Brus 1961); this means also that although among the targets and limits of the Plan financial goals (costs, profit, etc.) figure as well, the latter are subordinated to the physical indicators, and the financial position of enterprises is adjusted (through subsidies, dual price systems, differentiated product taxes, etc.) in such a way as to enable them to fulfil the physical tasks – the 'soft budget constraint' (Kornai 1980). Thus, the production sphere is separated from the market elements outside it (relations between the state and the households, and between the households), and consumers' choices are not transmitted to the producers via the market mechanism, but filtered through planners' preferences. Similarly, the domestic economy is separated from foreign markets, both Western and intra-Comecon, by the 'monopoly of foreign trade' which operates through import and export quotas and adjusts the financial position of importers and exporters via a 'price equalization mechanism' (Wiles 1969).

Consequently the command system fails to provide even the minimum conditions for Lange's 'trial and error' procedure: it can accommodate some kind of market in the consumption sphere with possibility of finding equilibrium prices for consumer goods, but it eliminates the market within the production sphere, where goods are rationed and prices are arbitrary. Obviously, the separation between the two spheres can never be complete; the feedback effect is particularly noticeable via wages which have – under normal circumstances and with all reservations due to

imperfection of labour markets anywhere – to reflect supply and demand, while at the same time constituting the major component of cost calculations that enter in one way or another into the considerations of the planners.

The Yugoslav Experiment

Market socialism first appeared as a practical challenge to the command system in the early 1950s in Yugoslavia, after the Stalin–Tito break. The primary motives of this challenge were not economic, although the economic difficulties arising from originally the most complete (for Eastern Europe) and – paradoxically – voluntary transplantation of the command system to a small country without resources on the Soviet scale, played a considerable part. The Yugoslav Communist Party searched mainly for political and ideological self-determination vis-à-vis the hitherto unquestioned authority of Stalin in the communist world. It was found in the concept of self-management, presented as an embodiment of this strain in Marxian ideas which emphasizes socialism as social order which overcomes alienation of labour by placing means of production under control of 'associated direct producers' (Ljubljana Programme 1958).

Contrary to Soviet doctrine, nationalization came to be regarded here as only the first step towards the socialization of the means of production, because even a socialist state is merely an indirect representative of the producers who remain wage labourers until they themselves decide how to use the means of production entrusted to them, and how to allocate the income generated. The process of socialization is thus tantamount to consistent development of self-management in every unit of the economy (and in other spheres of social life); the direct economic involvement of the state has to be curtailed gradually through decentralization of decision-making, not only with regard to current operations of enterprises, but also with regard to capital investment. The functions of the national plan are in principle only indicative, confined basically to provide information and framework for (voluntary) coordination, and to counteract monopolistic and oligopolistic behaviour; direct allocation of resources by state organs is an exception, for cases such as development aid to particularly backward regions or emergency measures in acute social situations. Otherwise the economy is to be regulated by the market, a *socialist* market – its participants being not private (individual or corporate) employers of labour, but associated producers, workers' collectives.

The process of implementation of these ideas was gradual and by no means straightforward. The problems of de-controlling prices and foreign economic relations, both essential for creating competitive conditions, proved to be particularly difficult. Despite numerous retreats in the field of prices, and reimpositions of controls on foreign operations, production in Yugoslavia ceased to be regulated by commands and input rationing, and money assumed an active role with prices tending to clear the market. Isolation from the outside world diminished substantially. In 1965 the country was launched into what was supposed to become the decisive stage of development of self-management and market socialism: the responsibility for 'expanded reproduction' (i.e. for the main bulk of capital investment) was to be shifted from the state budget to the self-managed units, which were to be free to decide about the shares of retained and distributed (as personal incomes) earnings, and about the use of the retained part. The mechanism of financial intermediation in the process of re-allocation of investment funds between sectors and areas was to be provided mainly by the network of commercial banks, with only a marginal role for the state budgets at various levels.

Yugoslavian market socialism aroused considerable interest and gave fresh impetus to theoretical debates, for example, to confrontations of this concept with the 'Lange–Lerner solution' (Bergson 1967). The behaviour of Yugoslav-type labour-managed firms was equated with (or held sufficiently similar to) cooperatives maximizing net income per member. Using assumptions of perfect competition, several authors beginning with Ward (1958) argued that a labour-managed firm pursuing its objective function will tend to

settle for a lower level of output and employment, and higher capital intensity, than would a capitalist firm in analogous conditions, and that it will even display a 'perverse' price-elasticity of supply (diminishing output and employment when the price of the product rises, and vice versa). Most of these peculiarities disappear however when imperfections of the market are taken into account. The labour-managed firm will try then to establish a maximum price (depending on the conditions of entry), and vary its output according to the movement of demand at that price, that is, in a 'normal' way (Lydall 1984).

Nevertheless, empirical evidence suggests that the attempt to combine market mechanism with self-management of the Yugoslavian kind generates problems unknown either to capitalist market economy or to full-fledged cooperatives operating in a market environment. They stem mostly from the fact that the workers' share in the enterprises' results is not based on any form of personal property rights, which they may carry with them, but exclusively on employment; upon termination of employment their stake disappears. This affects attitudes toward the distribution of returns between current personal incomes (for consumption or private savings), and collective investment; in particular, older workers and those without prospects or willingness to stay on the job will have a low propensity to invest out of the enterprise's income. The self-management organization of the economy also presents problems with regard to investment in other existing enterprises (there can be no sharing in profits), or in establishing new firms, especially in other sectors and regions (such firms become, as a rule, independent self-managing units). Absence of capital markets in which firms might participate directly puts even greater pressure on the banking system as a substitute. In the post-1965 period the banks were expected to establish themselves as fully fledged financial intermediaries, but the actual position proved rather disappointing, for reasons related at least to some extent to the specific features of the Yugoslav political system.

The one-party state used its power to impose a variety of formal and informal controls, for example through the so-called self-management compacts. Decentralization of state functions substantially enhanced the power of local organizations (particularly at the level of national republics and autonomous regions) which led to strong autarkic tendencies that not only had a disruptive effect on the unity of the national market, but also made it easier to overrule the commercial principles of operation (e.g. of the banks) by politico-administrative interference. This adversely affected the conditions of competition, especially as perennial balance of payments constraints frustrated the hopes of bringing competitive pressure from outside. At the same time, difficulties in promoting active participation in self-management of the workforces of large organizations gave rise to the so-called 'basic organizations of associated labour' (BOAL) – autonomous decisional and accounting units which may correspond to entire small or medium enterprises but form only self-contained parts of a large one. Excessive fragementation resulted in some cases, especially as links between workers' income and performance on a BOAL scale led to differences in remuneration for the same kind of work. In general, incentives linked to performance, particularly under imperfect markets, engendered problems that had been largely overlooked in Lange's model. This had assumed not only the viability of simulating perfect competition but also the existence of a motivational structure capable of inducing economic actors to observe fully the Board's rules, without any individual material stimulation beyond compensation of disutilities (the implicit interest in increasing the social dividend belongs to a different category of incentives). The scale and direction of change in income differentials – inter-enterprise, inter-sectorial, inter-regional – became a major issue not only in the Yugoslavian case but also in overall analysis of market socialism in comparison with both contemporary capitalist market economies and command systems.

For a considerable time Yugoslavian market socialism proved capable of combining fast growth with significant welfare gains that were unmarred by the shortages and glaring maladjustments so characteristic of command systems. However, the end of the 1970s and the beginning of the 1980s brought substantial

deterioration in this respect (slowdown of growth, high unemployment, accelerated inflation, fall in real earnings), which prompted renewed scrutiny of the effectiveness of the Yugoslavian model. In Yugoslavia itself the principle of selfmanagement was not subjected to open debate, although the question of property rights was raised again (Bajt 1982), and the role of political factors was quite widely recognized. With regard to the plan-market relationship, the predominant view seemed to be that the market had actually not been given a true chance, but accusations that excessive 'marketization' had precluded effective macroeconomic planning were also made (Mihailovic 1982).

The Hungarian Reforms

From the mid-1950s pressure to extend the role of the market began to manifest itself in countries belonging to the Council for Mutual Economic Assistance (CMEA), including the Soviet Union; towards the end of the 1970s a similar tendency appeared strongly in China. The reasons were basically economic – dissatisfaction with the performance of the economy under command systems, although in several cases (Hungary before the 1956 revolution, Poland in 1956–7 and again in 1980–81, Czechoslovakia in 1968) the presumed linkages between marketization of the economy and pluralization of the polity played an important part. Economic reforms – as the blueprints of the attempted changes came to be called – failed in most of the CMEA countries, or were reduced to rather secondary modifications within the framework of the command system. The failure was usually explained in academic literature by political resistance of the ruling elites, vested interests of the administrative state – and party – apparatus, coupled with reluctance on the part of the rank-and-file and managers to trade-off security for stronger incentives linked to efficiency. Difficulties of substance in devising and implementing a sufficiently consistent reform were mentioned less frequently, but they were certainly important and interacted with all other factors. By the mid-1980s among the CMEA countries only Hungary, where the 'new economic mechanism' (NEM) was introduced in 1968, could be regarded as actually outside the confines of command systems – despite the fact that the idea of market-oriented economic reforms kept returning in one form or another in most of the countries of the Soviet bloc, especially in response to crises. In 1981, during the existence of the independent trade union Solidarity, a wide ranging design of self-managed market socialism was worked out in Poland. A much more circumscribed reform, introduced after the suppression of Solidarity, met with a number of difficulties of both economic and political nature. China, having successfully revived the market mechanism in agriculture, embarked in 1984 upon a major programme of economic reform in industry and trade.

Conceptually, the Hungarian 'new economic mechanism' of 1968 is distinct from the Yugoslav market socialism, not only in leaving out self-management, but also in having a different relationship between the plan and the market. The principle of central planning is upheld, while the methods of realization are changed, with the market assigned an active role not only in relations between the state and the households (where the restrictions appearing in the practice of command systems are consistently removed), but also within the state production sector itself. Obligatory output targets for enterprises are abolished, as are physical allocations of production goods from the centre. Thus, enterprises are freed from hierarchical administrative commands and exposed to market-type self-regulatory mechanisms in their current operations, with profit as the main criterion and source both of incentives for the workforce (wage rises dependent on financial viability plus profit-sharing fund for bonuses) and of self-finance for autonomous investment. Prices, both in the consumption and production spheres, are meant to clear the market; but only some prices are allowed to fluctuate freely, and the most 'important' are fixed by state bodies, with other prices moving only within an established range. Isolation of internal from external markets is also lifted, again with substantial indirect controls retained. Thus, the question of incentives apart, the 'new economic mechanism' as a model meets

the Lange–Lerner requirement for the 'trial and error' procedure of establishing prices of production goods. Where it falls short of the Lange–Lerner solution is in the investment sphere: not only the rate of accumulation, but also the allocation of the *main bulk* of investment funds among sectors, areas and large individual projects is determined directly by the Board, whereas equilibrating supply of and demand for capital through appropriate variation of the interest rate takes a secondary place (only with regard to crediting enterprises' autonomous investment, which is considered secondary).

The capacity of the Board to harmonize economic activity on a micro-level with the general provisions of the plan is therefore supposed to rest on: (i) the macroeconomic framework created by the Board's fundamental decisions concerning distribution of national income (including principles of remuneration) and investment allocation; (ii) determination of 'rules of behaviour' for enterprises (success criteria and their incentive consequences) in such a way as to direct local interests onto a path convergent to general interests; (iii) fiscal, monetary and price policies which would effectively support (i) and (ii), in the first place by securing the parametric character of the 'indices of available alternatives' (Lange 1936–7), viz: prices, wages, interest and tax rates. The primacy of the plan so conceived means not only abandonment of direct forms of control, but elimination of central control as such over many aspects of economic activity (recognition of broad 'zones of indifference' as far as planners' preferences are concerned). The interaction between an effective central plan and a market mechanism which requires enterprises to adjust to general rules and conditions makes the model of *central planning with regulated market mechanism* (Brus 1961) an approximately adequate description of the concept of the 'new economic mechanism'.

These economic reforms were introduced in Hungary under mixed political circumstances. On the one hand, the party leadership became firmly committed to them, although the opposition was strong enough to force partial retreat from the principles of the reforms in the period 1973–8. On the other hand, the Soviet bloc offensive against the Czechoslovakian reforms of 1968 was an important adverse factor, among other things because it contributed to the abandonment of economic reforms elsewhere, leaving Hungary an exception within CMEA. The operation of the new economic mechanism was clearly affected by this, as Hungary had to adjust accordingly the management of her relations with other member-countries (particularly with the USSR), and with the CMEA as a whole. All this diminished the capacity of the new mechanism to respond to the deteriorating external conditions caused by the oil shocks of the 1970s and the Western recession. Hungary, poorly endowed in fuel and raw materials and at the same time highly dependent on foreign trade, was the worst hit country in Eastern Europe by the fall in the terms of trade, and the growing difficulties of exporting to the West.

Under the circumstances the performance of the Hungarian economy in the 1970s could be judged as relatively favourable, particularly in maintaining equilibrium on the domestic market. This was due in the first place to the successful development of genuinely cooperative activity combined with private initiative in agriculture, where the provisions of the reforms turned to the greatest advantage. With a rather broad consensus of opinion both among the political leaders and professional economists, the inconsistencies and retreats in implementation of the new economic mechanism began to be corrected at the end of the 1970s.

The most pertinent question however was whether, or to what extent, the failure of the systemic changes to live up to expectations was due to deviations from the 1968 blueprint, or to deficiencies in the blueprint itself. Special significance was attached to the search for reasons why, instead of applying the general rules and rigours of the market to state enterprises, the widespread practice was to tailor financial norms in such a way as to keep every enterprise afloat (cooperative enterprises were treated differently). This phenomenon, which replaced the former bargaining with the higher authorities over output targets and input allocations by new forms of bargaining over financial conditions, was noticed in the early stages of the reforms and attributed to the ideologically

motivated microeconomic job-security commitment (Granick 1975). However, the Hungarian debates at the beginning of the 1980s linked this also with the limitations on the investment activity of enterprises that was imposed by the principle of earmarking the main bulk of investment decisions for the central planner. An enterprise unsuccessful in its given line of business has only a very limited prospect on its own for restructuring or branching out if substantial capital outlays are involved, and this often narrows down the range of options to the stark choice between complete closure and subsidization, the latter course being that almost invariably taken.

Apart from the obvious softening of the 'budget constraint', with all ensuing consequences for the maintenance of pressure for efficiency in enterprises, and for distortions in market relations, this increased the enterprises' dependence on their administrative supervisors. In conjunction with criticism of the poor quality of many investment decisions taken by the centre (particularly when genuine *political* control is missing for lack of pluralism), this line of analysis convinced a substantial body of opinion in Hungary of the necessity to go beyond the product market (and the labour market in its existing form) to the creation of a *capital market.* Suggestions considered in Hungary in the first half of the 1980s envisaged a gradual and cautious movement along these lines, with a substantial part of investment ('infrastructural') still in the hands of the centre, and careful control over institutions of financial intermediation (commercially acting banks in the first place, but also direct issuance of bonds, and even equity shares in prospect). Nevertheless, the debates pointed clearly in the direction away from the mixed model of central planning cum regulated market mechanism, towards full-fledged market socialism, in which allocation of capital is accomplished through market instruments, with the rate of interest equilibrating supply and demand, as in Lange–Lerner. In similar vein, the *labour market* should provide the means to arrive at the equilibrium level of wages through the process of bargaining between management and the workforce; the latter – lacking the countervailing power of independent trade unions – would be able to make use of widely opened job-opportunities outside the state sector ('second economy') as a market instrument of pressure.

Conclusions

Thus, the evolution of both the Yugoslav self-management system and of the Hungarian economic reforms brings back on the agenda most of the problems debated theoretically in connection with the Lange–Lerner model of market socialism. Assuming that institutionalization of the capital market proves feasible in the framework of predominantly public ownership, the old question arises again of whether such a market, even with the help of fiscal and monetary tools of state intervention, is capable of securing continuously a macroeconomic level of demand appropriate for sustained economic growth with full employment, a goal that is regarded as an essential feature of socialism. Moreover, as any realistic concept of market socialism has to include incentives that are in some way linked to performance, capital markets and labour markets of the type referred to above must strongly affect the pattern of income distribution and of wealth as well. However, the assumption of the compatibility of capital markets with public ownership cannot be taken for granted, not only in view of the theoretical reasons advanced in the past, but to a considerable degree in the light of the practical experience of communist countries, where few instances of the relative success of fledgling capital markets can be found exclusively outside the state sector, whereas attempts to use them within that sector (e.g. the Yugoslav 'social sector') largely proved a failure. The effort to re-examine in principle the position of public ownership in close connection with the postulated enhancement of the role of the market (Tardos 1982), and particularly the search for institutional solutions which would effectively cut the umbilical cord linking public enterprises with state administration, may also be regarded as indicators that these are topical issues. On the other hand, by the mid-1980s there were no signs of any of the communist countries moving in the direction of pluralization of the political

system, which was regarded by some as providing a chance by which to reconcile central planning with the market mechanism (Brus 1975).

In the last quarter of the 20th century market socialism remains an active issue not only in the context of economic reform in communist countries, but also in the broader context of reappraisal of the validity of the socialist idea in general, faced with the growing challenge of new realities and new attitudes (Nove 1983).

Market Structure

John Sutton

Abstract

The term 'market structure' relates to the number and size distribution of firms in a market. Markets dominated by a few large firms are said to be 'concentrated'. This article offers a brief review of the modern literature that sets out to explain differences in concentration levels across different industries.

Why is the world market for large commercial jet aircraft dominated by just two firms, while oil tankers are produced by a large number of firms spread over many countries? This is the kind of question addressed in the literature on 'market structure', a field once seen as a rather arcane area, in which explanatory theories were weak and in which discussion tended to focus on rival interpretations of 'statistical regularities' reported in empirical studies. The most famous of these 'regularities' related to a supposed link, across different industries, between the degree to which the industry was dominated by a few large firms ('concentration'), and some average measure of the rate of return (profit) on fixed assets enjoyed by firms in the industry. (Popular summary measures of concentration include the 'k-firm concentration ratio', that is, the share of industry sales revenue accounted for by the top k firms, and the Herfindahl index, defined as the sum of squares of all firms' market shares.) Now the presence of a (positive) relation of this kind would raise the question, 'why do industries with high rates of profit not attract entry, to the point where such differences are eroded?' This question was countered in the older literature, following Bain (1956), by appealing to the supposed existence of 'barriers to entry' in various industries. These barriers fell into three categories. The first related to factors intrinsic to the industry's methods of production ('scale economies'). If the average cost of production falls sharply as output rises to a certain level, then we might regard that level as a 'minimum efficient scale', and postulate that the industry is large enough to accommodate only a small number of firms of this size. This point was, and remains, uncontroversial. The second category related to institutional barriers associated with legal or regulatory impediments, or poor access to financial markets, and so on, but, while barriers of this category may be important in some industries and for some countries, they are probably of secondary relevance to the general run of industries in market economies. The third type of barrier related to the role played by advertising and R&D, and it is here that some serious difficulties arise, a point to which we turn in what follows.

The series of ideas just set out came to be known as the Bain paradigm, or the Structure–-Conduct–Performance paradigm. Expressed briefly, this view held that a more concentrated structure, however sustained, allowed firms to operate less intensive forms of price competition ('conduct'), and this in turn led to high profits ('performance'). This view was seriously undermined in the 1980s as a result of two

developments in the literature. The first of these developments was empirical: it became clear, in the light of new empirical studies, that the claim for a positive relationship between concentration and profitability was not well-founded. (For a review of the evidence, see Schmalensee 1989.) The second development was theoretical: it was clear that any successful explanation of differences in concentration across industries could not rely solely on 'scale economies' and 'institutional barriers'; the role played by advertising and R&D in raising the stakes required of entrants to an industry seemed crucial. But here a problem arises: the levels of advertising and R&D, unlike the degree of scale economies, are matters that are under the control of the firms themselves. The levels of expenditure firms undertake in these areas are ground out as part of the competitive process – and so we cannot treat their levels as a given, and claim that, when we observe a high ratio of advertising and/or R&D to industry sales revenue, this constitutes a 'barrier to entry' that explains the industry's high level of concentration. Rather, an explanation of market structure must explain *both* the level of concentration *and* the levels of advertising and R&D intensity. The 'given' that distinguishes one industry from another must not be the observed (or 'equilibrium') *level* of advertising or R&D, but rather the underlying (industry-specific) relationship between any firm's level of spending on these fixed outlays and the resulting benefit ('perceived product quality', say, or, more generally, any effect leading to an outward shift in the firm's demand schedule or a fall in its unit cost of production).

These problems with the older literature led from the late 1980s onwards to the development of a new literature on market structure. (See, for example, Dasgupta and Stiglitz 1980; Shaked and Sutton 1986; Sutton 1991, 1998. A full technical review of the literature will be found in Sutton 2007.) The point of departure of this literature lies in modelling the evolution of structure by reference to a 'free entry' model, in which any one of a number of potential entrants is free to enter the industry, and to choose its level of outlays on advertising, R&D, and so on, in the light of the choices made by its rivals.

The Modern Game-Theoretic Literature

The models used in the modern literature take the form of 'multi-stage games'. In the simplest example, a firm decides, at stage 1, to enter (and pay some positive, minimal, entry fee whose size is a given, and which can, for example, be interpreted as the cost of building a production plant of 'minimum efficient scale'). At stage 2, each firm, knowing the number of firms that have entered, chooses its level(s) of advertising and/or R&D. Its choices will depend inter alia on the (industry-specific) degree of effectiveness of these expenditures in influencing consumer demand for its product(s). In 'commodity' type industries, where this effectiveness is very low, these outlays will be close to zero. Finally, in stage 3, firms compete in price, taking as given the attributes of their respective products, and they realize corresponding levels of (gross) profits. (It is always assumed that firms have constant marginal costs of production, and that they face downward-sloping demand schedules.)

The central idea that emerges from these ('endogenous sunk costs') models is as follows: as the size of the market increases (in the sense of having a larger number of consumers, so that each firm's demand schedule shifts outwards) the industry may adjust to this in two ways: the number of firms may rise ('entry'), and/or the spending level per firm on advertising, R&D, and so on, may rise – because, in the absence of a proportional rise in the number of firms, each firm now enjoys a higher level of demand, and so the marginal return it gains from being able to charge a given price premium for a higher-quality product rises ('escalation'). Now the degree to which one or other of these effects operates depends inter alia on the effectiveness of advertising and/or R&D. It also depends on the degree to which high-quality products can draw customers away from rival products of a lower quality. Suppose, for example, that products differ not only in quality, but in other attributes also, and that customers differ in their preferences over these latter attributes. Then it will be correspondingly harder for a firm that raises its 'perceived quality' level to attract sales from rivals. An example may be helpful here:

consider, for instance, the market for flowmeters. These devices are used to measure the rate of flow of liquids, and they come in a large number of types. An increase in R&D spending by a producer of 'electromagnetic' flowmeters will have only a limited impact in drawing consumers away from 'ultrasonic' flowmeters, since the latter type of meter has attributes that makes it better suited than the electromagnetic type in certain applications. By way of contrast, consider the case of the (civil) aircraft industry, as it developed since the late 1920s. At that period, there were many types of plane in operation (monoplanes/biplanes, metal/wood construction, land/seaplanes, and so on). Yet all makers faced a market where all buyers (airlines) sought to achieve the same objective: to minimize the carrying cost per passenger mile. As soon as it became clear which type of design best achieved this single aim, plane-makers converged on the solution (an all metal monoplane with a cantilever wing design, following the Douglas DC3). Thereafter, technical developments were focused on pushing forward the performance of this type of plane, and, as plane-makers escalated their efforts in this direction, the stakes required to keep up with rival firms' innovations rose, and there was a 'shake-out' of all but a handful of firms. This story was repeated at the dawn of the jet age in the 1950s. Here a growing world market led, not to the entry of new plane-makers, but to an increasing flow of development outlays by the surviving firms, so that only Boeing and Airbus remain in the wide-body commercial jet business today. (For the details of this story, and the rise of Airbus, see Sutton 1998, ch. 15.)

Where does this leave us? The kind of market profiles that emerge are these: (*a*) those with high R&D outlays and high global concentration (for example, wide-body commercial jets); (*b*) those with high R&D outlays, low concentration and a fragmented set of distinct product categories (for example, flowmeters); and (*c*) those with low R&D spending, where, once the size of the market is large, the level of concentration may become arbitrarily low.

Within advertising-intensive industries, a simpler picture emerges. Here, the fact that a firm can use a single brand to span a range of product types in a market means that we can, with few exceptions, define markets in a way that avoids the complication posed by the presence of sub-markets for distinct product types, of the kind we encountered in the flowmeter example above. Here, the theory leads to a very simple prediction: if we take a cross-section of markets of different sizes (by looking, say, at a single industry across a number of countries of different sizes), then we will find a sharp difference in the market size–concentration relationship as between the 'advertising-intensive' industries and a control group of industries in which advertising plays an insignificant role. In the latter group, very low levels of concentration may be reached as market size increases. In the former group, concentration levels will necessarily remain above some critical level in all countries, no matter how large the size of the country (the 'non-convergence' property). This prediction, and related predictions of the theory, have been widely tested over the past decade and appears to be closely in line with what is found in the data (for a review, see Sutton 2007).

One further comment is called for in relation to this prediction: what is predicted is not an actual or equilibrium level of concentration, but rather a *lower bound* to the level of concentration that can emerge under given circumstances. It is intrinsic to models of this kind that a range of different outcomes is possible, depending on such factors as the form of the entry process (simultaneous, sequential, and so on). The most graphic illustration of this point comes from thinking about the pattern of ownership of plants spread over some geographic region large enough to support many plants. There will be a 'fragmented' equilibrium in which every plant is owned by a different firm, and there will be other equilibria in which the number of plants will remain (roughly) the same, but several of these plants will be owned by the same firm. In other words, a range of outcomes can arise as equilibria, depending on the form of the entry process and the nature of price competition, and the theoretical focus of interest lies in asking, not about the actual outcome, but about the range of possible outcomes, or, more specifically, about the lower bound to the level of concentration that can emerge.

Extensions: Learning Effects and Network Externalities

Two further ('dynamic') mechanisms play a role in explaining high levels of concentration. First, if each firm's unit cost level falls over time as a function of its cumulated volume of output to date, then an early entrant may build a dominant market position by setting an initial low price – possibly below its current unit variable cost of production – with a view to achieving a high output volume, and so a relatively low level of unit cost in the future. In a small number of industries – aircraft, semiconductors and chemical fibres – this effect is quite large.

Second, if the attractiveness of a firm's product to new consumers increases with the number of consumers it has supplied in the past, then again a firm may use an initial low price to build up its early client base and so stimulate future demand (Katz and Shapiro 1985). Examples of such effects abound in the information technology sector: as an item of hardware becomes more widely owned, more firms in the software industry will find it attractive to develop dedicated software for it, thus reinforcing its initial popularity.

What both these examples have in common with the endogenous sunk cost models described earlier becomes clear once we interpret the 'planned losses' incurred in the initial phase as a fixed outlay – analogous to an outlay on R&D or advertising – which yields a payoff in the later phase, either through lower unit costs or increased demand. The novel element which arises in these 'learning' or 'network effects' models is that these effects can be cumulative over time, and so a small initial disparity in the costs or sales of two firms may in principle become amplified over time.

Structure, Conduct and Performance Revisited

What does this imply for the Structure–Conduct–Performance paradigm? If high concentration is merely the natural outcome of the competitive process, should we still see high concentration in an industry as an indication that policy intervention might be warranted?

At a conceptual level, what remains is this: it is still true within the modern 'free entry' models discussed above that structure affects conduct. It is also true that conduct affects performance; but now there is a feedback loop through which high levels of profit may attract new entry, that is, structure is not a given, but is now determined as part of the market process. One consequence that emerges from this is that there is no simple and general link, of the kind central to the old literature, between high concentration and high profitability: it is possible, for example, to have industries with widely different levels of concentration that exhibit no difference in their rates of return on investment. High ('supernormal') profits can, however, arise in these 'free entry' models, through a number of channels. Most notably, they may arise because of asymmetries in the entry process ('first mover advantages'): an early entrant to the market may build up a level of investment in R&D, for example, and so enjoy both a high market share and a high rate of return on its investments, so that the industry-wide levels of concentration and profitability are relatively high. A second channel relates to the important but neglected role of 'integer effects', that is, if there is room in market at equilibrium for only a small number of entrants, then it may be, for example, that two firms can both make supernormal profits, but the entry of a third firm would drive the profit rate below a normal rate of return, so further entry does not occur. Finally, and most importantly, variations in productivity (unit costs) across firms associated with non-imitable advantages can lead to positive (supernormal) profits for (all) intra-marginal firms – a free entry condition implies 'zero profits' only for the marginal entrant (Demsetz 1973).

One key issue remains: what of comparisons between alternative forms of market structure within any one industry? This is the question that lies at the heart of competition policy regarding mergers. As we have seen, the normal workings of the competitive process fix a lower bound to the level of concentration that must come about under free competition. This bound can, in the

case of some industries, be very high in absolute terms, even in a large market; but in other industries it will be very low. Above this bound, varying levels of concentration can emerge since various patterns of market structure can be sustained as equilibria (as in the example of geographically dispersed plants mentioned above). What remains true of the Structure–Conduct–Performance story is that these different market structures may have different welfare properties; a proposed merger that moves us towards a more concentrated structure which will lead to reduced consumer welfare will be subject to the traditional objections. On the other hand, it may be that a merger arises merely as a response to changes in external conditions, and represents a shift away from a form of market structure that constituted an equilibrium outcome under the previous setting, but is no longer sustainable as an equilibrium in this changed environment. Distinguishing between these two possibilities in any specific instance is one of the (many) challenges in dealing with merger cases.

Why Does it Matter?

The traditional rationale for studying market structure was based on its link to profitability and to social welfare. There is, however, another line of argument that has gained considerable force as a result of the empirical success of the modern free entry models in explaining cross-industry differences in concentration. This line of argument rests on the claim that the success of these models provides convincing, though indirect, evidence for the workings of some key competitive mechanisms that appear to operate in a more or less uniform way across a wide range of industries.

To place this in perspective, it is worth noting that the conventional wisdom in economics from the 1950s to the late 1980s was deeply pessimistic in respect of models that lay between the two polar cases of perfect competition or (Chamberlinian) monopolistic competition, on the one hand, and monopoly on the other. This pessimism was typically expressed in the observation, 'with oligopoly, anything can happen'. The new game-theoretic literature of the 1980s formalized oligopoly theory using the Nash equilibrium concept, and offered it as a general framework within which perfect competition and monopoly appeared as special (limiting) cases. While this new literature appeared to some critics to simply reinforce the negative view of oligopoly theory, the successful application of these game-theoretic models to the task of 'explaining market structure' suggests that the early pessimism is unwarranted: it seems that these models capture at least some 'robust' competitive mechanisms that operate in a more or less uniform way across the general run of industries.

Market Structure and Innovation

Morton I. Kamien

The study of the relationship between market structure and innovation by economists is a relatively recent phenomenon that can be traced back to the mid-1950s. Prior to that time the bulk of economic analysis took the number of products and their means of production as determined exogenously, just as consumers' tastes were taken as an exogenous given. With a few exceptions, economists appeared to be unconcerned with the economic incentives that determined the pace and direction of innovation despite the fact that this activity had begun to be institutionalized about 1876, when industrial research laboratories began to be established both in the United States and in Europe. The exceptions include Taussig (1915), Hicks (1932), Galbraith (1952), and most importantly Schumpeter (1961, 1964, 1975). It was Schumpeter who argued most persuasively that it was competition through introduction of new products and methods of production that was far more important than price competition, in the long run. For it was through innovative activity that economic development that resulted in higher per capita income took place.

The importance of technical advance as a source of growth in per capital income was dramatized by Solow's (1957) claim that ninety per cent of the doubling of per capita output in the US non-farm sector in the period 1909–49 was the result of technical advance and only the remaining ten per cent was the result of an increase in the amount of capital used by each worker. Despite subsequent refinements of this estimate to take into account increases in the quality of labour and capital, technical advance remained a major source of growth in per capita output.

Recognition that technical advance was a major source of economic growth caused attention to be turned to the study of the conditions in a market economy that facilitated it and those that retarded it. These conditions had largely been outlined by Schumpeter. He contended that possession of some degree of monopoly power by a firm was necessary in order for it to engage in innovative activity. There are two reasons for this contention. The first is that the monopoly profits associated with monopoly power provided an internal source of funding of research and development. Now internal funding of research and development, as opposed to financing through borrowing, is commonplace and essential. This is because a research and development project provides little in the form of tangible collateral for lenders to recoup should it fail. Moreover, since lenders are typically not in a good position to monitor carefully the progress of a research and development effort, or would find it prohibitively costly to do so, they are confronted with a moral hazard problem in the form of potential shirking by the managers of the project. A substantial investment in the project by its managers helps alleviate this concern of its external financiers. Finally, external financing of a research and development project may require disclosure of a level of information that is incompatible with maintaining its secrecy from potential imitators.

The second reason that some monopoly power is important for innovative activity is that its possession enables an innovator to reap profits from his investment and thereby provides him the incentive for undertaking it in the first place. The monopoly power here is in the form of the ability to prevent quick imitation and erosion of the profits from the innovation. This form of monopoly power is often embodied in a patent, a copyright, or a trademark but may also be embodied in a less formal manner such as possession of channels of distribution. To Schumpeter's contention that a degree of monopoly power was necessary for innovative activity Galbraith added the claim that large firm size was also essential. It was his claim that only large firms had adequate resources to finance internally current research and development projects, as all the cheap innovations, that could be undertaken by individuals, had already been done. Moreover, large firms could diminish the overall risk of research and development

activity by engaging in a large number of different, uncorrelated projects.

The hypotheses that have emerged from Schumpeter and others can be summarized as follows:

(1) Innovation is greater in monopolistic industries than in competitive ones because
   (a) a firm with monopoly power can prevent limitation and thereby can capture more profit from an innovation;
   (b) a firm with monopoly profits is better able to finance research and development.
(2) Large firms are more innovative than small firms because
   (a) a large firm can finance a large research and development staff. There are economies of scale in this activity also;
   (b) a large diversified firm is better able to exploit unforeseen innovations;
   (c) indivisibility in cost-reducing innovations makes them more profitable for large firms.
(3) Innovation is spurred by technological opportunity.
(4) Innovation is spurred by market opportunity.

Almost all the facets of these hypotheses have been subjected to some degree of empirical investigation. The leading figures in this effort include Griliches (1957, 1984), Mansfield (1968a, b, 1971, 1977) and Scherer (1980), as well as many others. Extensive surveys of this work can be found in Kamien and Schwartz (1982) and Stoneman (1983). Roughly speaking these investigations reveal that innovative activity is most intense in industries with a market structure intermediate between a perfectly competitive market and a perfectly monopolistic one. Too much competition appears to discourage innovative activity as innovators are unable to capture enough of the rewards from it. On the other hand, too much monopoly power appears to lead to complacency and less innovative activity. Large firms do spend more on research and development and obtain more patents than small firms in absolute terms but not proportionately more as measured by their market share, total sales, or value of assets except in the chemicals industry, especially pharmaceuticals manufacturers. There appears to be a threshold level of firm size below which firms do not engage in formal research and development efforts and above which they do. Research and development activity appears to grow proportionately with firm size up to a point and then grow less than proportionately as firm size increases beyond this point. Research and development activity appears to be more efficient in medium size firms than in large firms, as measured by the cost of developing a patent. Technological opportunity does spur innovative activity in an industry but so does market opportunity, in the form of demand for new products and methods of production. Research and development projects that are undertaken in response to market demand appear to succeed more than those that are undertaken as a result of technological opportunity.

These empirical findings have spawned a new generation of theoretical models that can be traced to Scherer (1967), Brazel (1968), Kamien and Schwartz (1972, 1976), Loury (1979), Dasgupta and Stiglitz (1980a, b), and Reinganum (1981, 1982). A survey of these models can be found in Kamien and Schwartz (1982) and a more recent overview in Reinganum (1984). These models have come to be referred to as patent race models and they constitute an area of intense research activity within the field of industrial organization. The continued interest in the economies of technical advance stems, of course, from the fact that technical advance is perhaps the most important determinant of our past, our present, and our future.

Market Value and Market Price

Anwar Shaikh

Marx defines the labour value of a commodity as the total (direct and indirect) abstract labour time required for its production. It is his contention that under capitalism the movements of commodity prices are dominated by changes in labour value magnitudes. This thesis, which he calls the law of value, requires him to connect labour values to the different *regulating prices* which act as centres of gravity of market prices under various assumed conditions of production and sale. He therefore undertakes to systematically develop the category of regulating price by introducing successively more complex factors into the analysis, linking it at each step to its foundation in labour value. It is only near the end of this developmental chain, when he begins to analyse the manner in which differences among conditions of production within an industry influence the process of regulating market prices, that we encounter the concept of *market value* (Marx 1894, ch. X). To grasp its significance, we must first consider the steps which precede it.

The simplest expression of the law of value is when exchange is directly regulated by labour values. If we define direct price as a money price proportional to a commodity's labour value, then the simple case corresponds to the situation in which the direct price of a commodity is the regulating price (i.e. centre of gravity) of its market price. Marx begins with this premise in Volume I of *Capital*, concretizes it in Volume II to account for turnover time and circulation costs, transforms it in Volume III into the notion of prices of production (prices reflecting roughly equal rates of profit) as regulating prices, and then goes on to develop even this concept further, to account for rental payments, trading margins and interest flows. It is important to note that throughout this whole process of developing the various forms of regulating price, the aim is not only to encompass the complexity of the

determinants of market prices, but also to show their connection to labour values.

The above path focuses on the complex character of the centres of gravity of various types of market prices. But the very concept of a gravitational centre itself requires some discussion of the forces of supply and demand, because it is through their variation that the market price of a commodity is made to orbit around its (generally moving) centre of gravity. Accordingly, Marx also engages in a second, parallel, discussion of the manner in which a regulating price exerts its influence over market price. And here, the basic idea is that when (for instance) the growth of demand exceeds that of supply, market price will rise above regulating price, and the resulting rise in profitability above its regulating level (as embodied in the assumed regulating price) will induce capitalists to accelerate supply relative to demand. The original gap between supply and demand will thereby be reduced or even reversed, thus driving the market price back towards or even below the regulating price. In this way, the dynamic adjustment of supply to demand serves to keep market price oscillating around the regulating price. Note that the whole argument is cast in terms of the relative *growth rates* of supply and demand rather than merely in terms of their (implicitly static) levels, and that market prices continually oscillate around regulating prices without ever having to converge to them in any mythical 'long run equilibrium' (Shaikh 1982).

The preceding analysis implicitly ignores any variations in unit production costs and unit labour values, so that the regulating price itself is assumed to be unchanged during the regulation process. This is adequate as long as we abstract from differences among conditions of production within a given industry, because then each individual producer in effect embodies the average conditions and the whole story can be told simply in terms of the average producer. Under these circumstances, it is the *social* (i.e. average) unit labour value which ultimately regulates the movements of market prices, through the mediation of a particular regulating price. As Marx puts it, it is the social value of the commodity which functions here as the labour value which is regulative of market price, i.e. as the *market value*.

The obvious next step is to introduce the issue of differences among producers within an industry. Accordingly, Marx examines the situation in which there are three types of production conditions in use, ranked in order from lowest efficiency (1), to medium (2), to best (3). The ranking of individual unit labour values (and unit production costs, other things being equal) will of course be in reverse order. As before, the social unit value is the total labour value of the total product divided by the amount of this total product. But this average now represents not only 'the average [unit] value of commodities produced' in this industry, but also the unit 'individual value of the ... average conditions' in the industry. Note that although the unit social value will be 'midway between the two extremes', it can nonetheless differ from the medium (2) unit value precisely because the average of existing conditions can differ from the medium (2) condition according to the weights of low (1) and high (3) conditions in total output.

The important thing at this juncture is to identify the specific conditions of production which operate to regulate market price through the ebb and flow of supply, *because it is the labour value of these particular conditions which will therefore function as the market value*. This leads him to identify three types of response to a deviation of market price from some pre-existing regulating price. The first case is when all three conditions of production are able to adjust their respective rates of supply, so that the average production condition continues to regulate the market. Here, the regulating price still rests upon the average unit production cost, and the unit social value is still the market value. The only new consideration is that the regulating price and market value may vary within certain strict limits, because the functioning average condition of production may itself change insofar as the weights of its three constituent types of production conditions alter over the adjustment process. To the extent that better conditions accelerate more in the up phase and worse conditions decelerate more on the down side, even this effect will more or less cancel out

over a given oscillation of market price around regulating price.

At the other extreme, Marx considers situations where the deviation of market price from regulating price goes so far as to bring either the worst or best production to the fore as the foundation of new regulating prices and market values. It is plausible, for instance, that the utilization of capacity is usually inversely correlated with the efficiency of production. Then, if demand rises sufficiently, the bulk of the slack will be taken up at first by the best, then by the intermediate, and finally by the worst conditions of production. A situation may therefore arise in which the unit production costs of the worst conditions of production will come to determine the regulating price, so that the individual unit labour value of these conditions becomes the market value. Conversely, a sufficiently rapid fall in demand relative to supply may precipitate just the opposite situation, in which only the best conditions survive to regulate the market price and thus determine the regulating price and market value. It should be noted, incidentally, that while the shift of regulating conditions to one extreme or the other is precipitated here by 'extraordinary combinations' of supply and demand, this need not be the case when we consider technical change (in which the regulating conditions will be the best *generally accessible* methods of production) or production in agriculture and mining (in which the regulating conditions are often the ones on the margin of cultivation and location, hence among the worst of the lands and locations in use). From this point of view, Marx's initial discussion of Market Value is merely prelude to the much broader question of regulating value and conditions of production.

Marketing Boards

Christopher B. Barrett and Emelly Mutambatsere

Abstract

Marketing boards (state-controlled or state-sanctioned entities legally granted control over the purchase or sale of agricultural commodities) flourished in the 20th century. Since the mid-1980s they have declined in number under pressure from domestic liberalization and from international trade rules that increasingly cover agriculture. Where reforms have been widespread and successful, marketing boards have vanished or retreated to providing public goods, such as strategic grain reserves or insurance against extraordinary price fluctuations. Elsewhere, the weaknesses of private agricultural marketing channels have been revealed by the rollback of marketing boards, often leading to calls for reinstatement of powerful marketing boards.

Q1

Marketing boards are state-controlled or state-sanctioned entities legally granted control over the purchase or sale of agricultural commodities. They can be divided into two broad categories. Monopolistic marketing boards that create a single-commodity seller are found mainly in developed countries. Monopsonistic marketing boards concentrating buyer-side market power in one institution were commonplace for many years in developing countries. Monopolistic marketing boards were typically established with the main objective of maintaining or raising and stabilizing farm prices and incomes in an administratively practical and politically acceptable manner. By contrast, monopsonistic marketing boards were typically established to give the state control over commodity prices – normally for the benefit of foreign and urban buyers – and capacity to tax agriculture so as to subsidize industrialization.

Marketing Boards in Developed Countries

Marketing boards are state-sponsored trading enterprises legally invested with monopoly powers to organize the marketing of agricultural commodities. These statutory entities typically operate under direct or indirect producer control. Among the earliest boards were the New Zealand Meat Producers Board and the New Zealand Dairy Board, each established in 1922, the Australia Queensland Sugar Board of 1923, and the Australia Wheat Board, formed in 1939. In Australia, marketing boards used import protection and home consumption price schemes to stabilize producer prices. They initially received financial support from the state, although such support later declined as the focus of the boards changed. A number of state and commonwealth-level marketing boards were later established, with varying degrees of authority and responsibilities in the marketing of agricultural products such as wool, dairy, meat, wine and brandy, honey and horticultural products. The marketing boards in New Zealand evolved in a similar manner, with regulatory authority in export marketing and licensing but no direct financial support from the state. These boards, involved in the marketing of dairy, apple and pear, kiwi fruit, horticulture, meat and wool products, all used activities such as single-desk selling, price pooling, revenue pooling and preferential financing to seek higher producer prices.

The earliest major marketing schemes in Britain were the milk, potatoes and bacon marketing boards formed under the British Marketing Acts of 1931 and 1933. These acts enabled producers to set up marketing schemes that had the legislative power to ensure conformity by all producers. The core purpose of the marketing boards was to maintain or raise producer prices of basic agricultural commodities through acreage restrictions, direct or indirect limits on saleable quantities, and price discrimination, with higher prices in sheltered markets and lower prices in exposed ones. In addition, monopolies of processed products were legalized, leading to the organization of processor and distributor schemes. The marketing boards thus held the monopoly power to control supply, the terms of sale and the channels and conditions of sale (Bauer 1948). By 1948 marketing boards had spread to include all major agricultural commodities. In Canada, marketing boards were also formed in response to the price fluctuations of the Great Depression. The Dominion Marketing Board, a federal agency established under the National Farm Products Act of 1934, exercised extensive market power over the sale of regulated products, transferable to provincial-level producer-organized boards. The Agricultural Marketing Acts of 1940 and 1956 delineated the powers of regulation and market control activities for the established and new federal and provincial marketing boards. The result was marketing boards with diverse market powers and scope of operations across provinces, and across boards within the same province. Some marketing boards act only in a supervisory capacity, whereas others wield more extensive powers in market regulation and control. Activities generally range from negotiating minimum prices, regulating quantity and quality of marketed products, collecting and distributing payments, as well as grading and quality control.

Several common features distinguish marketing boards in developed countries from those

found in developing nations. First, marketing boards in developed countries tend to be specialized in both scale and scope of operations. For example, New Zealand currently runs strictly export monopolies, such as the Dairy Board, that have control over the country's agricultural exports but negligible influence over domestic production, sales, imports or tariff rates.

Second, marketing boards in developed countries tend to subsidize farmers at the expense of consumers, as evidenced by their mandate to maintain high producer prices for farmers through limited supply. One result is that marketing boards in developed countries have tended to generate windfall profits for the owners of farm land and other sector-specific assets in agriculture.

Third, and following directly from their role in subsidizing farmers, state trading enterprises tend to encourage and support cartels at producer, processor and distributor levels. Developed country agricultural marketing boards have been a major issue in international trade because historically they dominated certain markets. For example, McCalla and Schmitz (1982) estimated that 95 per cent of world wheat trade in 1973–7 involved a state marketing board on at least one side of the transaction. Because marketing boards enjoy greater flexibility than private traders in pricing – for example, they can commonly delay payments to producers, pool payments so as to reduce producer price risk, and can practise discriminatory pricing among export or import markets – their operations are closely scrutinized by the World Trade Organization for prospectively anti-competitive practices.

Marketing Boards in Developing Countries

Marketing boards in developing countries were typically begun during colonial times for purposes distinct from those of their counterpart marketing boards in developed economies. And they have followed a somewhat different trajectory from those of marketing boards in developed countries.

European colonial powers formed marketing boards in large measure to facilitate the export of agricultural commodities to Europe and to stabilize prices faced by colonial elites (for food crops) and metropolitan buyers (for export crops). Post-independence governments generally maintained marketing boards because these were considered simpler to manage and more efficient in conducting organized trade than the traditional, decentralized private sector. More compellingly, marketing boards provided a convenient way for the governments to maintain control over the marketing of strategic commodities, such as the food staples and important export crops (Lele and Christiansen 1989). The marketing boards system was most prevalent in the anglophone African and South Asian countries, but widespread as well in francophone and lusophone African countries and in Asia and Latin America.

Marketing boards were both state-owned and state-funded, based on centralized decision making systems. They possessed the sole legal authority to purchase commodities from farmers and to engage in trade. Through the boards, governments typically fixed official producer prices for all controlled commodities, often in a pan-seasonal and pan-territorial manner whereby a single price was set for the whole marketing season and for all regions of the country. Marketing boards provided a guaranteed market for the farmers, absorbing all marketed surplus at the official producer prices, and maintaining extensive buying networks and storage facilities throughout the production regions. Pan-seasonal and pan-territorial pricing practices eliminated any opportunities for arbitrage, discouraging private investment in commodity storage or transport capacity, and reinforcing the government's control over the marketing channel. Unlike marketing boards in developed countries, producer sales into the network were rarely rationed, because the marketing boards'objective was normally to increase supply and lower prices for consumers, as opposed to controlling supply for the benefit of producers.

Two features of the export crop marketing boards – as distinct from those handling staple food commodities – are worth noting. First, the marketing boards held the sole legal rights in commodity export, and had a mandate to generate income for the state. Therefore, storage costs were

maintained at low levels through selling policies such as rapid evacuation and forward selling. In addition, local producer prices were typically set at levels lower than the international free-on-board prices, through price fixing or overvalued exchange rates. Essentially, export crop marketing boards were used as a means to tax agriculture in order to develop the industrial sector in these agrarian economies. The taxes were often quite severe. In Tanzania, for example, local producer prices for coffee and tobacco fell to 23 per cent and 15 per cent of international prices, respectively, by the mid-1980s.

Second, because export crop marketing boards served foreign demand, no price controls existed on the selling end. Marketing boards could trade on an open market for the highest possible selling prices. However, because most of the former European colonies enjoyed preferential access to European markets under the Lomé Convention, most commodities were sold to Europe. In addition, some export crops enjoyed commodity price stabilization through international commodity agreements such as the International Coffee Agreement or the International Rubber Agreement. In those cases where a country enjoys world market power, a state marketing board can, at least in theory, increase prices and thereby extract consumer surplus from foreign buyers to benefit the exporting country, including its producers. This is one of the concerns surrounding state trading enterprises within global trade policy fora.

Even though the export crop marketing boards were generally established first, in most developing countries staple food commodity marketing boards became at least as significant a part of the parastatal system. For food commodities, government control extended to every stage of the market chain, to include farm gate, wholesale and retail price controls. In-country commodity movement was restricted, especially the movement of strategic food commodities, and private trade was either illegal or legal only by licence. To achieve food security objectives, food subsidies were generally offered, mostly implicitly, in the form of fixed consumer prices set at levels lower than the market price. Although farm prices were generally set at a below-market level as well, the government often offered implicit subsidies to farmers, through price stabilization operations, and input and credit subsidies administered through the marketing boards (Lele and Christiansen 1989). Moreover, pan-territorial pricing typically implied subsidies for farmers in more remote smallholder regions. In some countries and for some crops, these arrangements likely stimulated greater crop production than would have occurred under open market arrangements.

Grain marketing boards commonly also handled the strategic food reserves for emergency situations, and had the responsibility to import food in shortage seasons. These parastatals therefore held most of their nations' inter-seasonal and inter-annual grain storage capacity, a legacy that would affect inter-seasonal commodity price movements after the liberalization of commodity marketing systems in the 1980s and 1990s. Although processing was not their core business, marketing boards, in some cases, were also involved in preliminary processing, such as milling rice or maize, or in licensing and monitoring the processing industry activities. This underscores an important difference from developed country marketing boards: the breadth of commodity marketing boards' mandate in most developing countries.

Over time, the fiscal sustainability of marketing boards in developing countries became questionable. The broad range of marketing operations handled by marketing boards and the politically charged manner in which these operations were typically handled led to massive inefficiencies and deficits that cash-strapped central governments had an increasingly difficult time covering. The subsidies embedded in grains pricing systems, coupled with heavy overhead costs associated with high administrative, transportation and storage costs, soon created huge tax burdens. In an attempt to ensure food security, the state would generally increase producer prices with less than proportional increases in consumer prices, taking on responsibility for a significant share of the marketing costs associated with moving food from farm to table. The pan-territorial pricing system meant higher transportation and handling costs in moving commodities from some remote areas, and the management of large volumes of

commodities in storage was costly. In addition, the monitoring of private trade was not only costly but generally ineffective, especially for food commodities in shortage seasons, when parallel markets flourished to meet local demand. In Mali, for example, even though private cereals trade was illegal before 1981, only 30–40 per cent of total grain trade was actually handled by the state trading agency, OPAM (Dembélé and Staatz 2002). On the international market, marketing boards faced decreasing real commodity prices for export crops, further undermining their sustainability.

By the end of the 1970s budget deficits resulting from the management and mismanagement of parastatals had reached astronomical levels in most countries. In Mali, OPAM's annual deficit reached US$80 million by 1980, three times the board's annual grain sales. In Tanzania, the National Marketing Corporation's overdrafts were about $250 million in 1993, against total state expenditures on agriculture of $12 million. The National Cereals and Produce Board (NCPB) of Kenya accumulated an estimated loss of about $300 million by 1993, in contrast with central government expenditure on agriculture of $33 million (Staaz et al. 2002; Lele and Christiansen 1989). These patterns were by no means exclusive to Africa. Indonesia's price stabilization scheme for rice, managed by the National Logistics Supply Organization (BULOG), also proved a high price to pay for self-sufficiency, as did the Food Corporation of India.

In addition to budgetary complications, marketing boards also faced organizational challenges. Their susceptibility to bureaucracy and corruption increased both the inefficiency in their operations and the transactions costs for farmers and consumers. For example, Arhin et al. (1985) argue that by the mid-1970s the Ghana Cocoa Marketing Board had become little more than an instrument of the government for the purpose of mobilizing political support for the incumbent government.

Mounting deficits, poor management and the perverse incentives created by anti-competitive behaviour brought marketing boards and price stabilization systems under attack, based in part on seminal research into the welfare effects of government interventions to stabilize commodity prices (Newbery and Stiglitz 1981). These deficit problems, coupled with the new economic insights, triggered widespread agricultural market reforms in the 1980s and 1990s throughout the developing world, implemented mainly but not exclusively, in the context of structural adjustment programmes (SAPs) of the World Bank and the International Monetary Fund.

Agricultural marketing reforms generally aimed to reduce the role of the public sector in marketing and to encourage private sector participation so as to let markets allocate scarce goods more efficiently. Marketing boards experienced major reforms under these programmes, comprising the elimination of price controls, termination of farm input and consumer food subsidies, removal of marketing boards' monopsony power and deregulation of private trade. In many cases, marketing boards were privatized or at least commercialized, the latter referring to cases where marketing boards remained government owned, but with autonomous decision-making power and an explicit objective to maximize profits. The logic was that, by removing political interference in the marketing process, market forces would lead to efficient resource allocation and price discovery. Market deregulation was thus expected to improve marketing efficiency by reducing transactions costs, increasing producer prices, thus inducing increased production and potentially also lowering consumer prices.

The response of the market was immediate and quite dramatic in many cases. Entry into formerly controlled agricultural markets was massive in most countries, although with continued bottlenecks in functions requiring significant capital outlays, such as bulk inter-seasonal storage and long-haul motorized transport, entry was typically restricted to niches with low entry barriers (Barrett 1997). Nonetheless, formal and informal private traders became a significant part of the marketing channel, performing most of the trade activities that the marketing boards previously performed.

In spite of widespread liberalization, marketing operations for most 'strategic' food and export crops changed little. Newly privatized or commercialized marketing boards were often replaced with 'new'

marketing boards that were initially intended to provide public goods, but eventually and predictably became involved in crop marketing. In Zambia, for example, the government-owned Food Reserve Agency (FRA) that replaced the National Agricultural Marketing Board (NAMBOARD) in 1995, charged with maintaining the strategic grain reserve and acting as a buyer of last resort for smallholder farmers, in time took up prior NAMBOARD responsibilities such as fertilizer distribution. Moreover, some of the commercialized marketing boards did not significantly change their pricing systems and continued to use the power of the state to remain dominant players in the current market system. In Indonesia for example, even though the market was opened to private traders, BULOG remained a price leader by operating a major buffer stock, purchasing rice when rice prices fell below a stated floor price and releasing stocks when prices rose above a price ceiling. Similarly, in the Kenyan maize sector the NCPB continued to intervene directly in markets to support maize prices; and in Malawi ADMARC remains the dominant maize buyer and distributor of inputs. Zimbabwe went so far as to reinstate the monopsony power of the Grain Marketing Board and its pre-reform operations. Not surprisingly, the budget deficit of these marketing boards actually increased after reforms.

These trends reflect governments' reluctance to relinquish control over marketing board operations, particularly the setting of prices for key food and export crops, given political sensitivity to these issues. As it turned out, such concerns were not completely unwarranted. In many developing countries the legacy of private underinvestment in storage and transport capacity, inadequate commercial trading skills in the nascent private sector, combined with limited access to finance, restricted entry into key niches of the marketing channel. These market conditions facilitated the emergence of new monopolies, often substituting private for public market power. Problems of weak contract enforcement, unreliable physical security and underdeveloped communications and transport infrastructure often impeded business expansion, market integration and price transmission. Despite increased private investment in transportation and storage infrastructure after reforms, the weaknesses of the existing systems implied considerable business risk. Consequently, private traders did not fully or quickly fill the voids left by the withdrawal of the marketing boards from core commodity market intermediation functions. Price volatility increased sharply in many countries. Moreover, farmers' access to seasonal credit dropped significantly as market liberalization ended formerly monopsonistic marketing boards' willingness to extend seasonal credit to growers that were collateralized by future sales. Reduced credit often led to fewer purchased inputs and lower crop output. In an attempt to restore market stability and production volumes, states often suspended or reversed reforms, reinstating price controls and trade restrictions, thereby further exacerbating instability and undermining investor confidence. The result has been incomplete reforms in most developing countries, where private sector involvement remains pervasive but small-scale and weak, while unprofitable commercialized marketing boards remain prominent and prone to government interference.

The Current State of Play

Far fewer marketing boards exist than previously. Because they reduce or eliminate competition, marketing boards are widely believed to induce inefficiency in marketing and sluggishness in price discovery. Therefore, government involvement in agricultural marketing has been weakening in both developed and developing countries since the mid-1980s, a result of the adoption of more liberal domestic economic policies, coupled with global pressure to conform to international trade rules steadily expanding their coverage of agriculture. The monopoly or monopsony powers of all but a few marketing boards have been lifted, and the marketing and processing activities of the boards have been streamlined. Where reforms have been widespread and successful, marketing boards have vanished or retreated to providing public goods, such as strategic grain reserves or insurance against extraordinary price fluctuations. Where reforms have been halting or unsuccessful, the weaknesses of private agricultural marketing

channels have been laid bare by the rollback of marketing boards.

Marketplaces

Winifred B. Rothenberg

Abstract

'Marketplace' was defined by the great 18th century jurist, William Blackstone, as 'a spot of ground set apart by custom for the sale of particular goods.' The definition is striking in its simplicity, but the simplicity is deceptive, for each word should give us pause. If a marketplace is a 'spot' it is both bounded and of little consequence. Having said it was a 'spot', 'of ground' would seem to be redundant were it not that this, the market as a *place* located in space is the feature that over time will change the most. 'Set apart' underscores the irreconcilability of Commerce and Community, and, by implication, bestows upon Community the greater authenticity. 'Sale'–legally to divest a seller – presupposes a body of legal rules protecting title and the alienability of title, at least to 'particular goods'. And 'particular goods', in turn, implies the inalienability of title to *other* goods. Finally, there is 'custom'. In Blackstone's syntax, custom's role appears limited to the setting of the spot. But when Commerce threatens to overwhelm the barriers that Community has erected against it, it will be custom that writes the regulations into law. 'Marketplace' is not at all 'simple,' and reckoning with it in one or another of the protean forms it has assumed over the millennia deserves to engage, as indeed it has, the attention of archaeologists, historians, anthropologists, sociologists, and economists.

Marketplaces in the Long-Run

The history of marketplaces is traced here as a sequence of pivotal events that began at least 60,000 years ago when, archaeologists suggest, the earliest appearance of trade in Europe can be inferred from the discovery of made objects – amber, mollusc shells and worked stone – that had been moved to sites hundreds of kilometers from their sources. But the origins of trade may extend back even further in time, for 'the

archaeological record does not reveal *any* time in the history of man in Europe in which there was no movement of "manufactured" objects' (Grantham 1997, p. 18).

A giant leap takes us to Mesopotamia 10,000 years ago. Having by now collected abundant evidence of the deleterious effect of settled agriculture on human health in the Neolithic, it has been suggested by some paleopathologists that the Agricultural Revolution – the sedentary cultivation of grain, sugar, flax, wool, sisal, jute and hemp – may have been driven less by the quest for food security than by the high value these staple crops could earn in trade.

Study of the 4,000 year-old Heqanakht Papyri reveals Heqanakht himself to have been 'obsessed' with running his farm to make a profit and augment his wealth, and the economy of Pharaonic Egypt to have been one *not* of priestly redistribution, as had been thought, but of private property, money prices, cash crops, rental land, wage labour and marketplaces (Allen 2002).

Ten centuries before the Christian era, the marketplaces rimming the Aegean Basin were specializing in the export of high-value wines, olives and oil to trade for imports of grains, raw materials and slaves from the 'barbarians' north of the Mediterranean.

In the eighth and seventh centuries BC, Phoenicia's legendary traders integrated the markets of the eastern and western Mediterranean; the Etruscans made contact with the Celts; and the merchants of India reached the northwest coast of England.

In the Bible, The Book of Ezekiel, written, it is thought, in the sixth century BC, describes in chapters 26–27 the prosperous city of Tyre whose marketplaces overflowed with an abundance of fir trees from Senir, cedars from Lebanon, ivory benches from the isle of Chittim, fine linen from Egypt, silver, iron, tin and lead from Tarshish, emeralds, purple, coral, agate and fine linen from Syria, wheat from Minnith, honey, oil and balm from Pannag, wine and white wool from Helbon, lambs, rams and goats from Arabia, spices from Sheba and Ra-amah, and skilled artisans, laborers seafaring men, and merchants from all over the eastern Mediterranean.

Most exotic of all were the marketplaces that grew up along the Silk Road, established by the Han Dynasty in the second century BC as China's only link to the West. Along much of its length, the Silk Road was less a 'road' than a hazardous path around the world's most unlivable desert, through the world's most inaccessible mountain passes, over the world's highest peaks, and among the world's most isolated and hostile peoples. The Road started in what is now Xian on China's northwest border, and made its way west through Kazakstan, Kyrgyzstan, Uzbekistan, Tajikistan, and Afghanistan, encircling the Hindu Kush, until crossing the Black Sea, it ended in Roman Syria – which is as much as to say, in Venice! The market-places of this commerce were the oases of central Asia and the fabled 'Arabian Nights' cities they became: Xian, Islamabad, Tehran, Kashi, Samarkand, Bukhara, Kabul, Kandahar, Tashkent, Aleppo, Lahore, Baghdad, Ankara, Istanbul. For 15 centuries, caravans of up to 1,000 camels each made the journey from oasis to oasis for months on end, under armed guard, bearing gold, metals, ivory, precious stones, myrrh, frankincense, ostrich eggs, horses, glass, silks, porcelain, guns, powder, jade, bronzes, lacquer – and the great religious civilizations of Buddhism and Islam.

On the European end of the Silk Road great 'diaspora networks' were founded by Greek, Armenian and Jewish merchant families of the eastern Mediterranean, who traded a world away with the diaspora networks of India, China, Japan and Indonesia (McCabe, Harlaftis and Minoglou 2005).

In time, the Romans would discover the secret of making silk, Europeans would find a sea route to China, the Silk Road with its storied past would disappear beneath the sand, the Mongol hordes would burst out of the East, and Europe would reap the whirlwind. In the Black Death that ravaged the continent between 1348 and 1351, Europe lost as much as 40 per cent of its population.

To a demographic event so catastrophic no system, no institution, no mode of production could remain impervious. Especially transformed were Europe's labour markets. In England, those

who survived the Black Death lived to enjoy 'the sole golden age of the English peasantry' (Hatcher 1987, p. 281). The Statute of Artificers notwithstanding, the general response of the manorial economy to the desperate scarcity of labour, the abundance of abandoned land, and rising prices in grain markets was to relax feudal constraints on the mobility of labour, to raise nominal wages, lower rents, and make concessions on customary dues and obligations. In a word, peasants under villein tenure were able to secure copyhold and leasehold tenancies. By the 17th century, England had become 'a peasant-free zone' (R.M. Smith in Scott 1998, p. 346).

In Russia, in stunning contrast, the response to depopulation was the establishment of serfdom. In the face of acute labour scarcity and expanding grain markets, the Boyars demanded tighter and tighter legal restrictions on the mobility of peasants until, by an Act of the Duma in 1649, serfs and their households were made the personal property of the lord – effectively slaves (Domar 1970, pp. 13–32).

Thus, 'peasant' in the European context came to be a status that defies definition: some were well on the way to yeomanry by 1600, others were only a technicality away from a heritable condition of slavery.

Marketplaces and Peasants

From the 14th century to the 18th, the history of marketplaces is linked to the history of peasants, as that of peasants is to marketplaces. In Brueghel's exuberant paintings of peasants tumbling about in overflowing marketplaces the link has become an icon of Flemish art. 'Historically, peasants only exist when markets exist, even if they do not fully participate in them' (Scott 1998, p. 2).

Having for well over a century minutely observed a vast number of peasant societies, the characteristics of peasant markets, and the behaviour of peasants with respect to them, it has been anthropology, rather than economics, that has become, to use Grantham's phrase (1997, p. 19), 'the referent social science' of the peasant economy. Peasant villages, whether in Indo-China, West Africa, the Stone Age, or – improbably – colonial New England, are said to have this in common: that the village marketplace is 'embedded in' the social fabric of the community; the rules governing it, and the motivations of buyers and sellers and borrowers and lenders transacting in it are subordinate to and constrained by the non-market values of the ambient culture, and stand as epicentres of resistance to the encroachment of the 'disembedded', proto-capitalist, dynamic, hegemonic Market, with a capital M.

Influential as this model has been, there is a counter-narrative, accepted even by some anthropologists. Thus, for example, among the Panajachelenos of the Guatemalan highlands, 'Commerce is the breath of life' (Tax 1963, p. 132). According to Sol Tax, both men and women spend more time buying and selling and talking about buying and selling than doing anything else. When they have nothing to sell, they buy something in a cheap market and carry it to a dear one to sell. The Maoris of New Zealand, the Ifugao of the Philippines, the Senegambian, Afikpo, Esusu, Yoruba, Hausa, Tiv and Dahomean peoples of West Africa, the northeastern Malays, the Javanese and the Trobriand Islanders have all been found to engage in price- and quantity-bargaining, to 'seek maximal advantage' in marketplace transactions (Firth and Yamey 1964), and to exhibit in their market-dependence the same U-shaped relationship to their disposable assets as is associated with risk-averse behaviour in developed economies.

A case in point is a new study of African markets by Marcel Fafchamps (2004) who argues that sub-Saharan Africa today is decisively 'market-oriented'. The development of Africa, Fafchamps insists, has been impeded not by the cultural incongruity of markets, or the absence of markets, or the lack of a market *mentalité,* but by the accommodation that traders in sub-Saharan markets have had to make to the ubiquity of market imperfections. In the absence of well-defined property rights, intermediary institutions, notaries public and contract enforcement, the sole bar against asymmetric information, adverse

selection and moral hazard has been what might be called 'insider trading': repeated transactions among networks of friends and relations bound to one another by webs of trust. In the context of sub-Saharan Africa these webs, although intimate, are not cooperative, says Fafchamps, but strategic; the object is not to avoid the discipline of the market but more nearly to satisfy its assumptions.

Few peasant economies fit the 'moral economy' model (Rothenberg 1992, ch. 2). And those that do may, like 15th-century French villages, have been torn by strife, the collective experience 'rubbed raw' (Hoffman 1996, p. 77) by the face-to-face pursuit of what Avner Offer (1997) has called 'regard'. But the principal critique of a non-market model is that it is a steady-state model, and that has tended to impart a Durkheimian steady-state bias to peasant studies. It is a bias very much 'at home' with a methodology in anthropology itself in which scrutiny ever closer is leveled at subjects ever narrower – from tribe, to village, clan, household, extended family, nuclear family, gender – thereby surrendering to economists the trade *among* groups and the articulation *between* marketplaces that generates growth. It is in regulating that process that the community asserts its dominion over what Braudel (1982, p. 58) has called 'the insidious tentacles of the economy'.

Regulating the Marketplace

Such interventions have a very long history, coming down to us, Blackstone thought, from Saxon times when no title to goods valued above 20 pence could change hands without witnesses. But such impediments to trade could not have persisted were it not for law. It is the province of any law worthy of the name to recognize in 'You have got what belongs to me' its sphere of action (Pollock and Maitland, 1895, p. 33), and nowhere more urgently than at the point of transferring the ownership of chattels by sale. For what but law can distinguish sale from theft, right from use, ownership from possession, *dominium* from *seisin*?

As the frequency of trade increased in the 13th century, exchange in an open market established by royal grant – a 'market ouvert' – sufficed, in lieu of witnesses, to divest a seller. With outdoor marketplaces came rules, regulations and ordinances establishing, locating, restricting, and supervising open markets, covered markets, fairs, merchant courts and piepoudre courts for itinerant merchants; appointing ringers of opening and closing bells, monitors of weights and measures, collectors of fees and fines, inspectors of quality, enforcers of Just Prices, and wardens to patrol the perimeters of the marketplace. This regulatory 'apparatus' was brought to the American colonies and given the force of law in the municipal marketplaces of all large towns in Massachusetts and throughout the colonies.

'The Laws and Liberties of Massachusetts', codified between 1641 and 1691, declared the taking of excessive wages by mechanics and day labourers and the charging of unreasonable prices by shopkeepers and merchants punishable by double restitution or imprisonment. They set the weight of the pennyloaf of white bread, and authorized the selection of two able persons annually to enter into the houses of all bakers 'as oft as they see cause' to inspect and weigh all bread found there on pain of forfeiture. Two persons were appointed annually to ascertain the range of prevailing wheat prices each month and set the price at which bakers shall bake their bread. 'The Laws and Liberties' also set the days of the week when a marketplace shall be kept in Boston, Salem, Lynn and Charlestown, set the times of the ringing of the opening and closing bells, forbade all trade outside the perimeter of the marketplace, and set the two days a year when Boston, Salem, Watertown and Dorchester shall have fairs (Cushing 1976).

In 1737, Faneuil Hall, Boston's beleaguered marketplace, was besieged by farmers from the surrounding hinterland who 'donned the livery of heaven' (disguised themselves as clergy) and burned it to the ground (Brown 1900, ch. 8). By the early 1820s, the regulated 'market ouvert' and the legal doctrine of implied contract expressed by it were abandoned in favour of the rule of *caveat emptor*. Contract, not Community, would come increasingly to regulate markets.

Marshallian Markets: The Marketplace After 1900

With the publication of Alfred Marshall's *Principles of Economics* in 1900, economics became the referent social science of markets. It may therefore come as something of a surprise to discover that in this, the urtext of economics, marketplaces have vanished! Marshall's definition of a market is of an abstraction, outside of spatial coordinates, oblivious of cultural context, and functioning homeostatically in accordance with laws of its own making. 'The distinction of locality is not necessary,' he wrote. 'Economists understand by the term "Market" not any particular market-place in which things are bought and sold, but the whole of any region in which buyers and sellers are in such free intercourse with one another that the prices of the same good tend to equality easily and quickly' (Marshall 1890, p. 324).

Thus, the market is not a place but a *process* that expands in space and unfolds in time, driven by the pace at which different prices for the same good converge toward a single price. Called the Law of One Price, that convergence is the unintended consequence of arbitrage between buyers seeking cheap markets and sellers seeking dear markets.

But as long as a wedge between 'cheap' and 'dear' markets persists, that is, as long as the convergence process is incomplete, marketplaces remain significant, not as 'spots of ground' but as transitional nodes of price-formation that become 'folded in' as the market process advances along its dendritic expansion-path. The story we have followed for 60,000 years has not, even in a Marshallian sense, become irrelevant.

At the same time, economics itself, as the referent social science of markets, is expanding its narrow field of vision beyond its Marshallian boundaries in an attempt to comprehend the wider social and psychological foundations of economic behaviour. I am reminded of the earthquake of 8 October 2005 which struck high up in the Kashmiri Himalayas. Within a week of the catastrophe, survivors set up a village marketplace (BBC News). Seventy-three thousand had been killed, three million were made homeless, none had necessities, none had surpluses, but within days they made a marketplace.

Markets

Geoffrey M. Hodgson

Abstract

Until recently, and despite strong interest in market outcomes, economists have paid relatively little attention to the institutional structure of markets. This article considers the historical evolution of markets and poses some dilemmas concerning their definition. Several alternative definitions are considered, involving different degrees of historical specificity. It is argued that developments in economics and elsewhere since the 1980s point to a more nuanced view of markets, involving a recognition of different types of market mechanisms and institutions. These developments include work in experimental economics and auction theory. A definition of markets is offered that is consistent with these developments.

Markets dominate modern life, and economists have for long been concerned about market prices, but, despite this ongoing preoccupation, until recently there has been little discussion of the nature and operation of markets themselves.

No fewer than three Nobel Laureates in economics have noted this paradox. George Stigler (1967, p. 291) wrote: 'The efficacy of markets should be of great interest to the economist: Economic theory is concerned with markets much more than with factories or kitchens. It is, therefore, a source of embarrassment that so little attention has been paid to the theory of markets and that little chiefly to speculation.' Stigler made a plea for the theoretical study of markets, which for a long time went unheard.

Ten years later Douglass North (1977, p. 710) similarly remarked: 'It is a peculiar fact that the literature on economics and economic history contains so little discussion of the central institution that underlies neoclassical economics – the market'. Another 11 years had passed when

Ronald Coase (1988, p. 7) observed that 'in modern economic theory the market itself has an even more shadowy role than the firm'. Economists are interested only in 'the determination of market prices' whereas 'discussion of the market place itself has entirely disappeared'.

Economists have had little to say about the nature of markets, other than classifying them by their degrees of competition and their numbers of buyers and sellers. Beyond this, the institutional aspects of markets have been widely neglected. For much of the 20th century there has been little discussion of how specific markets are structured to select and authenticate information, and of how specific prices are actually formed. Furthermore, 'the market' was treated as a relatively homogeneous and undifferentiated entity, with little consideration of different market mechanisms and structures. When market mechanisms were addressed this was typically confined within the framework of general equilibrium theory, with relatively little attention to the institutional details and alternative market structures.

Inspection of standard economics textbooks confirms these observations. While market outcomes such as prices are always central to the discussion, there is generally little consideration of the detailed rules and mechanisms through which prices are formed, and the concept of the market itself often goes undefined. Indeed, there is an entry on markets in neither the massive 1968 edition of the *Encyclopaedia of the Social Sciences* nor the otherwise comprehensive 1987 edition of *The New Palgrave: A Dictionary of Economics.*

Three questions arise. First, what briefly is the nature of markets and how can the market be defined? Second, why has the specific anatomy of markets been neglected by economists? Third, what recent developments in economics and elsewhere help to remedy the deficiency? After a brief historical discussion this article addresses these questions.

Historical Background

Goods have changed hands within human societies for hundreds of thousands of years. However, much of this internal circulation was powered by custom and tradition. Transfers of goods often involved ceremony and personal, reciprocal actions. These personal and kin-based exchanges contrast with the organized and competitive pecuniary ambiance of modern markets. Ceremonial transfers involved 'the continuous definition, maintenance and fulfilment of mutual roles within an elaborate machinery of status and privilege' (Clarke 1987, p. 4). Most of this internal circulation of goods was devoid of any conception of the voluntary, contractual transfer of ownership or property rights. These reciprocal transfers of goods were more to do with the validation of custom and social rank.

Something more akin to trade existed at least as far back as the last ice age. However, this trade was largely peripheral and occurred at the meeting of different tribal groups. As Max Weber (1927, p. 195) attested, it did not take place 'between members of the same tribe or of the same community' but was 'in the oldest social communities an external phenomenon, being directed only towards foreign tribes'. This contention that trade began externally and between communities rather than within them has withstood subsequent scholarly examination. Trade was typically a collective and *inter-social* enterprise between one tribe and another.

With the rise of the ancient civilizations, both external and internal trade increased substantially. The development of money and coinage facilitated its expansion. A definable internal commodity market (or agora), with multiple buyers and sellers, first appeared in a designated open space in Athens in the sixth century BC (Polanyi 1971; North 1977). The *agora* opened frequently and had strict trading rules. At around the same time there existed an annual auction market on Babylonia: young women were put on display and male bidders competed for marriage rights (Cassady 1967). Nevertheless, some scholars have warned against the view that these ancient civilizations were generally and predominantly market economies (Finley 1962; Polanyi et al. 1957). By contrast, researchers such as Peter Temin (2006) have argued that the Roman Empire in particular contained developed and interlocking markets

with variable prices, albeit without a highly developed banking system and with a relatively limited market for capital.

European and Mediterranean trade contracted after the fall of the Roman Empire. When commerce began to develop again in medieval times, internal markets then had a limited role in the medieval economy. 'Strange though it may seem', wrote the historian Henri Pirenne (1937, p. 140), 'medieval commerce developed from the beginning not of local but of export trade.' Although there are likely to have been other earlier organized markets in England, systematic evidence of the king enforcing his right to license all markets and fairs does not appear until the 13th century.

Markets for slaves existed in classical antiquity and persisted in some regions until the modern era. By contrast, feudal serfs were not owned as chattels, but they did not enjoy the right to choose their masters. Feudal institutions, driven by traditional obligations rather than voluntary contract, meant that the hiring of labourers was marginalized and markets for wage labourers were rare. With the decline of bonded labour, which began as early as the 14th century in England, employment contracts were limited largely to casual labourers, alongside a large number of self-employed producers and others in peasant family units. In England it was not until about the 18th century that a class of potentially mobile wage labourers emerged who constituted the most important source of labour power. Organized markets for employees, involving labour exchanges or employment agents, did not become prominent until the 19th century.

To turn to capital markets, an early market for debts was the French *courratier de change* in the 12th century. In the 13th century, after the development of a banking system in Venice, trade began in government securities in several Italian cities. In 1309 a 'Beurse' was organised in Bruges in Flanders, named after the Van der Beurse family, who had previously hosted regular commodity exchanges in their residence. Soon after, similar 'Beurzen' opened in Ghent and Amsterdam. In 1602 the Dutch East India Company issued the first shares on the Amsterdam Bourse or Stock Exchange. The London Stock Exchange, founded in 1801, traces its origins to 1697 when commodity and stock prices began to be published in a London coffee house. The origins of the New York Stock Exchange go back to 1792, when 24 stockbrokers organized a regular market for stocks in Wall Street. Accordingly, developed capital markets first appeared in the Netherlands in the 17th century and later spread to other countries.

Overall, in the last 400 years markets have expanded enormously in scope, volume and economic importance. Markets have come to pervade internal as well as external trade and to dominate the global economic system. The modern era of globalization is often identified with the growth of global commodity and financial markets since the middle of the 19th century.

This brief historical sketch is background for the task of defining markets. At least three options emerge, involving different degrees of historical specificity. The broadest definition would be to use the term 'market' to refer to all forms of transfer of goods or services between persons, including the age-old customary or ceremonial transfers within tribes and households, exchanges of property between tribes, and modern organized markets with multiple buyers and sellers. We consider this option and some more restrictive alternatives next.

The Nature of Markets

The Austrian school economist Ludwig von Mises (1949) is exceptional among economists in devoting a lengthy chapter to 'the market'. He sees the market economy as 'the social system of the division of labour under private ownership of the means of production' (1949, p. 257). He explicitly excludes economies under social or state ownership of the means of production from this category, but nevertheless regards such systems as strictly 'not realizable'. Consequently, the historical and territorial boundaries of his concept of the market depend very much on what is regarded as 'private ownership'. He associates private ownership with the rise of civilization, and defines ownership in terms of full control of the services that derive from a good, rather than in legal terms. Together these specifications amount to a definition of the market that embraces all forms of trade or exchange that

involve private property, defined loosely as assets under private control.

Although von Mises associates secure private property and exchange with the rise of civilization, these terms are defined in a manner that does not exclude their application to earlier periods of human history. It then becomes problematic whether or not ceremonial transfers and ritualistic gift-giving are regarded as 'exchanges' of 'property' and whether or not these activities come within the sphere of 'the market'. Essentially, the historical compass of the latter term depends very much on what we mean by notions such as exchange and property.

In downplaying the legal aspects of property and exchange, von Mises also fails to probe the nature of the rights that form part of the exchange. Instead he sustains the notion that uncoerced and informed consent by the parties to the transaction is a sufficient basis to constitute the contractual and property rights involved. A problem with this idea is that mutual individual consent itself requires a legislative and institutional framework to legitimize, scrutinize and protect those individual rights. The importance of this legal and constitutional framework is widely recognized, including by other Austrian theorists such as Friedrich Hayek (1960). Several historical cases of the spontaneous evolution of systems of enforced property rights do exist, but they generally rely on reputational and other monitoring mechanisms that are more difficult to sustain in large-scale, complex societies (Sened 1997).

An alternative intellectual tradition places more emphasis on the legal and statutory basis of individual rights. This approach pervaded the 19th-century German Historical School and their predecessors such as Karl Heinrich Rau, and continued into the 20th century in the original American Institutionalist School, particularly in the writings of John Rogers Commons. Both Rau and Commons (1924) argued that exchange is more than a voluntary and reciprocal transfer of resources: it also involves the contractual interchange of statutory property rights. For them, exchange had to be understood and analysed in terms of the key institutions that are required to sustain it.

This narrower and more legalistic understanding of private property and contractual exchange confine them both in longevity and scale. Statutorily endorsed property rights, applied to moveable goods and services, were not codified until the ancient civilizations. In feudal times, much of the transfer of goods and services was achieved by custom or coercion rather than by contract and consent. Indeed, economic historians such as North (1981), who attempt to explore the origins of modern markets and commodity exchange, generally focus on the late medieval or early modern period as the era in which well-defined individual property rights began to spread widely from specific parts of the world.

A second important dilemma emerges. This is whether the market is regarded as coextensive with the exchange of private property per se or whether it is given an even narrower meaning and used to refer to forms of *organized* exchange activity. Two major factors lead us to consider an even narrower meaning for the term.

The first consideration is the commonplace use of the term 'market' itself and its equivalent in other languages. The word 'market' originally appeared as a noun to describe a specific place where people gathered and exchanges of a particular kind took place. The first market in Athens in the sixth century BC had rules concerning who could buy or sell, what could be bought or sold, and how trading should take place. In medieval England markets were permitted by royal charters and located in specific towns. In Europe and elsewhere in the last 300 years organized town and village markets have become commonplace. There are also permanent buildings that function as 'exchanges' for agricultural products, minerals, financial stocks, and so on. Although it has acquired additional meanings, the noun 'market' still refers to a place or gathering where trade is organized.

The second issue is the existence of a well-researched form of exchange that takes place in different contexts and involves different considerations. In three seminal and influential works, George B. Richardson (1972), Victor P. Goldberg (1980) and Ronald Dore (1983) point out that many real-world commercial

transactions do not take place in the competitive arena of a market. Instead they involve firms in ongoing contact, which exchange relevant information before, during and after the contract itself. The relationship is durable and the contract is often renewed. This is most often described as 'relational exchange'. A question in the derivative literature is to examine the reason for the mutual choice of an ongoing exchange relationship rather than the more competitive institution of the market. Among the explanations is the importance of establishing ongoing trust in circumstances of uncertainty where product characteristics are complex, relatively unique or involve continuous potential improvements. Whatever the reason for its existence, such relational contracting is very different from the more anonymous exchanges in organized markets. Relational exchanges are nevertheless still contractual exchanges of property rights, in their fullest and most meaningful sense. If they are distinguished by definition from market exchanges, then not all exchanges take place in markets. Furthermore, the exchange of goods or services that are strictly unique may be regarded as a non-market phenomenon, even if the exchange is not relational. The term 'market' is thus reserved for forms of exchange activity with many similar exchanges involving multiple buyers or sellers.

In part, it is the degree of organization of exchange activity that makes markets different from relational exchange. In financial markets, for example, there are typically strict rules concerning who can trade and how trading should be conducted. In such relatively volatile markets, specific institutions sift information and present it to traders to help the formation of price expectations and norms. Market institutions in other contexts monitor the quality of goods and the instruments of weight and measure. Within these structures, trading networks emerge on the basis of business connections and reputations.

Modern telecommunications mean that a market does not have to be organized in a specific location. Either bidders can communicate with the market centre over long distances, as with many financial markets, or the market *place* can itself disappear, as in the case of Internet-based markets, such as eBay. The latter case nevertheless remains a market, because it is an organized (virtual) forum, subject to specific procedures and rules.

We thus arrive at a definition of a market in the following terms. Markets involve multiple exchanges, multiple buyers or multiple sellers, and thereby a degree of competition. A market is defined as an institution through which multiple buyers or multiple sellers recurrently exchange a substantial number of similar commodities of a particular type. Exchanges themselves take place in a framework of law and contract enforceability. Markets involve legal and other rules that help to structure, organize and legitimize exchange transactions. They involve pricing and trading routines that help to establish a consensus over prices, and often help by communicating information regarding products, prices, quantities, potential buyers or possible sellers. Markets, in short, are organized and institutionalized recurrent exchange.

Of course, it is often difficult to draw the line between organized and relational exchange. There are many possible intermediate cases. However, such difficulties are typical when dealing with highly varied phenomena and are commonplace in some other sciences, notably biology. Similar difficulties exist in distinguishing other economic forms, such as making the important distinction between employment contracts and contracts for services. Nevertheless, such distinctions are important. The difficulty of defining a species does not mean that species should not be defined.

The operation of the law of one price is often taken as an indication of the existence of a market. Of course, imperfect information and quality variations can explain variations within a market from a single price. Nevertheless, the organized competition of the market and its associated information facilities are necessary institutional conditions for any gravitation by similar commodities to a single price level.

Taking stock, we may contrast the narrower definition of the market given above – as an institution with multiple buyers or multiple sellers, and recurrent exchanges of a specific type of commodity – with the much broader definitions raised earlier. These differences in definition do

not simply affect the degree of historical specificity of 'market' phenomena, they also sustain different theoretical frameworks and promote different questions for research. Some explanations for this divergence arise in the next section.

Why Have Economists Neglected the Institutional Character of Markets?

For much of the 20th century, the institutional character of markets has been neglected by economists because institutions generally have been neglected. The exceptions consist of economists who placed a special emphasis on institutions. The institutional character of markets was emphasised by German historical economists such as Gustav Schmoller and Werner Sombart in the 19th century (Hodgson 2001). The British dissident economist John A. Hobson (1902, p. 144) wrote: 'A market, however crudely formed, is a social institution'. Likewise, for the American institutionalist John Maurice Clark (1957, p. 53): 'the mechanism of the market, which dominates the values that purport to be economic, is not a mere mechanism for neutral recording of people's preferences, but a social institution with biases of its own'. Coase, North and others have effectively revived an interest in the institutional structure of markets that was eclipsed by developments in mainstream economics during much of the 20th century.

A further clue to help explain why generations of economists have neglected the institutional character of markets lies in the preceding section, where the problem of defining the boundaries of key concepts such as property, exchange and market was raised. Many economists have maintained that the principles of the subject should be as universal as possible – like physics – to the extent that substantial consideration of historically or nationally specific institutional structures is lost. The idea that economics should be defined as a general 'science of choice' (Robbins 1932) is part of this tradition. Consequently, terms such as property, exchange and market are given a wide meaning. Accordingly, many forms of human interaction have been regarded as 'exchange' and the summation of such 'exchanges' as 'markets'. In these terms, there is little difficulty in applying these concepts to many different types of system, from tribal societies through classical antiquity to the modern capitalist world.

Consequently, the idea of the market assumes a de-institutionalized form, as if it was the primeval and universal ether of all human interactions. Whenever people gather together in the name of self-interest, then a market somehow emerges in their midst. The market springs up simply as a result of these spontaneous interactions: it results neither from a protracted process of multiple institution-building nor from the full development of a historically specific commercial culture.

Incidentally, many sociologists have also assumed a de-institutionalized concept of the market. This is partly the result of the influence of a notion, promoted by Talcott Parsons and others, that sociology should also aspire to a high degree of historical generality. It is also a result of the influence of Marxism within sociology. Despite its emphasis on historical specificity, Marxism also treats markets as uniform entities, ultimately permeated by just one specific set of pecuniary imperatives and cultural norms.

From the 1940s to the 1970s, general equilibrium theory provided the framework in which economists attempted to understand the functioning of markets in wide-ranging terms. Even here, however, some significant attention had to be paid to institutional mechanisms and structures. Something special like the 'Walrasian auctioneer' had to be assumed in order to make the model work (Arrow and Hahn 1971). Some elemental institutional structures had to be brought in to make the model function in its own terms. The limits to this project of theoretical generalization became more apparent in the 1970s, when it was shown that few general conclusions could be derived. In particular, Hugo Sonnenschein (1972) and others demonstrated that within general equilibrium theory the aggregated excess demand functions can take almost any form (Rizvi 1994).

The existence of 'missing markets' always poses a problem for the general equilibrium approach: a complete set of markets for all present and future commodities in all possible states of the

world is typically assumed as a basis for general clearance in all markets. However, if market institutions are themselves scarce and costly to establish, then some may be missing for that reason. Furthermore, while capitalism has historically promoted market institutions, modern developed capitalism prohibits several types of market, such as markets for slaves, votes, drugs, or futures markets for labour. In so far as capitalism makes such prohibitions, 'missing markets' are inevitable within capitalism.

The technical problems exposed by Sonnenschein and others led economists to shift their attention away from general equilibrium theory. Instead, game theory became the cutting edge of theoretical analysis. By its nature, game theory tends to lead to less general propositions and points instead to more specific rules and institutions. As game theory became fashionable in the 1980s, it became a theoretical tool in the 'new institutionalist' revival in economic theory.

The Revival of the Notion of Markets as Institutions

At least three further developments helped to promote the study of markets as social institutions. First, the basic theory of auctions emerged in the 1970s and 1980s (McAfee and McMillan 1987; Wolfstetter 1996). It was assumed from the outset that participants in an exchange did not have complete information, and on this basis it was shown that choices concerning auction forms and rules could significantly affect market outcomes. These ideas assumed centre stage in the 1990s with the use by governments of auction mechanisms in electricity and telecommunications deregulation, most notably in the selling of the electromagnetic spectrum for telecommunications services, and subsequently with the growth of auctions on the Internet (McAfee and McMillan 1996).

A second and closely related development was the rise of experimental economics, which began to be recognized as an important subdiscipline in the 1980s. Modern experimental economists, in simulating markets in the laboratory, have found that they have had also to face the unavoidable problem of setting up its specific institutional structure. Simply calling it a market is not enough to provide the experimenter with the institutionally specific structures and procedural rules. As leading experimental economist Vernon Smith (1982, p. 923) wrote: 'it is not possible to design a laboratory resource allocation experiment without designing an institution in all its detail'. Work within experimental economics has underlined the importance of these specific rules, by showing that market outcomes are sometimes relatively insensitive to the information processing capacities of the agents involved, because particular constraints govern the results (Gode and Sunder 1993).

In reality, each particular market is entwined with other institutions and a particular social culture. Accordingly, there is not just one type of market but many different markets, each depending on its inherent routines, cultural norms and institutional make-up. Differentiating markets by market structure according to textbook typology – from perfect competition through oligopoly to monopoly – is not enough. Institutions, routines and culture have to be brought into the picture. Experimental economists have discovered an equivalent truth in laboratory settings, and have learned that experimental outcomes often depend on the tacit assumptions and cultural settings of participants. Different types of market institution are possible, involving different routines, pricing procedures, and so on. This has been acknowledged by a growing number of economists, as the notion of a single universal type of market has lost credibility (McMillan 2002).

Third, these theoretical developments were dramatized by events. Following the collapse of the Eastern bloc in 1989–91, a number of economists presumed that many markets would emerge spontaneously in the vacuum created by the breakdown of central planning. This view turned out to be mistaken, as capital and other markets were slow to develop and their growth was thwarted by the lack of an appropriate institutional infrastructrure. Several formerly planned economics slipped back into recession. Critics such

as Coase (1992, p. 718) drew attention to the necessary institutional foundations of the market system: 'The ex-communist countries are advised to move to a market economy . . . but without the appropriate institutions, no market of any significance is possible'.

While sociologists, like economists, had previously paid relatively little attention to market institutions, the revitalization of the sub-discipline of economic sociology led to a series of studies by sociologists of financial and other markets (Abolafia 1996; Baker 1984; Burt 1992; Fligstein 2001; Lie 1997; Swedberg 1994; White 1981; 1988). These works show how specific networks and social relationships between actors structure exchanges, and how cultural norms govern market operations and outcomes. Similar considerations have emerged in empirical and simulation work by economists that stresses the importance of learning and previous experience in trading partner selection and in the decision to accept a transaction (Kirman and Vignes 1991; Härdle and Kirman 1995).

Taken as a whole, these literatures testify to a much more nuanced conception of market phenomena. As a result of all these developments, the treatment by economists and others of markets began to change. Both economists and sociologists are now paying detailed attention to the nature of specific market rules and mechanisms. A milestone paper by Alvin Roth (2002) challenges the view of a single universal theory of market behaviour. While those economists who had paid attention to different market mechanisms had typically been preoccupied with a search for 'optimal' rules and institutional forms, gradually this has become a will- o'-the-wisp with the realization that typical assumptions in the emerging literature concerning cognitive and information impairments have made this search difficult or impossible (Lee 1998; Mirowski 2007).

Nevertheless, while the search for optimal institutional blueprints is intractable, these theoretical developments have begun to provide an analytical framework within which the limits and potentialities of different types of market mechanism can be appraised. An outcome is to abandon the former widespread notion – shared by all kinds of theorists from Marxists to the Austrian School – that 'the market' is a singular type of entity entirely understandable in terms of the same principles or laws. While Hayek and his followers should be given inspirational credit for their emphasis on the informational limitations inherent in all complex economic systems, they stressed that markets are the most effective processors of information while downplaying or ignoring the differences between various types of market.

In this context, markets reappear as varied and historically specific phenomena. The general equilibrium approach has been overshadowed by an array of theoretical and empirical methodologies, including game theory, agent-based modelling, laboratory experimentation and real-world observation.

Conclusions

A number of options for defining a market have been outlined here. The broadest option is to regard the market as the universal ether of human interaction, depending on little more than the division of labour. A second option is to regard the market as synonymous with commodity exchange, in which case it dates at least as far back to the dawn of civilization.

By contrast, several considerations militate in favour of a narrower definition, and recent developments in economic theory point in this direction. In the narrower sense, markets are organized exchange. Where they exist, markets help to structure, organize and legitimize numerous exchange transactions. Pricing and trading procedures within markets help to establish a consensus over prices, and communicate information regarding products, prices, quantities, potential buyers or possible sellers.

Variation in market rules and procedures means that markets differ substantially, especially when we consider markets in different cultures. The markets of 2000 years ago were very different from (say) the electronic financial markets of today. In the real world, and even in a single country, we may come across many different

examples of the market. The market itself is neither a natural datum nor an ubiquitous ether, but is itself a social institution, governed by sets of rules restricting some and legitimizing other behaviours. Furthermore, the market is necessarily entwined with other social institutions, such as in many cases the local or national state. It can emerge spontaneously, but it can also be promoted or guided by conscious design.

A clear implication of this argument is that the unnuanced but familiar pro- and anti-market policy stances are both insensitive to the possibility of different types of market institution. Instead of recognizing the important role of different possible cultures and trading customs, both the opponents and the advocates of the market have focused exclusively on its general features. Thus, for instance, Marxists have deduced that the mere existence of private property and markets will themselves encourage acquisitive, greedy behaviour, with no further reference in their analysis to the role of ideas and culture in helping to form the aspirations of social actors. This is the source of their 'agoraphobia', or fear of markets. Obversely, overenthusiastic advocates of the market claim that its benefits stem simply and unambiguously from the existence of private property and exchange, without regard to possible variations in detailed market mechanism or cultural context. As strange bedfellows, both Marxists and some market advocates have underestimated the degree to which all market economies are unavoidably made up of densely layered social institutions.

Markov Chain Monte Carlo Methods

Siddhartha Chib

Abstract

MCMC methods, an important class of Monte Carlo methods, have played a major role in the growth of Bayesian statistics and econometrics. In an MCMC simulation, one samples a given distribution (say the posterior distribution in a Bayesian model) by simulating a suitably constructed Markov chain whose invariant distribution is the target distribution. The Metropolis–Hastings algorithm and its

special case, the Gibbs sampler, are two common ways of devising an MCMC simulation. We discuss how these methods originate, discuss implementation issues and provide examples. The use of MCMC methods in Bayesian prediction and model choice problems is also discussed.

Introduction

Markov chain Monte Carlo methods, popularly called MCMC methods, are a class of Monte Carlo methods for sampling a given univariate or multivariate probability distribution (the target distribution). These methods play a central role in the theory and practice of modern Bayesian methods where they are used for the numerical calculation of quantities (such as the moments and quantiles of posterior and predictive densities) that arise in the Bayesian prior–posterior analysis. They have transformed the fields of Bayesian statistics and econometrics.

Suppose that in a given Bayesian model the prior density is $\pi(\boldsymbol{\theta})$ and the sampling density or likelihood function is $f(\mathbf{y}|\boldsymbol{\theta})$, where $\mathbf{y}$ is a vector of observations and $\boldsymbol{\theta} \in \mathcal{R}^d$ is an unknown parameter. In the Bayesian context, inferences about $\boldsymbol{\theta}$ are based on the posterior density $\pi(\boldsymbol{\theta}|\mathbf{y}) \propto \pi(\boldsymbol{\theta}) f(\mathbf{y}|\boldsymbol{\theta})$. Now suppose that one is interested in finding the mean of the posterior density

$$E(\boldsymbol{\theta}|\,\mathbf{y}) = \int \boldsymbol{\theta}\pi(\boldsymbol{\theta}|\mathbf{y})d\boldsymbol{\theta}$$

but that the integral cannot be computed analytically. In that case one can compute the integral by Monte Carlo sampling methods. The general idea is to calculate the integral from a sample

$$\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(M)} \sim \pi(\boldsymbol{\theta}|\mathbf{y}),$$

that is drawn from the posterior density. This sample can be used to estimate the posterior mean and other features of the posterior density. For instance, the posterior mean can be estimated by the average of the sampled draws, and the quantiles of the posterior density by the quantiles of the sampled output.

The requisite sampling of the target density is made possible by MCMC methods. In a MCMC simulation, one samples the target density in an indirect way: by simulating a suitably constructed Markov chain whose invariant distribution is the target density. Then the draws beyond some chosen burn-in period are taken as a (correlated) sample from the target density. The defining feature of Markov chains is the property that the conditional density of $\boldsymbol{\theta}^{(j)}$ (the jth element of the sequence) conditioned on the entire preceding history of the chain depends only on the previous value $\boldsymbol{\theta}^{(j-1)}$. Denote this conditional density, the transition density of the Markov chain, by $p(\boldsymbol{\theta}^{(j-1)}, \cdot|\mathbf{y})$. Then, in the MCMC framework, a sample is produced by simulating the transition density as

$$\boldsymbol{\theta}^{(1)} \sim p\left(\boldsymbol{\theta}^{(0)}, \cdot\,|\mathbf{y}\right) \vdots\, \boldsymbol{\theta}^{(j)} \sim p\left(\boldsymbol{\theta}^{(j-1)}, \cdot\,|\mathbf{y}\right) \vdots$$

If we let the first n_0 cycles represent the burn-in phase, for some choice of n_0, the draws

$$\boldsymbol{\theta}^{(n_0+1)}, \boldsymbol{\theta}^{(n_0+2)}, \ldots, \boldsymbol{\theta}^{(n_0+M)}$$

are treated as those from $\pi(\boldsymbol{\theta}|\mathbf{y})$. Even though the sampled variates are correlated, laws of large numbers for Markov sequences can be used to show that, under regularity conditions, the sample average of any integrable function $g(\boldsymbol{\theta})$ converges to its posterior expectation:

$$M^{-1}\sum_{j=1}^{M} g\left(\boldsymbol{\theta}^{(j)}\right) \to \int g(\boldsymbol{\theta})\pi(\boldsymbol{\theta}|\mathbf{y})d\boldsymbol{\theta}, \qquad (1)$$

as M becomes large.

There are two common ways of constructing a transition density $p(\boldsymbol{\theta}^{(j-1)},\cdot|\mathbf{y})$ whose limiting distribution is the required target density. One way is by a method called the Metropolis–Hastings (M–H) algorithm, which was introduced by Metropolis et al. (1953) and Hastings (1970). Key references about this method are Tierney (1994), and Chib and Greenberg (1995). A second approach is by the so-called Gibbs sampling algorithm. This method was introduced by Geman and Geman (1984), Tanner and Wong (1987) and Gelfand and Smith (1990), and was the impetus for the current interest in Markov chain sampling methods. A summary of many aspects of MCMC methods is contained in Chib (2001) while textbook accounts include Gilks, Richardson and Spiegelhalter (1996), Chen, Shao and Ibrahim (2000), Liu (2001) and Robert and Casella (2004).

Metropolis–Hastings Algorithm

Suppose that we are interested in sampling the target density $\pi(\boldsymbol{\theta}|\mathbf{y})$, where $\boldsymbol{\theta}$ is a vector-valued parameter and $\pi(\boldsymbol{\theta}|\mathbf{y})$ is a continuous density. The idea behind the M–H algorithm is to simulate a proposal value $\boldsymbol{\theta}'$ from a transition density $q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ that is convenient to stimulate but does not necessarily have the correct limiting distribution and then to subject the proposal value to a specific randomization to ensure that the resulting Markov chain has the correct limiting distribution.

To define the M–H algorithm, let $\boldsymbol{\theta}^{(j-1)}$ be the current value. Then the next value $\boldsymbol{\theta}^{(j)}$ is produced by a two-step process consisting of a 'proposal step' and a 'move step'.

- *Proposal step*: Sample a proposal value $\boldsymbol{\theta}'$ from $q(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}|\mathbf{y})$ and calculate the quantity

$$\alpha\left(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}' \,|\, \mathbf{y}\right) = \min\left\{1, \frac{\pi(\boldsymbol{\theta}'|\,\mathbf{y})}{\pi\left(\boldsymbol{\theta}^{(j-1)}|\,\mathbf{y}\right)} \frac{q\left(\boldsymbol{\theta}', \boldsymbol{\theta}^{(j-1)}|\,\mathbf{y}\right)}{q\left(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}'|\,\mathbf{y}\right)}\right\}. \quad (2)$$

- *Move step*: Let $\boldsymbol{\theta}^{(j)} = \boldsymbol{\theta}'$ with probability $\alpha(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}'|\mathbf{y})$; remain at the current value $\boldsymbol{\theta}^{(j-1)}$ with probability $1 - \alpha(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}'|\mathbf{y})$.

In terms of nomenclature, the source density $q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ is called the candidate generating density or proposal density, and $\alpha(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}'|\mathbf{y})$ the *acceptance probability* or, more descriptively, the *probability of move*. Note also that the function $\alpha(\boldsymbol{\theta}^{(j-1)}, \boldsymbol{\theta}'|\mathbf{y})$ in this algorithm can be computed without knowledge of the norming constant of the posterior density $\pi(\boldsymbol{\theta}|\mathbf{y})$. In addition, if the proposal density is symmetric, satisfying the condition $q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = q(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y})$, then the acceptance probability reduces to $\pi(\boldsymbol{\theta}'|\mathbf{y})/\pi(\boldsymbol{\theta}^{(j-1)}|\mathbf{y})$; hence, if $\pi(\boldsymbol{\theta}') \geq \pi(\boldsymbol{\theta}^{(j-1)}|\mathbf{y})$, the chain moves to $\boldsymbol{\theta}'$, otherwise it moves to $\boldsymbol{\theta}'$ with probability given by $\pi(\boldsymbol{\theta}'|\mathbf{y})/\pi(\boldsymbol{\theta}^{(j-1)}|\mathbf{y})$. The latter is the algorithm of Metropolis et al. (1953).

Remark 1: Derivation of the M–H algorithm A question of some interest is the justification of this two-step approach. This question was tackled by Chib and Greenberg (1995) who derived the method from the logic of reversibility. A Markov transition density $p(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ is said to be reversible for $\pi(\boldsymbol{\theta}|\mathbf{y})$ if the following condition holds for every $(\boldsymbol{\theta}, \boldsymbol{\theta}')$ in the support of the target distribution:

$$\pi(\boldsymbol{\theta}|\mathbf{y})p(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = \pi(\boldsymbol{\theta}'|\mathbf{y})p(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y}). \quad (3)$$

The reversibility condition is important because reversible chains are invariant. Invariance refers to the property that

$$\pi(\boldsymbol{\theta}'|\mathbf{y}) = \int p(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})\pi(\boldsymbol{\theta}|\mathbf{y})\, d\boldsymbol{\theta} \quad (4)$$

which means that, if the transition density is invariant for the target density, then, once convergence is achieved, a subsequent value $\boldsymbol{\theta}'$ drawn from the transition density is also from the target density. To see that reversibility implies invariance one simply integrates both sides of Eq. (3) over $\boldsymbol{\theta}$. This leads to the invariance condition since $\int p(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})\, d\boldsymbol{\theta}' = 1$ by virtue of being a transition density. Now consider the Markov chain induced by the

proposal density $q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$. Because this was formulated without the reversibility condition in mind it is unlikely to satisfy reversibility. Suppose that for a pair of points $(\boldsymbol{\theta}, \boldsymbol{\theta}')$ it is true that

$$\pi(\boldsymbol{\theta}|\mathbf{y})q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) > \pi(\boldsymbol{\theta}'|\mathbf{y})q(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y}), \qquad (5)$$

which means informally that the process moves from $\boldsymbol{\theta}$ to $\boldsymbol{\theta}'$ too frequently and too rarely in the reverse direction. This situation can be corrected by reducing the flow from $\boldsymbol{\theta}$ to $\boldsymbol{\theta}'$ by introducing probabilities $\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ and $\alpha(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y})$ of making the moves in either direction so that

$$\begin{aligned}&\pi(\boldsymbol{\theta}|\mathbf{y})q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})\\ &\quad = \pi(\boldsymbol{\theta}'|\mathbf{y})q(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y})\alpha(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y}).\end{aligned}$$

One now sets $\alpha(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y})$ to be as high as possible, namely, equal to 1. Solving for $\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ one then gets

$$\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = \frac{\pi(\boldsymbol{\theta}'|\mathbf{y})}{\pi(\boldsymbol{\theta}|\mathbf{y})} \frac{q(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y})}{q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})}.$$

Because one started from Eq. (5) this is clearly less than 1. On the other hand, if the inequality in Eq. (5) were reversed, the same argumentation leads to the conclusion that $\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = 1$. Thus, on combining these two cases we reproduce the expression of $\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ given in Eq. (2).

Remark 2: Transition density of the M–H chain The transition density of the M–H chain has two components – one for the move away from $\boldsymbol{\theta}$ and given by $\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ and one for the probability of staying at $\boldsymbol{\theta}$ given by $r(\boldsymbol{\theta}|\mathbf{y}) = 1 - \int \alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})\, d\boldsymbol{\theta}'$. In particular,

$$\begin{aligned}p_{MH}(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = {} & \alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})\\ & + \delta_\theta(\boldsymbol{\theta}')r(\boldsymbol{\theta}|\mathbf{y})\end{aligned}$$

where $\delta_\theta(\boldsymbol{\theta}')$ is the Dirac-function at $\boldsymbol{\theta}$ defined as $\delta_\theta(\boldsymbol{\theta}') = 0$ for $\boldsymbol{\theta}' \neq \boldsymbol{\theta}$ and $\int \delta_\theta(\boldsymbol{\theta}')\, d\boldsymbol{\theta}' = 1$. It is easy to check that the integral of the transition density over all possible values of $\boldsymbol{\theta}$ is 1, as required.

Remark 3: Convergence properties The theoretical properties of the M–H algorithm (in particular the ergodic behaviour of the chain from an arbitrarily specified initial value) depend crucially on the nature of the proposal density. One requirement is that the proposal density be everywhere positive in the support of the posterior density, which means that the M–H chain can make a transition to any point in its support in one step. Further discussion of the conditions is given in Tierney (1994) and Robert and Casella (2004).

Remark 4: Mixing The sampled values from the M–H algorithm (as from any Markov chain) are correlated. The goal in any particular application is to ensure that the serial correlation is not excessive. One diagnostic to check for the degree of serial correlation in the sampled draws is the *autocorrelation time* or *inefficiency factor* of each component $\boldsymbol{\theta}_k$ of $\boldsymbol{\theta}$ defined as

$$a_k = \left\{1 + 2\sum_{s=1}^{M}\left(1 - \frac{s}{M}\right)\rho_{k_s}\right\},$$

where ρ_{ks} is the sample autocorrelation at lag s from the M sampled draws $\theta_k^{(n_0+1)}, \ldots, \theta_k^{(n_0+M)}$. One can interpret this quantity in terms of the *effective sample size*, or ESS, defined for the kth component of $\boldsymbol{\theta}$ as $ESS_k = \frac{M}{a_k}$. With independent sampling the autocorrelation times are theoretically equal to 1, and the effective sample size is M. When the inefficiency factors are high, the effective sample size is much smaller than M.

Choice of Proposal Density

One family of candidate-generating densities is given by $q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = q(\boldsymbol{\theta}' - \boldsymbol{\theta})$. The candidate $\boldsymbol{\theta}'$ is thus drawn according to the process $\boldsymbol{\theta}' = \boldsymbol{\theta} + \mathbf{z}$, where $\mathbf{z}$ follows the distribution q, and is called the *random walk M–H* chain. The random walk M–H chain is quite popular in applications. One has to be careful in setting the variance of $\mathbf{z}$ because if it is too large the chain may remain stuck at a particular value for many iterations, while if it is too small the chain will tend to make small moves and move inefficiently through the support of the target distribution.

Another possibility is to let $q(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = q(\boldsymbol{\theta}'|\mathbf{y})$, an *independence M–H chain* in the terminology of Tierney (1994). One way to implement such chains is by tailoring the proposal density to the target at the mode by a multi-variate normal or multivariate-t distribution with location given by the mode of the target and the dispersion given by inverse of the Hessian evaluated at the mode (Chib and Greenberg 1994, 1995).

Yet another way to generate proposal values is through a Markov chain version of the accept–reject method (Tierney 1994; Chib and Greenberg 1995). To explain this method, suppose $c > 0$ is a known constant and $h(\boldsymbol{\theta})$ a source density. Let $C = \{\boldsymbol{\theta} : \pi(\boldsymbol{\theta}|\mathbf{y}) \leq ch(\boldsymbol{\theta})\}$ denote the set of value for which $ch(\boldsymbol{\theta})$ dominates the target density. Given $\boldsymbol{\theta}^{(j-1)} = \boldsymbol{\theta}$ the next value $\boldsymbol{\theta}^{(j)}$ is obtained as follows. First, a candidate value $\boldsymbol{\theta}'$ is obtained, independent of the current value $\boldsymbol{\theta}$, by applying the accept–reject algorithm with $ch(\cdot)$ as the 'pseudo-dominating' density. The candidates $\boldsymbol{\theta}'$ that are produced under this scheme have density $q(\boldsymbol{\theta}'|\mathbf{y}) \propto \min\{\pi(\boldsymbol{\theta}'|\mathbf{y}); ch(\boldsymbol{\theta}')\}$. Then, the M–H probability of move is given by

$$\alpha(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y}) = \begin{cases} 1 & \text{if} \quad \boldsymbol{\theta} \in C \\ 1/w(\boldsymbol{\theta}) & \text{if} \quad \boldsymbol{\theta} \notin C, \boldsymbol{\theta}' \in C \\ \min\{w(\boldsymbol{\theta}')/w(\boldsymbol{\theta}), 1\} & \text{if} \quad \boldsymbol{\theta} \notin C, \boldsymbol{\theta}' \notin C \end{cases} \tag{6}$$

where $w(\boldsymbol{\theta}) = c^{-1}\pi(\boldsymbol{\theta}|\mathbf{y})/h(\boldsymbol{\theta})$.

Example

To illustrate the M–H algorithm, consider the binary response data in Table 1, on the occurrence or non-occurrence of infection following birth by Caesarean section. The response variable y is 1 if the Caesarean birth resulted in an infection, and zero if not. There are three covariates: x_1, an indicator of whether the caesarean was non-planned; x_2, an indicator of whether risk factors were present at the time of birth; and x_3, an indicator of whether antibiotics were given as a prophylaxis. The data in the table contains information from 251 births. Under the column of the response, an entry such as 11/87 means that there were 98 deliveries with covariates (1,1,1) of whom 11 developed an infection and 87 did not. Suppose that the probability of infection for the ith birth ($i \leq 251$) is

$$\Pr(y_i = 1|\mathbf{x}_i, \beta) = \Phi(\mathbf{x}_i'\beta), \tag{7}$$

$$\beta \sim N_4(0, 5\mathbf{I}_4) \tag{8}$$

where $\mathbf{x}_i = (1, x_{i1}, x_{i2}, x_{i3})^{\mathrm{T}}$ is the covariate vector, $\beta = (\beta_0, \beta_1, \beta_2, \beta_3)$ is the vector of unknown coefficients, Φ is the cdf of the standard normal random variable and $\mathbf{I}_4$ is the four-dimensional identity matrix. The target posterior density, under the assumption that the outcomes $\mathbf{y} = (y_1, y_2, ..., y_{251})$ are conditionally independent, is

$$\pi(\beta|\mathbf{y}) \propto \pi(\beta)\prod_{i=1}^{251}\Phi(\mathbf{x}_i'\beta)^{y_i}\{1 - \Phi(\mathbf{x}_i'\beta)\}^{(1-y_i)}$$

where $\pi(\beta)$ is the density of the $N(0,10\mathbf{I}_4)$ distribution.

To define the Chib and Greenberg (1994) tailored proposal density, let

$$\hat{\beta} = (-1.093022\ 0.607643\ 1.197543 - 1.904739)'$$

be the maximum likelihood estimate and let

$$\mathbf{v} = \begin{pmatrix} 0.040745 & -0.007038 & -0.039399 & 0.004829 \\ & 0.073101 & -0.006940 & -0.050162 \\ & & 0.062292 & -0.016803 \\ & & & 0.080788 \end{pmatrix}$$

M

be the symmetric matrix obtained by inverting the negative of the Hessian matrix (the matrix of second derivatives) of the log-likelihood function evaluated at $\hat{\beta}$. To generate proposal values, we use a multivariate-t density with 15 degrees of freedom, location given by $\hat{\beta}$ and dispersion given by $\mathbf{V}$. The M–H algorithm is run for 5000 iterations beyond a burn-in of 100 iterations. The prior–posterior summary is reported in Table 2. It contains the first two moments (the mean and the standard deviation) of the prior and posterior and the 2.5th (lower) and 97.5th (upper) percentiles of the marginal densities of β.

In addition, we plot in Fig. 1 the four marginal posterior densities. These are derived by smoothing the histogram of the simulated values with a Gaussian kernel. In the same plot we also report the autocorrelation functions (correlation against

Markov Chain Monte Carlo Methods, Table 2 Caesarean data: prior–posterior summary based on 5000 draws (beyond a burn-in of 100 cycles) from the tailored M–H algorithm

lag) for each of the sampled parameter values. The serial correlations decline quickly to zero indicating that the algorithm is mixing well.

Multiple-Block M–H Algorithm

When the dimension of $\boldsymbol{\theta}$ is large it is often necessary to divide the parameters into smaller groups or blocks and then to sample the blocks in turn. For simplicity suppose that two blocks are adequate and that $\boldsymbol{\theta}$ is written as $(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$, with $\boldsymbol{\theta}_k \in \Omega_k \subseteq \mathcal{R}^{d_k}$. To sample these blocks let

$$q_1(\boldsymbol{\theta}_1, \boldsymbol{\theta}_1' | \mathbf{y}, \boldsymbol{\theta}_2); q_2(\boldsymbol{\theta}_2, \boldsymbol{\theta}_2' | \mathbf{y}, \boldsymbol{\theta}_1),$$

denote the two proposal densities, one for each block $\boldsymbol{\theta}_k$, where the proposal density q_k may depend on the current value of the remaining block. Also, define

$$\alpha(\boldsymbol{\theta}_1, \boldsymbol{\theta}_1' | \mathbf{y}, \boldsymbol{\theta}_2) = \min\left\{\frac{\pi(\boldsymbol{\theta}_1', \boldsymbol{\theta}_2 | \mathbf{y}) q_1(\boldsymbol{\theta}_1', \boldsymbol{\theta}_1 | \mathbf{y}, \boldsymbol{\theta}_2)}{\pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 | \mathbf{y}) q_1(\boldsymbol{\theta}_1, \boldsymbol{\theta}_1' | \mathbf{y}, \boldsymbol{\theta}_2)}, 1\right\}$$

and

$$\alpha(\boldsymbol{\theta}_2, \boldsymbol{\theta}_2' | \mathbf{y}, \boldsymbol{\theta}_1) = \min\left\{\frac{\pi(\boldsymbol{\theta}_1', \boldsymbol{\theta}_2 | \mathbf{y}) q_2(\boldsymbol{\theta}_2', \boldsymbol{\theta}_2 | \mathbf{y}, \boldsymbol{\theta}_1)}{\pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 | \mathbf{y}) q_2(\boldsymbol{\theta}_2, \boldsymbol{\theta}_2' | \mathbf{y}, \boldsymbol{\theta}_1)}, 1\right\}$$

as the probability of move for block $\boldsymbol{\theta}_k$ conditioned on the other block. Then, in what may be called the multiple-block M–H algorithm, one updates each block using an M-H step with the above probability of move, given the most current value of the other block. The method can be extended to several blocks in the same way.

Remark 5 An important special case arises if each proposal density is the full conditional density of that block. Specifically, if we set

$$q_1(\boldsymbol{\theta}_1, \boldsymbol{\theta}_1' | \mathbf{y}, \boldsymbol{\theta}_2) \propto \pi(\boldsymbol{\theta}_1', \boldsymbol{\theta}_2 | \mathbf{y}),$$
$$q_1(\boldsymbol{\theta}_1', \boldsymbol{\theta}_1 | \mathbf{y}, \boldsymbol{\theta}_2) \propto \pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 | \mathbf{y})$$

and

$$q_2(\boldsymbol{\theta}_2, \boldsymbol{\theta}_2' | \mathbf{y}, \boldsymbol{\theta}_1) \propto \pi(\boldsymbol{\theta}_1', \boldsymbol{\theta}_2 | \mathbf{y}),$$
$$q_2(\boldsymbol{\theta}_2', \boldsymbol{\theta}_2 | \mathbf{y}, \boldsymbol{\theta}_1) \propto \pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 | \mathbf{y})$$

then an interesting simplification occurs. The probability of move (for the first block) becomes

$$\alpha_1(\boldsymbol{\theta}_1, \boldsymbol{\theta}_1' | \mathbf{y}, \boldsymbol{\theta}_2) = \min\left\{1, \frac{\pi(\boldsymbol{\theta}_1', \boldsymbol{\theta}_2 | \mathbf{y}) \pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 | \mathbf{y})}{\pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 | \mathbf{y}) \pi(\boldsymbol{\theta}_1', \boldsymbol{\theta}_2 | \mathbf{y})}\right\} = 1,$$

and similarly for the second block, implying that, if proposal values are drawn from their full conditional densities, then the proposal values are accepted with probability one. This special case is called the Gibbs sampling algorithm.

The Gibbs Sampling Algorithm

The Gibbs sampling was introduced by Geman and Geman (1984) in the context of image processing and then discussed in the context of missing data problems by Tanner and Wong (1987). It was brought into prominence by Gelfand and Smith (1990) who demonstrated its use in a range of Bayesian problems.

The Algorithm

Suppose that the parameters are grouped into two p blocks $(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \ldots, \boldsymbol{\theta}_p)$ with the associated set of full conditional distributions

$$\{\pi(\boldsymbol{\theta}_1 | \mathbf{y}, \boldsymbol{\theta}_2, \ldots, \boldsymbol{\theta}_p); \pi(\boldsymbol{\theta}_2 | \mathbf{y}, \boldsymbol{\theta}_1, \boldsymbol{\theta}_3, \ldots, \boldsymbol{\theta}_p); \ldots \pi(\boldsymbol{\theta}_p | \mathbf{y}, \boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_{d-1})\},$$

where each full conditional distribution is proportional to $\pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \ldots, \boldsymbol{\theta}_p) | \mathbf{y})$. Then, one cycle of the Gibbs sampling algorithm is completed by simulating $\{\boldsymbol{\theta}_k\}_{k=1}^{p}$ from these distributions, recursively refreshing the conditioning variables.

Sufficient Conditions for Convergence

Under rather general conditions, the Markov chain generated by the Gibbs sampling algorithm converges to the target density as the number of

M

iterations become large. Formally, if we let $p_G(\boldsymbol{\theta}, \boldsymbol{\theta}'|\mathbf{y})$ represent the transition density of the Gibbs algorithm and let $p_G^{(M)}(\boldsymbol{\theta}', \boldsymbol{\theta}|\mathbf{y})$ be the density of the draw $\boldsymbol{\theta}'$ after M iterations given the starting value $\boldsymbol{\theta}_0$, then

$$\left\| p_G^{(M)}(\boldsymbol{\theta}^{(0)}, \boldsymbol{\theta}' | \mathbf{y} - \pi(\boldsymbol{\theta}' | \mathbf{y}) \right\| \to 0, \quad \text{as} \quad M \to \infty. \tag{9}$$

Roberts and Smith (1994) (see also Chan 1993) have shown that this convergence occurs under the following weak conditions: (i) $\pi(\boldsymbol{\theta}|\mathbf{y}) > 0$ implies there exists an open neighbourhood N_θ containing $\boldsymbol{\theta}$ and $\varepsilon > 0$ such that, for all $\boldsymbol{\theta}' \in N_\theta$, $\pi(\boldsymbol{\theta}'|\mathbf{y}) \geq \varepsilon > 0$; (ii) $\int \pi(\boldsymbol{\theta}|\mathbf{y}) d\boldsymbol{\theta}_k$ is locally bounded for all k, where $\boldsymbol{\theta}_k$ is the kth block of parameters; and (iii) the support of $\boldsymbol{\theta}$ is arc connected.

MCMC Sampling with Latent Variables

MCMC sampling can involve not just parameters but also latent variables. This idea was called data augmentation by Tanner and Wong (1987) in the context of missing data problems.

To fix notations, suppose that $\mathbf{z}$ denotes a vector of latent variables and let the modified target distribution be $\pi(\boldsymbol{\theta}, \mathbf{z}|\mathbf{y})$. If the latent variables are tactically introduced, the conditional distribution of $\boldsymbol{\theta}$ (or sub-components of $\boldsymbol{\theta}$) given $\mathbf{z}$ may be easy to derive. Then, a multiple-block M–H simulation is conducted with the blocks $\boldsymbol{\theta}$ and $\mathbf{z}$ leading to the sample

$$\left(\boldsymbol{\theta}^{(n_0+1)}, \mathbf{z}^{(n_0+1)}\right), \ldots, \left(\boldsymbol{\theta}^{(n_0+M)}, \mathbf{z}^{(n_0+M)}\right) \sim \pi(\boldsymbol{\theta}, \mathbf{z} | \mathbf{y}),$$

where the draws on $\boldsymbol{\theta}$, ignoring those on the latent data, are from $\pi(\boldsymbol{\theta}|\mathbf{y})$, as required.

To demonstrate this technique in action, consider the probit regression example discussed in section "Example". Albert and Chib (1993) introduced a technique for this and related models that capitalizes on the simplifications afforded by introducing latent data into the sampling. The Albert–Chib method has found wide use and has made possible the routine analysis of models for categorical responses. To begin, let

$$z_i | \beta \sim N(\mathbf{x}_i' \beta, 1),$$
$$y_i = I[z_i > 0], \quad i \leq n,$$
$$\beta \sim N_k(\beta_0, \mathbf{B}_0). \tag{10}$$

This specification is equivalent to the probit model since $\Pr(y_i = 1 | \mathbf{x}_i, \beta) = \Pr(z_i > 0 | \mathbf{x}_i, \beta) = \Phi(\mathbf{x}_i' \beta)$. Now the MCMC sampling is based on the full conditional distributions

$$\beta | \mathbf{y}, \{z_i\}; \quad \{z_i\} | \mathbf{y}, \beta,$$

which are both tractable. In particular, the distribution of β conditioned on the latent data becomes independent of the observed data and has the same form as in the Gaussian linear regression model with the response data given by $\{z_i\}$ and is multivariate normal with mean $\hat{\beta} = \mathbf{B}\left(\mathbf{B}_0^{-1}\beta_0 + \sum_{i=1}^n \mathbf{x}_i z_i\right)$ and variance matrix $\mathbf{B} = \left(\mathbf{B}_0^{-1} + \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i'\right)^{-1}$. Next, the distribution of the latent data conditioned on the data and the parameters factor into a set of n independent distributions with each depending on the data through y_i:

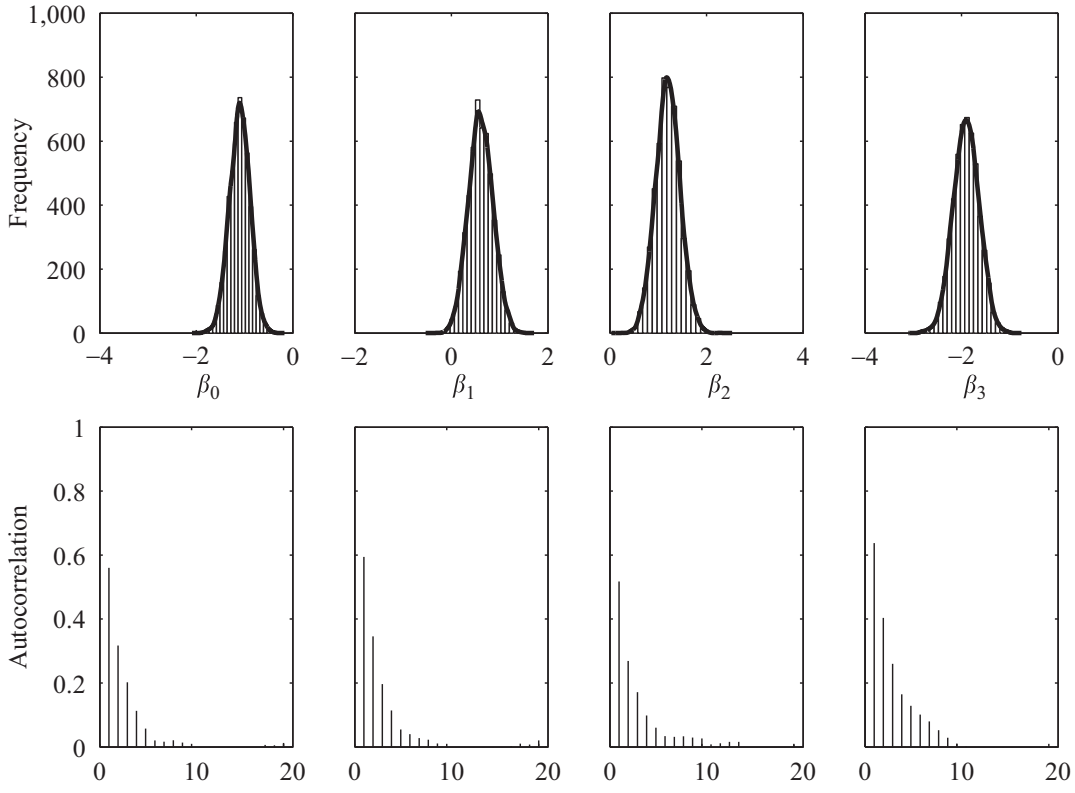
$$\{z_i\} | \mathbf{y}, \beta \overset{d}{=} \prod_{i=1}^n z_i | y_i, \beta,$$

where the distribution $z_i|\mathbf{y}_i, \beta$ is the normal distribution $z_i|\beta$ truncated by the knowledge of y_i; if $y_i = 0$, then $z_i \leq 0$ and if $y_i = 1$, then $z_i > 0$. Thus, one samples z_i from $TN_{(-\infty,0)}(\mathbf{x}_i'\beta, 1)$ if $y_i = 0$ and from $TN_{(0,\infty)}(\mathbf{x}_i'\beta, 1)$ if $y_i = 1$, where $TN_{(a;b)}(\mu, \sigma^2)$ denotes the $N(\mu, \sigma^2)$ distribution truncated to the region (a, b).

We apply this method to the example considered in section "Example" above and report the results in Fig. 2. We see the close agreement between the two sets of results.

Strategies for Improving Mixing

In practice, while implementing MCMC methods it is important to construct samplers that mix well, where mixing is measured by the autocorrelation



Markov Chain Monte Carlo Methods, Fig. 2 Caesarean data with Albert–Chib algorithm: marginal posterior densities (*top panel*) and autocorrelation plot (*bottom panel*)

time, because such samplers can be expected to converge more quickly to the invariant distribution.

Choice of Blocking

As a general rule, sets of parameters that are highly correlated should be treated as one block when applying the multiple-block M–H algorithm. Otherwise, it would be difficult to develop proposal densities that lead to large moves through the support of the target distribution.

Blocks can be combined by the method of composition. For example, suppose that $\boldsymbol{\theta}_1$, $\boldsymbol{\theta}_2$ and $\boldsymbol{\theta}_3$ denote three blocks and that the distribution $\boldsymbol{\theta}_1|\mathbf{y}, \boldsymbol{\theta}_3$ is tractable (that is, can be sampled directly). Then, the blocks $(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ can be collapsed by first sampling, $\boldsymbol{\theta}_1$ from $\boldsymbol{\theta}_1|\mathbf{y}, \boldsymbol{\theta}_3$ followed by $\boldsymbol{\theta}_2$ from $\boldsymbol{\theta}_2|\mathbf{y}, \boldsymbol{\theta}_1; \boldsymbol{\theta}_3$. This amounts to a two-block MCMC algorithm. In addition, if it is possible to sample $(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ marginalized over $\boldsymbol{\theta}_3$ then the number of blocks is reduced to one. Liu (1994) discusses the value of these strategies in the context of a three-block Gibbs MCMC chain. Roberts and Sahu (1997) provide further discussion of the role of blocking in the context of Gibbs Markov chains used to sample multivariate normal target distributions.

Tuning the Proposal Density

The proposal density in an M–H algorithm has an important bearing on the mixing of the MCMC chain. Chib and Greenberg (1994, 1995), Tierney (1994), Tierney and Mira (1999) and Liu (2001) discuss various possibilities for formulating proposal density that can be helpful in a variety of problems.

Prediction and Model Choice

In some settings, for example in models for time series data, an important goal is prediction. In the

Bayesian context, a future observation y_f is predicted through the (predictive) density defined as

$$f\left(y_f|\mathbf{y}\right) = \int f(y_f|\mathbf{y},\boldsymbol{\theta})\pi(\boldsymbol{\theta}|\,\mathbf{y})\,d\boldsymbol{\theta},$$

where $f\left(y_f|\,\mathbf{y},\mathcal{M},\,\boldsymbol{\theta}\right)$ is the conditional density of y_f given (y, $\boldsymbol{\theta}$). In general, the predictive density is not available in closed form. It can be shown, however, that, if one simulates $y_f^{(j)} \sim f\left(y_f|\mathbf{y},\boldsymbol{\theta}^{(j)}\right)$ for each sampled draw $\boldsymbol{\theta}^{(j)}$ from the MCMC simulation, then the collection of simulated values $\left\{y_f^{(1)},\ldots,y_f^{(M)}\right\}$ is a sample from $f(y_f|\mathbf{y})$. This simulated sample can be summarized in the usual way.

MCMC methods have also been widely applied to the problem of the model choice. Suppose that there are K possible models $\mathcal{M}_1,\ldots,\mathcal{M}_K$ for the observed data defined by the sampling densities $\{f(\mathbf{y}|\,\boldsymbol{\theta}_k,\mathcal{M}_k)\}$ and proper prior densities $\{p(\boldsymbol{\theta}_k|\mathcal{M}_k\}$ and the objective is to find the evidence in the data for the different models. In the Bayesian approach this question is answered by placing prior probabilities $\Pr(\mathcal{M}_k)$ on each of the K models and using the Bayes calculus to find the posterior probabilities $\{\Pr(\mathcal{M}_1|\,\mathbf{y}),\ldots,\Pr(\mathcal{M}_K|\mathbf{y}\}$ conditioned on the data but marginalized over the unknowns $\boldsymbol{\theta}_k$ (Jeffreys 1961). Specifically, the posterior probability of $\mathcal{M}_k$ is given by the expression

$$\begin{aligned}\Pr(\mathcal{M}_k|\,\mathbf{y}) &= \frac{\Pr(\mathcal{M}_k)m(\mathbf{y}|\,\mathcal{M}_k)}{\sum_{l=1}^{K}\Pr(\mathcal{M}_l)m(\mathbf{y}|\,\mathcal{M}_l)}\\ &\propto \Pr(\mathcal{M}_k)m(\mathbf{y}|\,\mathcal{M}_k),\quad (k\le K)\end{aligned}$$

where $m(\mathbf{y}|\,\mathcal{M}_k)$ is the marginal likelihood of $\mathcal{M}_k$.

A problem in estimating the marginal likelihood is that it is an integral of the sampling density over the prior distribution of $\boldsymbol{\theta}_k$. Thus, MCMC methods, which deliver sample values from the posterior density, cannot be used to directly average the sampling density. One method for dealing with this difficulty is due to Chib (1995). The starting point is the expression

$$m(\mathbf{y}|\,\mathcal{M}_k) = \frac{f(\mathbf{y}|\,\boldsymbol{\theta}_k,\mathcal{M}_k)p(\boldsymbol{\theta}_k|\,\mathcal{M}_k)}{\pi(\boldsymbol{\theta}_k|\,\mathbf{y},\mathcal{M}_k)}$$

which is an identity in $\boldsymbol{\theta}_k$. From here an estimate of the marginal likelihood on the log-scale is given by

$$\begin{aligned}\log\hat{m}(\mathbf{y}|\,\mathcal{M}_k) = &\log f\left(\mathbf{y}|\,\boldsymbol{\theta}_k^*,\mathcal{M}_k\right)\\ &+\log p\left(\boldsymbol{\theta}_k^*|\,\mathcal{M}_k\right)\\ &-\log\hat{\pi}\left(\boldsymbol{\theta}_k^*|\,\mathbf{y},\mathcal{M}_k\right)\end{aligned}$$

where $\boldsymbol{\theta}_k^*$ denotes an arbitrarily chosen point and $\hat{\pi}\left(\boldsymbol{\theta}_k^*|\,\mathbf{y},\mathcal{M}_k\right)$ is the estimate of the posterior density at that single point. To estimate the posterior ordinate one utilizes the Gibbs output in conjunction with a decomposition of the ordinate into marginal and conditional components. Chib and Jeliazkov (2001) extend this approach for output produced by the M–H algorithm while Basu and Chib (2003) show how the method can be applied in semiparametric models.

In some cases one is interested in a large number of candidate models, each with parameters $\boldsymbol{\theta}_k \in B_k \subseteq R^{d_k}$. In such cases one can get information about the relative support for the contending models from a model space-parameter space MCMC algorithm. In these algorithms, the models are represented by a categorical variable $\mathcal{M}$ which is then sampled along with the parameters of each model. The posterior distribution of $\mathcal{M}$ is computed as the frequency of times each model is visited. Methods for doing this have been proposed by Carlin and Chib (1995) and Green (1995). Both methods are closely related as shown by Dellaportas et al. (2002) and Godsill (2001). Related methods for the problem of variable selection have also been developed starting with George and McCulloch (1993).

Markov Equilibria in Macroeconomics

Dirk Krueger and Felix Kubler

Abstract

We review the recent literature in macroeconomics that analyses Markov equilibria in dynamic general equilibrium model. After defining the Markov equilibrium concept we first summarize what is known about the existence and uniqueness of such equilibria in models where sequential equilibria can be obtained by solving a suitable social planner

problem. We then discuss the existence problems of Markov equilibria in models where equivalence of equilibrium allocations and solutions to social planner problems cannot be established and review techniques the literature has developed to deal with the existence problem, as well as recent applications of these techniques in macroeconomics.

We say that a dynamic economy has a Markovian structure (or is Markovian, for short) if the stochastic processes that specify the fundamentals of the economy (such as endowments, preferences and technologies) are Markov processes. Note that deterministic economies are special cases in which the stochastic processes for the fundamentals have degenerate distributions. In many applications attention is restricted to first-order Markov processes in which the probability distributions over fundamentals today are functions exclusively of their values yesterday.

In dynamic economies sequential equilibria are sequences of functions mapping histories of realizations of the stochastic process of the fundamentals into allocations and prices such that all agents in the economy maximize their objectives, given prices, and all markets clear. Under fairly mild conditions (that is, convexity and continuity assumptions on the primitives) such equilibria exist. However, in order to characterize and compute equilibria it is often useful to look for equilibria of a different form.

Recursive Markov equilibria can be characterized by a state space, a policy function and a transition function. The policy function maps the state today into current endogenous choices and prices, and the transition function maps the state today into a probability distribution over states tomorrow (see, for example, the definition in Ljungqvist and Sargent's 2000 textbook). In most of this survey we will use the terms 'Markov equilibria' and 'recursive Markov equilibria' interchangeably; however, below we also consider Markov equilibria which are not recursive and refer to these as 'generalized Markov equilibria'. This characterization leaves open, of course, what the appropriate state variables are that constitute the state space.

Most simply, the state space would consist of the set of possible exogenous shocks governing endowments, preferences and technologies. But, other than in exceptional cases (see, for example, Lucas's 1978 asset pricing application where asset prices are solely functions of the underlying shocks to technology), such a strongly stationary Markov equilibrium does not exist.

In addition to the exogenous shocks, endogenous variables have to be included in the state space to assure existence of a Markov equilibrium. We define as the minimal state space the space of all exogenous shocks and endogenous variables that are payoff-relevant today, in that they affect current production or consumption sets or preferences (see Maskin and Tirole 2001).

We call Markov equilibria with this minimal state space 'simple Markov equilibria'. In the remainder of this article we want to discuss what we know about the existence and uniqueness of such Markov equilibria, both in general and for important specific examples. As it turns out, when equilibria are Pareto efficient, and thus equilibrium allocation can be determined by solving a suitable social planner problem, simple Markov equilibria can be shown to exist under fairly mild conditions. We therefore discuss this case first. On the other

hand, when equilibria are not Pareto efficient – for example, when markets are incomplete or economic agents behave strategically – forward-looking variables often have to be included for a Markov equilibrium to exist; therefore, simple Markov equilibria in the sense defined above do not exist in general. We discuss this case in Section 2.

Markov Equilibria in Economies Where Equilibria Are Pareto Optimal

In this section we discuss the existence and uniqueness of simple Markov equilibria in economies whose sequential market equilibrium allocations can be determined as solutions to a suitable social planner problem. In these economies the problem of proving the existence of a Markov equilibrium reduces to showing that the solution of the social planner can be written as a time-invariant optimal policy function of the minimal set of state variables, as defined above.

This is commonly done by reformulating the optimization problem of the social planner as a functional equation and showing that the optimal Markov policy function generates a sequential allocation which solves the original social planner problem; this is what Bellman (1957) called the principle of optimality. This principle can be established under weak conditions (see Stokey et al. 1989). Equipped with this result, the existence of a Markov equilibrium then follows from the existence of a solution to the functional equation associated with the social planner problem.

If the functional equation can be shown to be a contraction mapping (sufficient conditions for this were provided by Blackwell 1965), then it follows that there exists a unique value function solving the functional equation and an optimal policy correspondence. In addition, the contraction mapping theorem also gives an iterative procedure to find the solution to the functional equation from any starting guess, which is helpful for numerical work.

Under weaker conditions other fixed-point theorems may be employed to argue at least for the existence (if not uniqueness) of a solution to the functional equation, with associated optimal Markov policy correspondence. In order to establish that the policy correspondence is actually a function (and thus the Markov equilibrium is unique), in general strict concavity of the return function needs to be assumed. Stokey et al. (1989) provide a summary of the main results in the general theory of dynamic programming.

This technique of analysing and computing dynamic equilibria in Pareto optimal economies is now widely used in macroeconomics. Its first application can be found in Lucas and Prescott (1971) in their study of optimal investment behaviour under uncertainty. Lucas (1978) used recursive techniques to study asset prices in an endowment economy and showed that the Markov equilibrium has a particularly simple form. Kydland and Prescott (1982) showed how powerful these techniques are for a quantitative study of the business cycle implications of the neoclassical growth model with technology shocks to production. The volume by Cooley (1995) provides a comprehensive overview over this line of research.

M

Generalized Markov Equilibria

In models where the first welfare theorem is not applicable (for example, models with incomplete financial markets or with distorting taxes), in models where there are infinitely many agents (such as overlapping generations models) or in models with strategic interaction the existence of simple Markov equilibria (that is, Markov equilibria with minimal state space) cannot be guaranteed. See Santos 2002; Krebs 2004; Kubler and Schmedders 2002; and Kubler and Polemarchakis 2004, for simple counter-examples. An important exception is Bewley-style models with incomplete markets where simple recursive Markov equilibria exist; see, for example, Krebs 2006. The functional equations characterizing equilibrium have no contraction properties, and more general fixed-point theorems than the contraction mapping theorem, such as Schauder's fixed-point theorem, cannot be applied because it is difficult to guarantee compactness of the space of admissible functions.

Coleman (1991) is an important example where existence can be shown. However, his results rely on monotonicity conditions on the equilibrium dynamics which are not satisfied in general models.

In the applied literature a solution to this problem was suggested early on. For example Kydland and Prescott (1980) analyse a Ramsey dynamic optimal taxation problem. To make the problem recursive they add as a state variable last period's marginal utility.

On the theoretical side Duffie et al. (1994) were the first to rigorously analyse situations where recursive equilibria may fail to exist in general equilibrium models. Kubler and Schmedders (2003) and Miao and Santos (2005) refine their approach and make it applicable for computations. Miao and Santos (2005), also give a clear explanation of how this approach relates to the work by Abreu et al. (1990). We now present their basic idea.

Consider a Markovian economy where a date-event (or node) can be associated with a finite history of shocks, $S^t = (s_0, \ldots, s_t)$. The shocks follow a Markov chain with support $\mathcal{S} = \{1, \ldots, S\}$. Denote by $z(s^t)$ the vector of all endogenous variables at node s^t. Typically this would include the vector of household asset holdings across individuals and the capital stock at the beginning of the period, but also prices and endogenous choices at note s^t, as well as shadow variables such as Lagrange multipliers. A competitive equilibrium is a process of endogenous variables $\{z(s^t)\}$ with $z(s^t) \in \mathcal{Z} \subset \mathbb{R}^M$, which solve the optimization problems of all agents in the economy, and clear markets. The set $\mathcal{Z}$ denotes the set of all possible values of the endogenous variables.

We focus on dynamic economic models where an equilibrium can be characterized by a set of equations relating current-period exogenous and endogenous variables to endogenous and exogenous variables next period. It is straightforward to incorporate inequality constraints into this framework. For expositional purposes we focus on equations. Examples of such equations are the Euler equations of individual households, first order conditions of firms, as well as market-clearing conditions for all markets. We assume that such a set of equations characterizing equilibrium is given and denote it by

$$h(\hat{s}, \hat{z}, z_1, \ldots, z_S) = 0.$$

The arguments $(\hat{s}, \hat{z})$ denote the exogenous state variables and endogenous variables for the current period. Note that the endogenous variables might contain variables which were determined in the previous period, such as the capital stock and individuals' assets. The variables $(z_s)_{s=1}^S$ denote endogenous variables in the subsequent period, in states $s = 1, \ldots, S$, respectively. We refer to $h(\cdot) = 0$ as the set of 'equilibrium equations'.

As explained above, to analyse Markov equilibria one needs to specify an appropriate state space. We assume that the equilibrium set $\mathcal{Z}$ can be written as the product $\mathcal{Y} \times \hat{\mathcal{Z}}$, where $\mathcal{Y}$ denotes the set into which the endogenous state variables fall. In the neoclassical growth model, $\mathcal{Y}$ would consist of the set of possible values of the capital stock; in models with heterogeneous agents one would need to add the set of possible wealth distributions across agents. Unfortunately, as the references cited above show, a recursive Markov equilibrium with this state space may not exist. We therefore require a more general notion of Markov equilibrium for these types of economies.

A *generalized Markov equilibrium* consists of a (non-empty valued) 'policy correspondence', P, that maps the state today into possible endogenous variables today, and a 'transition function', F, that maps the state and endogenous variables today into endogenous variables next period. Formally, the maps

$$P : \mathcal{S} \times \mathcal{Y} \rightrightarrows \hat{\mathcal{Z}} \text{ and } F : \text{graph}(P) \to \mathcal{Z}^S$$

should satisfy that for all shocks and endogenous variables in the current period, $(\hat{s}, \hat{z}) \in \text{graph}(P)$, the transition function prescribes values next period that are consistent with the equilibrium equations, that is,

$$h(\hat{s}, \hat{z}, F(\hat{s}, \hat{z})) = 0,$$

and lie in the policy correspondence, that is,

$$(s, F_s(\hat{s}, \hat{z})) \in \text{graph}(P) \text{ for all } s \in \text{S}.$$

It follows that a generalized Markov equilibrium is recursive, according to our earlier definition, if the associated policy correspondence is single valued. It is simple if the state space is the natural minimal state space.

It is easy to see that Markov equilibria are in fact competitive equilibria in the usual sense. Duffie et al. (1994) show that, under mild assumptions on the primitives of the model, generalized Markov equilibria exist whenever competitive equilibria exist. The basic idea of their approach is very similar to backward induction, using critically a natural monotonicity property of the inverse of the equilibrium equations. (See their original paper, Kubler and Schmedders (2003), or Miao and Santos (2005), for details.)

For practical purposes it is of course crucial that the chosen state space is relatively small and that the Markov equilibrium is recursive. In an asset pricing model with heterogeneous agents, Kubler and Schmedders choose the state space to consist of the beginning-of-period wealth distribution, but can show the existence only of a generalized Markov equilibrium. One cannot rule out the possibility that the equilibrium is not recursive; the same value of the state variables might occur with different values of the endogenous variables. The counter-examples to existence mentioned above show that this is precisely the problem. If for given initial conditions there exist multiple competitive equilibria, the one that realizes is pinned down by lagged variables. Without ruling out multiplicity of equilibria, it does not seem possible to prove the existence of recursive equilibria with the natural state space.

Miao and Santos (2005) enlarge the state space with the shadow values of investment of all agents and prove that with this larger state space a recursive Markov equilibrium exists. The basic insight of their approach is that one needs to add variables to the natural state space that uniquely select one out of several possible endogenous variables.

The main practical problem with the approach originated by Duffie et al. (1994) and refined by Miao and Santos (2005) is that it provides a method to construct all Markov equilibria. There might exist some recursive equilibria for the natural (minimal) state space, but this approach naturally solves for all other recursive Markov equilibria as well. Datta et al. 2005, provide ideas for solving for the one Markov equilibrium with minimal state space.

In many recent applications of recursive methods to macroeconomics the focus of researchers studying non-optimal economies is to find a recursive equilibrium with minimal state space. Notable examples in which even this natural state space is large are Rios-Rull (1996), Heaton and Lucas (1996) and Krusell and Smith (1998). They mark the boundary of economies that currently can be analysed with recursive techniques.

In dynamic endowment economies with either informational frictions or limited enforceability of contracts, constrained-efficient (efficient, subject to the informational or enforcement constraints) consumption allocations usually display a high degree of dependence on past endowment shocks, even though the natural state space contains only the current endowment shock. Therefore, Markov equilibria with minimal state space do not exist. However, using ideas by Spear and Srivastava (1987) and Abreu et al. (1990), the papers by Atkeson and Lucas (1992) and Thomas and Worrall (1988) demonstrate that nevertheless the constrained social planner problem has a convenient recursive structure if one includes promised lifetime utility as a state variable into the recursive problem. This approach or its close alternative, namely, to introduce as an additional state variable Lagrange multipliers on the incentive or enforcement constraints (as in Marcet and Marimon 1998), has seen many applications in macroeconomics, since it facilitates making a large class of dynamic models with informational or enforcement frictions recursive and hence tractable. Miao and Santos (2005) show how such problems with strategic interactions can be incorporated into the framework above.

In optimal policy problems in which the government has no access to a commitment technology, a discussion has emerged about the

desirability of a restriction to Markov policies with minimal state space. Such restrictions rule out reputation if one confines attention to smooth policies. See Phelan and Stacchetti (2001) and Klein and Rios-Rull (2003) for examples of the two opposing views on this issue. However, as Krusell and Smith (2003) argue, if one allows discontinuous policy functions reputation effects can be generated even with Markov policies. (While Krusell and Smith discuss optimal decision rules in a consumption–savings problem with quasi-geometric discounting, their results carry over to optimal policy problems without commitment on the part of the policymaker.)

Markov Processes

Daniel W. Stroock

Abstract

In this article the theory of Markov processes is described as an evolution on the space of probability measures. Following a brief historical account of its origins in physics, a mathematical formulation of the theory is given. Emphasis has been placed on the ergodic properties of Markov processes, and their presence is checked in a simple example.

Keywords

Unless one is clairvoyant, the only temporally evolving processes which are tractable are those whose future behaviour can be predicted on the basis of data which is available at the time when the prediction is being made. Of course, in general, the behaviour of even such an evolution will be impossible to predict. For example, if, in order to make a prediction, one has to know the detailed history of everything that has happened during the entire history of the entire universe, one's chance of making a prediction may be a practical, if not a theoretical, impossibility. For this reason, one tries to study evolutions mathematically with models in which most of the distant past can be ignored when one makes predictions about the future. In fact, many mathematical models of evolutions have the property that, for the purpose of predicting the future, the past becomes irrelevant as soon as one knows the present, in which case the evolution is said to be a 'Markov process', the topic at hand, after Andrei Andreyevich Markov (1856–1922).

The components of a Markov process are its *state space* S and its *transition rule T*. Mathematically, S is just some non-empty set, which in applications will encode all the possible states in which the evolving system can find itself, and $T : S \to S$ is a function from S into itself which gives the *transition rule*. More precisely, if now the system is in state x, it will be next in state $T(x)$, from which it will go to $T^2(x) = T(T(x))$, and so on. (Here we are thinking of time being discrete. Thus, 'next' means after one unit of time has passed.)

To give a sense of the sort of reasoning required to construct a Markov process, consider a (classical) physical particle whose motion is governed by Newton's equation $\Rightarrow F = m \Rightarrow a$ ('force equals mass times acceleration'). At least in theory, Newton's equation says that, on the assumption that one knows the mass of the particle and the force field $\Rightarrow F$ which acts on it, one can predict where the particle will be in the future as soon as one knows what its position and velocity are now. On the other hand, knowing only its present position is not sufficient by itself. Thus, even though one may care about nothing but its position, in order to produce a Markov process for a particle evolving according to Newton's equation it is necessary to adopt the attitude that the *state* of the particle consists of its position *and* velocity, not just its position alone. Of course, in that velocity is the derivative of position, the two are so inextricably intertwined that one might be tempted to concentrate on position on the grounds that one will be able to compute the velocity whenever necessary. However, this tack destroys the Markov property, namely, there is no

way of computing the velocity of a particle 'now' if all one knows is its position 'now'. For this reason, physicists consider the state of a particle to be a composite of its position and velocity, and the resulting state space $\mathbb{R}^6 = \mathbb{R}^3 \times \mathbb{R}^3$ (three coordinates for position and three for velocity) they call the *phase space* of the particle.

The same point may be clearer in the following example. Suppose that one has an evolution on a state space S which proceeds according to the rule that, if the present state is x_n and the preceding state was x_{n-1}, then the next state will be $x_{n+1} = T(x_{n-1}, x_n)$. This is *not* a Markov process. Nonetheless, it can be 'Markovized'. Indeed, replace the original state space by $\hat{\mathbb{S}} = \mathbb{S} \times \mathbb{S}$, the set of ordered pairs (x, y) with x and y from S, and define $\hat{T}((x,y)) = (y, T(x,y))$. It is then an easy matter to check that, if the original system was in state x_{-1} at time -1 and state x_0 at time 0, then its state at time $n \geq 1$ will be x_n, the second component of the pair $(x_{n-1}, x_n) = \hat{T}^n((x_{-1}, x_0))$.

The moral to be drawn from these examples is that *the presence or absence of the Markov property is in the eye of the beholder*. That is, a change of venue (the state space) can make the Markov property appear in circumstances where it was not originally apparent. In fact, by making the state space sufficiently large, any evolution can be forced to be Markov. On the other hand, the more complicated the state space, the less useful is the Markov property. Thus, in practice, what one seeks is the 'simplest' state space on which one's evolution possesses the Markov property.

Stochastic Markov Processes

Roughly speaking, Markov processes fall into one of two categories. Those in the first category are 'deterministic' in the sense that their state space is sufficiently detailed that the individual states give complete and unambiguous information. Both the examples given above are deterministic. The mathematical analysis of deterministic Markov processes has a proud history going back to Newton which includes major contributions by such luminaries as P. Chebyshev, A. Markov, A. Lyapounov, H. Poincaré, and J. Moser. The second category of Markov processes, and the one on which the rest of this article will concentrate, are 'probabilistic' or 'stochastic' Markov processes. To understand where and why these processes arise, consider the problem of describing the state of all the gas molecules in a room. Each litre of gas contains approximately Avogrado's number, $6.02214199 \times 10^{23}$, of molecules. Thus, even a small room will contain something on the order of 10^{26} molecules. Moreover, because, by Newton's laws of motion, the state of each individual molecule will lie in its individual phase space, the state of the entire system of molecules will have to specify the positions and velocities of all 10^{26} molecules. Stated mathematically, the state space of the system will be $\mathbb{R}^{6\times 10^{26}}$, on which any sort serious analysis is too daunting to contemplate.

When one is confronted with a problem which is intractable as presented, the time-honoured procedure of choice is to reformulate the problem in a way which makes it more tractable. In the case just described, the reformulation was made by G.W. Gibbs (1902) and L. Boltzmann (1896, 1898), the fathers of statistical mechanics. They abandoned any hope of saying exactly where all the molecules will be and reconciled themselves to settling for a description of the statistics of the molecules. That is, instead of asking exactly where all the molecules would be, they asked what would be the probability of finding a molecule in various regions of phase space. From this point of view, the state of the system will not be an element of $\mathbb{R}^{6\times 10^{26}}$ but of $\mathbf{M_1}(\mathbb{R}^6)$, the space probability distributions on the individual phase space $\mathbb{R}^6$. Of course, Gibbs and Boltzmann's reformulation only changes the problem, it does not solve it. Indeed, although Newton's equation determines how the system of molecules evolves and therefore how their distribution will evolve, the use of Newton's equation would remove the advantage which Boltzmann and Gibbs hoped to gain from their reformulation. Thus, they had to come up with an alternative way of describing the transition rule which governs the evolution of the distribution of the system as a Markov process on $\mathbf{M_1}(\mathbb{R}^6)$. The description proposed by Boltzmann is given by the famous Boltzmann equation.

Unfortunately, Boltzmann's equation is itself so complicated that it is only recently that substantial progress has been made toward understanding it in any generality. On the other hand, Gibbs and Boltzmann's idea of studying Markov processes on the space of probability distributions is seminal and has proved to be both ubiquitous and powerful.

The abstract setting for a stochastic Markov process starts with a non-empty set S, the deterministic state space, and the associated space $\mathbf{M}_1(\mathrm{S})$ of probability distributions on S. The easiest and most commonly studied stochastic Markov processes are those for which the transition rule $T : \mathbf{M}_1(\mathrm{S}) \to \mathbf{M}_1(\mathrm{S})$ is a linear (more correctly, an affine) function. To be definite, suppose S is a finite set. Then $\mathbf{M}_1(\mathrm{S})$ is the set of all functions μ on S which assign each $x \in \mathrm{S}$ a number $\mu(\{x\}) \in [0, 1]$ (the probability of $\{x\}$ under μ) in such a way that $\sum_{x \in \mathrm{S}} \mu(\{x\}) = 1$. (The use of $\mu(\{x\})$ instead of $\mu(x)$ here is a little pedantic. However, one must remember that probabilities are assigned to *events* – that is, subsets of the sample space – and that $\{x\}$ is the event that 'x occurred'.) Clearly, if μ and ν are in $\mathbf{M}_1(\mathrm{S})$ and $\theta \in [0, 1]$, then the convex combination $\theta\mu + (1 - \theta)\nu$ is again an element of $\mathbf{M}_1(\mathrm{S})$. Sets with this property are said to be 'affine' (as distinguished from 'linear', which refers to sets which are closed under all linear, not just convex, combinations), and a function on an affine set is said to be affine if it commutes with convex combinations. Thus, for $\mathbf{M}_1(\mathrm{S})$, the transition rule T is affine if $T(\theta\mu + (1 - \theta)\nu) = \theta T(\mu) + (1 - \theta)T(\nu)$. Because S is finite, one can dissect such transition rules in the following way. First, for each $x \in \mathrm{S}$, let δ_x denote the element of $\mathbf{M}_1(\mathrm{S})$ which assigns 1 to $\{x\}$ (and therefore 0 to $\mathrm{S}/\{x\}$). Next, set $\mathbf{P}(\mathrm{x}, \cdot) = T(\delta_{\mathrm{x}})$. That is, $\mathbf{P}(\mathrm{x}, \cdot)$ is the element of $\mathbf{M}_1(\mathrm{S})$ to which T takes $T(\delta_x)$, and so $\mathbf{P}(x, \{y\}) = [T(\delta_x)](\{y\})$. Because, for any $\mu \in \mathbf{M}_1(\mathrm{S})$ which is not equal to δ_x, $\mu = \mu(\{x\})\delta_x) + (1 - \mu(\{x\}))\mu^x$, where $\mu^x \in \mathbf{M}_1(\mathrm{S})$ is determined so that $\mu^x(\{y\})$ equals $(1 - \mu(\{x\}))^{-1}\mu(\{y\})$ or 0 depending on whether $y \neq x$ or $y = x$, the affine property of T means that $T(\mu) = \mu(\{x\})\mathbf{P}(x, \cdot) + (1 - \mu(\{x\}))T(\mu^x)$. Hence, after peeling off one x at a time, one concludes that

$$T(\mu) \sum_{x \in \mathbb{S}} \mu(\{x\})\mathbf{P}(\mathrm{x}, \cdot) \tag{1}$$

when T is affine.

Probabilistic Interpretation

The representation of T given by (1) admits an intuitively pleasing probabilistic interpretation: namely, $\mathbf{P}(\mathrm{x}, \{\mathrm{y}\})$ can be thought of as the probability that the system will next be in the state y given that is now in state x. With this interpretation in mind, probabilists call $x \in \mathrm{S} \mapsto \mathbf{P}(\mathrm{x}, \cdot) \in \mathbf{M}_1(\mathrm{S})$ a *transition probability* on the state space S. The terminology here is confusing. From the point of view adopted earlier, one might, and should, have thought that $\mathbf{M}_1(\mathrm{S})$ is the state space. However, the probabilistic interpretation is most easily appreciated if one thinks of S as the state space and $x \in \mathrm{S} \to (\mathrm{x}, \cdot) \in \mathbf{M}_1(\mathrm{S})$ as a random transition rule. To complete this picture, probabilists introduce random variables to represent the random points in S visited. More precisely, again assume that S is finite, and suppose that $\mu \in \mathbf{M}_1(\mathrm{S})$ describes the initial distribution of the process under consideration. Then probabilists construct a sequence $\{X_n : n \geq 0\}$ of random variables, called a *Markov chain*, in such a way that, for any $n \geq 0$,

$$\begin{aligned}&\mathbf{P}(X_0 = x_0, \ldots, X_n = x_n)\\ &\quad = \mu(\{x_0\})\mathbf{P}(\mathrm{x}_0, \{\mathrm{x}_1\}) \cdots \mathbf{P}(\mathrm{x}_{\mathrm{n}-1}, \{\mathrm{x}_\mathrm{n}\}).\end{aligned}$$

In words, this says that the right-hand side above is the probability that the chain with initial distribution μ starts at x_0 and then goes on to visit, successively, the points x_1 through x_n.

To see that the probabilistic interpretation is completely consistent in the deterministic case, observe that a deterministic Markov process can be formulated as a stochastic Markov process. That is, if T is the transition rule for the deterministic process, take $\mathbf{P}(\mathrm{x}, \cdot) = \delta_{\mathrm{T(x)}}$, and check that, with probability 1, the Markov chain with transition probability $\mathbf{P}(\mathrm{x}, \cdot)$ follows the same path as the deterministic one with transition rule T. Equivalently, with probability 1, $X_n = T^n(X_0)$ for all $n \geq 1$.

Ergodic Theory of Markov Chains

Continue in the setting of the preceding section. One of the phenomena predicted by Gibbs in connection with his and Boltzmann's study of gases was that, no matter what the initial distribution of the gas, after a long time the gas should equilibrate in the sense that it will achieve a *stationary distribution* (that is, a distribution that does not change with time) which does not depend on how it was distributed initially. One's experience with the behaviour of gases makes this prediction entirely plausible: place an opened bottle of perfume in the corner of a room; wait an hour, and confirm that the perfume will have become more or less equidistributed throughout the room. Be that as it may, the prediction, which goes by the name of Gibbs's 'ergodic hypothesis', has been mathematically verified in only one physically realistic model. Nonetheless, as will be explained next, ergodicity is relatively easy to verify for most stochastic Markov processes on a finite state space.

To develop some intuition for what ergodicity means and why it might hold for a stochastic Markov process on a finite state space S, it is best to first know how to recognize when a $\mu \in \mathbf{M}_1(\mathrm{S})$ is stationary. But, if μ is stationary, then it is left unchanged as the system evolves, and, in terms of the transition probability, this means that

$$\mu(\{y\}) = \sum_{x \in \mathbb{S}} \mu(\{x\})\mathbf{P}(\mathrm{x}, \{\mathrm{y}\}) \text{ for all } \mathrm{y} \in \mathbb{S}. \tag{2}$$

Now suppose that $\mathrm{S} = \{1, 2\}$, and consider the problem of finding a solution to (2). That is, we want to find $\mu \in \mathbf{M}_1(\{1, 2\})$ so that

$$\begin{aligned} \mu(\{1\}) &= \mu(\{1\})\mathbf{P}(1, \{1\}) \\ &\quad + \mu\big(\{2\}\mathbf{P}(2, \{1\})\mu(\{2\}) \\ &= \mu(\{1\})\mathbf{P}(1, \{2\}) + \mu\big(\{2\}\mathbf{P}(2, \{2\}). \end{aligned} \tag{3}$$

At first sight, there appear to be too many conditions on μ: not only must it satisfy the two equations in (3), it also has to satisfy $\mu(\{1\}) + \mu(\{2\}) = 1$ as well as being non-negative. Even if one ignores the non-negativity, one suspects that three linear equations are just too many for a pair of numbers to satisfy. On the other hand, after a little manipulation, one sees (remember that $\mathbf{P}(1, \cdot)$ and $\mathbf{P}(2, \cdot)$ are probability distributions) that both the equations in (3) are equivalent to $\mu(\{1\})\mathbf{P}(1, \{2\}) = \mu(\{2\})\mathbf{P}(2, \{1\})$. Hence the two equations in (3) are equivalent, and so there are really only two equations to be satisfied: $\mu(\{1\})\mathbf{P}(1, \{2\}) = \mu(\{2\})\mathbf{P}(2, \{1\})$ and $\mu(\{1\}) + \mu(\{2\}) = 1$. There are two cases to be considered. The first case is when the chain never moves, or, equivalently, $\mathbf{P}(1, \{2\}) = 0 = \mathbf{P}(2, \{1\})$. In this case there are two solutions, namely, δ_1 and δ_2, which is exactly what one should expect for a chain which never moves. In the second case, the one corresponding to a chain which can move, either $\mathbf{P}(1, \{2\}) > 0$ or $\mathbf{P}(2, \{1\}) > 0$. In both these cases, one can easily check that the one and only solution to (3) is given by

$$\begin{aligned} \mu(\{1\}) &= \frac{\mathbf{P}(2, \{1\})}{\mathbf{P}(1, \{1\}) + \mathbf{P}(2, \{1\})} \text{ and } \mu(\{2\}) \\ &= \frac{\mathbf{P}(1, \{2\})}{\mathbf{P}(1, \{2\}) + \mathbf{P}(2, \{1\})}. \end{aligned}$$

Continuing in the setting of the preceding, we want to examine when Gibbs's ergodic hypothesis holds. Obviously, at the very least, ergodicity requires that there be only one stationary μ, otherwise we could start the chain with one of them as initial distribution, in which case it would never get to the other. Thus, we need to assume that $\mathbf{P}(1, \{2\}) + \mathbf{P}(2, \{1\}) > 0$, and, to simplify matters, we will assume more, namely, that $m \equiv m_1 + m_2 > 0$, where $m_1 = \min\{P(1, \{1\}), P(2, \{1\})\}$ and $m_2 = \min\{P(1, \{2\}), P(2, \{2\})\}$, and, under this assumption we (following Doeblin) will show that, for any $\nu \in M_1(\{1, 2\})$

$$\|\nu\mathbf{P} - \mu\| \leq (1 - m)\|\nu - \mu\|, \tag{4}$$

where $\nu\mathbf{P} \in \mathbf{M}_1(\{1, 2\})$ is determined by

$$\nu\mathbf{P}(\{\mathrm{y}\}) \sum_{\mathrm{x}=1}^{2} \nu(\{\mathrm{x}\})\mathbf{P}(\mathrm{x}, \{\mathrm{y}\})$$

and, for any pair $\nu_1, \nu_2 \in \mathbf{M}_1(\{1,2\})$, $\|\nu_2 - \nu_1\| \equiv \sum_{x=1}^{2} |\nu_2(\{x\}) - \nu_1(\{x\})|$. To prove (4), first observe that, because μ is stationary, $\mu = \mu\mathbf{P}$, and therefore, since $\sum_{x=1}^{2} (\nu(\{x\}) - \mu(\{x\})) = 1 - 1 = 0$,

$$\nu P(\{\mathrm{y}\}) - \mu(\{\mathrm{y}\}) = \sum_{\mathrm{x}=1}^{2} (\nu(\{\mathrm{x}\}) - \mu(\{\mathrm{x}\}))$$
$$\mathbf{P}(\mathrm{x}, \{\mathrm{y}\}) = \sum_{\mathrm{x}=1}^{2} (\nu(\{\mathrm{x}\}) - \mu(\{\mathrm{x}\}))$$
$$\left(\mathbf{P}(\mathrm{x}, \{\mathrm{y}\}) - m_{\mathrm{y}}\right).$$

Next, take the absolute value of both sides, remember that the absolute value of a sum of numbers is dominated by the sum of their absolute values, and arrive at

$$\begin{aligned}
&\|\nu P - \mu\| \\
&\leq \sum_{\mathrm{y}=1}^{2} \left(\sum_{\mathrm{x}=1}^{2} |\nu(\{\mathrm{x}\}) - \mu(\{\mathrm{x}\})| \mathbf{P}\left(\mathrm{x}, \{\mathrm{y}\} - m_{\mathrm{y}}\right) \right) \\
&= \sum_{\mathrm{x}=1}^{2} \left(\sum_{\mathrm{y}=1}^{2} |\nu(\{\mathrm{x}\}) - \mu(\{\mathrm{x}\})| \mathbf{P}\left(\mathrm{x}, \{\mathrm{y}\} - m_{\mathrm{y}}\right) \right) \\
&= (1 - m)\|\nu - \mu\|.
\end{aligned}$$

Given (4), it becomes an easy matter to check ergodicity. Indeed, νP is the distribution of the chain at time 1 when it is started with initial distribution ν. Similarly, its distribution at time 2 will be $\nu\mathbf{P}^2 = (\nu P)\mathbf{P}$, and so: $\|\nu\mathbf{P}^2 - \mu\| \leq (1 - m)\|\nu P - \mu\| \leq (1 - m)^2\|\nu - \mu\|$. Proceeding by induction, one sees that distribution $\nu\mathbf{P}^{\mathbf{n}} = (\nu\mathbf{P}^{\mathbf{n}-1})\mathbf{P}$ at time n will satisfy $\|\nu\mathbf{P}^{\mathbf{n}} - \mu\| \leq (1 - m)^{\mathbf{n}}\|\nu - \mu\|$. Hence, because $m > 0$, this implies that $\|\nu\mathbf{P}^{\mathbf{n}} - \mu\|$ tends to 0 exponentially fast, which means that the chain possesses an extremely strong form of ergodicity.

Other Directions

In this article we have discussed only the most elementary examples of Markov processes. In particular, in order to avoid technical difficulties, all our considerations have been about processes for which the time parameter is discrete. As soon as one moves into the realm of processes with a continuous time parameter, the theory becomes much more technically involved. However, the price which one has to pay in technicalities is amply rewarded by the richness of the continuous time theory. To wit, Brownian motion (also known as the Wiener process) is a continuous parameter Markov process which makes an appearance in a surprising, and ever growing, number of places: harmonic analysis in pure mathematics, filtering and separation of signal from noise in electrical engineering, the kinetic theory of gases in physics, price fluctuations on the stock market in economics, and so on. Thus, for the sake of the curious, the bibliography below gives a very brief and enormously inadequate list of places where one can learn more about Markov processes.

Abstract

Harry M. Markowitz shared the 1990 Nobel Memorial Prize in Economics with Merton Miller and William Sharpe for their contributions to financial economics. He is principally known for his Cowles Foundation monograph, *Portfolio Selection: Efficient Diversification of Investments*, in which he developed and made accessible to general readers the concept of an efficient portfolio, that is, a collection of assets that has a maximum rate of return for an arbitrary rate of return variance. The monograph provided a rigorous justification for portfolio diversification. He has also developed important applied mathematical tools for working with sparse matrices and performing simulations.

Harry M. Markowitz is a Nobel laureate who shared a 1990 prize with Merton Miller and William Sharpe for their contributions to financial economics. A native of Chicago, he received undergraduate and graduate degrees from the University of Chicago, culminating in a Ph.D. in 1954. His article on portfolio selection (1952a), drawn from his dissertation, was a path-breaking contribution that would be fully developed in his 1959 Cowles Foundation monograph, *Portfolio Selection: Efficient Diversification of Investments*. The monograph provided a strong case for receiving the Nobel Memorial Prize.

Markowitz is a gifted applied mathematical economist who responds creatively to observed behaviour and has a strong interest in providing tools that facilitate applications of economics. As a graduate student he published a second influential article (1952b), which extended and qualified an important contribution by Friedman and Savage (1948) that proposed an explanation for why individuals both insure and gamble. Specifically, he transformed their argument to describe bets that involved deviations from an individual's 'customary wealth', which is wealth exclusive of recent windfall gains or losses, and imposed a third inflection point, which was needed to satisfy the expected utility hypothesis requirement that a utility function be bounded from below. By describing how the Friedman and Savage model could not account for some commonly observed behaviour, this article afforded a clear insight into the way Markowitz analysed decisions about risk. It takes only one simple division to transform deviations from an individual's customary wealth to rates of return on customary wealth.

Markowitz's article on portfolio selection lucidly explained why focusing on the expected rate of return (hereafter, 'return' means 'rate of return') was inadequate to account for widely observed portfolio diversification. By simultaneously considering expected return and the variance of return (E and V), he developed a set of efficient EV portfolios that would have a maximum return for an arbitrary variance of return. Further, almost all of these efficient portfolios would have more than one asset and thus be diversified. Using elegant geometric arguments, the article explained how in a problem involving N securities the set of efficient portfolios could be represented by a set of connected line segments. This insight underlies the algorithm for computing efficient portfolios that is presented in his monograph.

In that article and in his monograph, Markowitz was careful to emphasize that he was developing a method for using an investor's beliefs (or perhaps those of security analysts) about expected return and variance so that he or she could use them in an optimal way. In neither did he explain how expectations should be formed. Similarly, he was agnostic about whether the probabilities investors used in

forming expectations were objective or subjective. Finally, he did not assume that returns were normally distributed or that an investor had a quadratic utility function, although one of these conditions is formally necessary to describe portfolio choice in terms of expected return and variance of return. The complications raised in the preceding three sentences are briefly considered in the final section of the monograph and would absorb many journal pages in the coming years. Levy and Markowitz (1979) addressed the limitations of restricting attention to expected return and variance and argued that by focusing on these two measures investors were not likely often to be misled.

The monograph was an expositional tour de force and consequently had an enormous impact on the theory and practice of finance. Its first chapters were quite intuitive and made no technical demands on the reader. The third and fourth chapters contain elementary discussions of the concepts of expected return and variance, the fifth and sixth generalize the discussion to cover large numbers of securities and aggregation over time, and the seventh provides a clear geometric interpretation of efficient portfolios. The eighth chapter presents the critical line method for isolating efficient portfolios and solving the underlying quadratic programming problem. The ninth chapter restates the argument using a semivariance. The remaining four chapters describe rational portfolio behaviour and discuss how the expected utility hypothesis can be applied to the portfolio selection problem. They include the topics of portfolio choice over time and when objective and subjective probabilities differ.

Technical derivation of the critical line method is reported in Appendix A in the monograph, which generalizes its original exposition in Markowitz (1956). The method works because the set of efficient portfolios is convex, in part because there are assumed to be upper and lower bounds on the holdings of any asset. In the monograph no short sales are allowed, although this restriction can be relaxed. If we ignore some minor technical issues involving singularities that cannot be dealt with here, the method can be described intuitively. It is initiated by finding the security with the highest expected return. A portfolio fully invested in this security is an element in the set of efficient portfolios. Then, find the security or linear combination of securities that can be substituted for that highest-yielding security in a manner which respects the balance sheet identity that the sum of asset shares equals unity and provides the minimum reduction in return per unit decrease in variance. This substitution is continued until one or more of the securities reach zero (or a lower bound) or until a security not in this combination can be beneficially introduced, at which point another linear combination is chosen. The algorithm stops when no substitution is possible that further lowers the variance of a portfolio.

The monograph and a contemporaneous paper by Tobin (1958) underlay the development of the capital asset pricing model (CAPM) by Sharpe (1964), which argued that an asset's return was determined by its correlation with the return of the market portfolio. This model greatly increased interest in EV models among practitioners and the academic community. In his presidential address to the American Finance Association, however, Markowitz (1983) expressed some reservations about the CAPM because it failed to take into account limits on borrowing.

Apart from his work on modelling portfolio decisions, Markowitz made significant contributions to management science. In Markowitz (1957a), he developed sparse matrix techniques for simplifying the solution of linear programming problems, which continue to be used in present-day algorithms that employ Cholesky factorizations. In Markowitz and Manne (1957b) an important set of applications, discrete programming problems, were analysed. In Manne and Markowitz (1963b), applications of 'process analysis' are reported in which Markowitz was a co-author on several papers that studied metal-working industries. Process analysis examines production capabilities in an industry. Also, he made many contributions that led to improvements in simulations, including the construction of a programming language, SIMSCRIPT (see Markowitz, Hausner and Karr 1963a, and Dimsdale and Markowitz 1999).

Markowitz spent much of his career outside academia. From 1952 through 1963 he was on

the staff of the RAND Corporation and from 1974 through 1983 he was at IBM's T. J. Watson Research Center. His monograph was largely written when he was a visitor at Yale University in 1955–6, on leave from RAND. He joined the faculty of Baruch College of the City University of New York as a distinguished professor of finance and economics in 1982, and in 2004 was a research professor at the University of California at San Diego. In 1989 he was awarded the prestigious Von Neumann Prize in Operations Research by the Operations Research Society of America and The Institute of Management Science for his work on 'portfolio selection, mathematical programming, and simulation'.

Marriage and Divorce

Yoram Weiss

Abstract

We document the increase in marital turnover and survey economic models of the marriage market. Couples match based on attributes but sorting is constrained by costs of search. Divorce is caused by new information on match quality, and remarriage requires further search. Although most men and women marry, they are single more often than before and more children live in one-parent household. The impact on children depends on child-support transfers. Such transfers may rise with the aggregate divorce (remarriage) rates.

This article summarizes the economic analysis of marriage markets. The first section provides a description of stylized facts that motivate the interest of economists in this problem. It is shown that marital status is closely tied with 'economic' variables such as work and wages. We illustrate these facts using mainly US data but the patterns are similar in all developed countries. The second section demonstrates how the tools of economists bear on 'non-economic' subjects such as marriage, fertility and divorce, often analysed by researchers from other fields. The final section highlights some connections between the theory and empirical evidence.

Basic Facts

Marriage and Divorce

The 20th century was characterized by substantial changes in family structure (Fig. 1). More men and women are now divorced and unmarried or have alternative arrangements, such as cohabitation. Interestingly, the rise in divorce rates is associated with an increase in remarriage rates (relative to first marriage rates), reflecting higher turnover. Most people had a first marriage, and most divorces end in remarriage. Moreover, the remarriage rate is greater than the first marriage rate and far exceeds the divorce rate, suggesting that, despite the larger turnover, marriage is still a 'natural' state (Table 1). Women enter the first marriage faster than men. However, following divorce, men remarry at higher rates than women, especially at

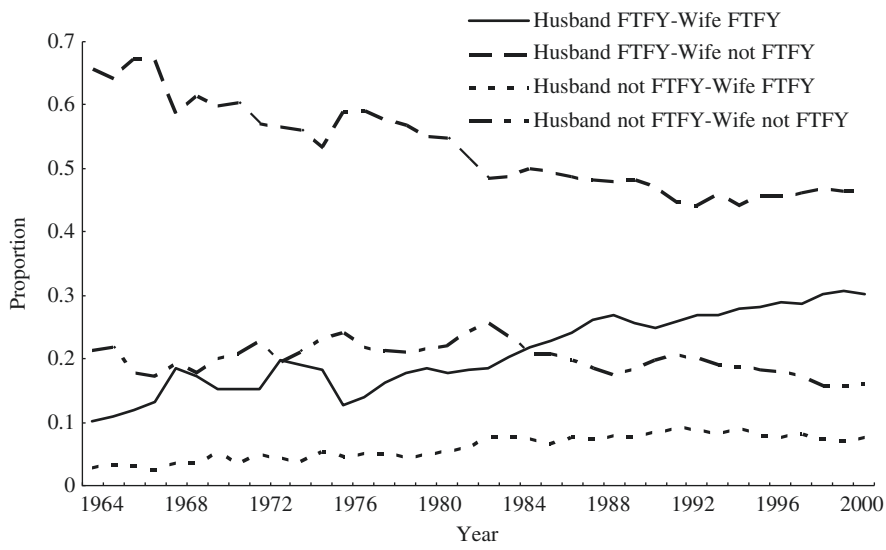
old ages. This pattern reflects the earlier marriage of women and their longer lives, which causes the ratio of men to women to decline with age.

One consequence of higher marital turnover is the large number of children who live in single-parent and step-parent households. In 2002, 23 per cent of US children younger than 18 years lived only with their mother, and five per cent lived only with their father. Children of broken families are more likely to live in poverty and to underperform in school. Lower attainments of such children are observed also prior to the occurrence of divorce, suggesting that bad marriage rather than divorce may be the cause (Piketty 2003).

Marriage and Work

Time use data (Table 2) show that men work more than women in the market; women do more housework than men. Per day, single women work at home three hours while single men work less than two hours. These figures roughly double for married couples with young children, showing clearly that children require a substantial investment of time and that most of this load is carried



Marriage and Divorce, Fig. 2 Work patterns of husbands and wives (age 30–40), United States, 1964–2001. *Note*: A spouse is employed full-time-full-year (FTFY) if he/she works 50 weeks or more and hours exceed 34 per week. *Source*: Current Population Surveys

by the mother. The total time worked and the corresponding amount of leisure is about the same for married men and women.

Figure 2 displays the work patterns within couples. The most common situation is that the husband works full-time and the wife works part-time or does not work at all. However, the proportion of such couples has declined and the proportion of couples where *both* partners work full-time has risen sharply, reflecting the increased entry of married women into the labour force.

Marriage and Wages

Male–female wage differences of full-time workers are larger among married than among single persons. Married men have consistently the highest wage among men, while never-married women have the highest wage among women. The wage gap between married men and women rises as the cohort ages, reflecting the cumulative effects of gender differences in the acquisition of labour market experience (Figs. 3 and 4). The increased participation of married women, associated with the increase in their wages, has increased their wage relative to those of never-married women and their husbands (Table 3).

Economic Theory of Marriage and Divorce

From an economic point of view, marriage is a voluntary partnership for the purpose of joint production and joint consumption. As such, it is comparable to other economic organizations that aim to maximize some private gains but are subject to market discipline.

Gains from Marriage

Consumption and production in the family are broadly defined to include non-marketable goods and services, such as companionship and children. Indeed, the production and rearing of children is the most commonly recognized role of the family. We mention here five broad sources of *economic* gain from marriage, that is, why 'two are better than one':

1. Sharing of collective (non-rival) goods; both partners can equally enjoy their children, share the same information and use the same home.
2. Division of labour to exploit comparative advantage or increasing returns; one partner works at home and the other works in the market.

3. Extending credit and coordination of investment activities; one partner works when the other is in school.
4. Risk-pooling; one partner works when the other is sick or unemployed.
5. Coordination of child care, which is a collective good for the parents. Although children can be produced and raised outside the family, the family has a substantial advantage in carrying out these activities. Two interrelated factors cause this advantage: by nature, parents care about their own children and, because of this mutual interest, it is more efficient that the parents themselves determine the expenditure on their children. If the parents live separately, whether single or remarried, the non-custodian parent loses control of child expenditures. Lack of contact further reduces the incentive or ability to contribute time and money to the children. Together, these factors reduce the welfare of both parents and children when they live apart (Weiss and Willis 1985).

Family Decision Making

The existence of potential gains from marriage is not sufficient to motivate marriage and to sustain it. Prospective mates are concerned whether the potential gains will be realized and how they are divided. Family members have potentially conflicting interests and a basic question is how

Marriage and Divorce, Table 3 Relative wage gaps associated with marital status for fully employed men and women, by year and age, United States, 1965–2001

Source: Current Population Surveys

families reach decisions. The old notion that families maximize a common objective appears to be too narrow. Instead of this *unitary* model, it is now more common to consider *collective* models in which partners with different preferences reach some binding agreement that specifies an *efficient* allocation of resources and a *stable sharing rule*. (Browning et al. 2005, ch. 3).

In a special case, referred to as *transferable utility*, it is possible to separate the issues of efficiency and distribution. This situation arises if there is a commodity (say, money) that, upon changing hands, shifts utilities between the partners at a fixed rate of exchange. In this case, the family decision process can be broken into two steps: actions are first chosen to maximize a weighted *sum* of the individual utilities, and then money is transferred to divide the resulting marital output. In general, the problems of efficiency and distribution are intertwined. We may still describe the family as maximizing a weighted sum of the individual utilities, but the weights depend on the individual bargaining powers, and any shift in the weights will affect the family choice. The bargaining power may depend on individual attributes such as earning capacity, subjective factors such as impatience and risk aversion, and on market conditions, such as the sex ratio and availability of alternative mates (Lundberg and Pollak 1993).

The question remains: what enforces the coordination between family members? One possibility is that the partners sign a formal 'marriage contract' that is enforced by law. However, such contracts are quite rare in modern societies, which can be probably ascribed to a larger reliance than in the past on emotional commitments and the presumption that too much contracting can 'kill love'. In the absence of legal enforcement, efficient contracts may be supported by repeated interactions and the possibility to trade favours and punishments. This possibility arises because marriage is a durable relationship, forged by the long-term investment in children and the accumulation of marital specific capital, which is lost or diminished in value if separation occurs. However, repeated game arguments cannot explain unconditional giving, such as taking care of a spouse stricken by Alzheimers who would never be able to return the favour. Emotional commitments and altruism play a central role in enforcing family contracts (Becker 1991, ch. 8).

The Marriage Market

Individuals in society have many potential partners. An undesired marriage can be avoided or replaced by a better one. This situation creates competition over the potential gains from marriage. In modern societies, explicit price

mechanisms are not observed. Nevertheless, the assignment of partners and the sharing of the gains from marriage can be analysed within a market framework.

Matching models provide a starting point for such analysis. These models investigate the mapping from preferences over prospective matches into a stable assignment (Roth and Sotomayor 1990). An assignment is said to be *stable* if no married person would rather be single and no two (married or unmarried) persons prefer to form a new union. To illustrate, assume that each male is endowed with a single trait, m, and each female is endowed with a single trait, f. Let

$$z = h(m,f). \tag{1}$$

be the *household production function* that summarizes the impact of traits of the matched partners on marital output, z, and assume that $h(m,f)$ is increasing in m and f.

Suppose, first, that z is a public good that the partners must consume jointly. Then, the only stable assignment is such that males with high m marry females with high f, and, if there are more (fewer) eligible men than women, the men (women) with the fewest endowments remain unmarried. All men want to marry the best woman, and she will accept only the best man. After this pair is taken 'out of the game', we can apply the same argument to the next-best couple and proceed sequentially. Such a matching pattern is called positive *assortative matching*.

If one assumes, instead, that z can be divided between the two partners and that utility is transferable, then a man with low m may obtain women with high f by giving up part of his private share in the gains from marriage. The type of interaction in the gains from marriage determines the willingness to pay for the different attributes. Complementarity (substitution) means that the two traits interact in such a way that the benefits from a woman with high f are higher (lower) for a male with high m than for a male with low m. Thus, a positive (negative) assortative matching occurs if the two traits are complements (substitutes). An important lesson is that in a marriage market with sufficient scope for compensation within marriage, the best man is not necessarily the one married to the best women, because, with negative interaction, either one of them can be bid away by the second-best of the opposite sex (Becker 1991, ch. 4).

What determines the division of marital gains? If each couple is considered in isolation then, in principle, any efficient outcome is possible, and one has to use bargaining arguments to determine the allocation. However, in an 'ideal' frictionless case, where partners are free to break marriages and swap partners at will, the outcome depends on the joint distribution of male and female characteristics in the market at large. Traits of the partners in a particular marriage have no direct impact on the shares of the two partners, because these traits are endogenously determined by the requirement of stable matching.

These features show up more clearly if one assumes a continuum of agents and continuous marital attributes. Let $F(m)$ and $G(f)$ be the cumulative distributions of the male and female traits, respectively, and let the measure of women in the total population be r, where the measure of men is normalized to 1. Assume that the female and male traits are complements and transferable utility. Then, if man m' is married to woman f', the set of men with m exceeding m' must have the same measure as the set of women with f above f'. Thus, for all m and f in the set of married couples,

$$1 - F(m) = r(1 - G(f)). \tag{2}$$

This simple relationship determines a positively sloped matching function, $m = (f)$.

A *sharing rule* specifies the shares of the wife and husband in every marriage that forms. Let $v(m)$ be the *reservation utility* that man m requires in *any* marriage and let $u(f)$ be the reservation utility of woman f. Then the sharing rule that supports a stable assignment must satisfy

$$\begin{gathered} v(m) = \max_f \left(h(f,m) - u(f)\right), \\ \text{and} \\ u(f) = \max_y (h(z,y) - v(y)). \end{gathered} \tag{3}$$

That is, each married partner gets the spouse that maximizes his or her 'profit' from the

partnership over all possible alternatives. As we move across matched couples, the welfare of each partner changes according to the *marginal* contribution of his/her *own* trait to the *marital* output, irrespective of the potential impact on the partner whom one marries. With a continuum of agents, there are no rents in the marriage market because everyone receives roughly what can be obtained in the next-best alternative. Another condition for a stable assignment is that, if there are unmarried men, the least attractive married man cannot get any surplus from marriage. Otherwise, slightly less attractive men could bid away his match. A similar condition applies for unmarried women.

From these considerations, one can obtain a unique sharing rule, provided that $r \neq 1$. Basically, one first finds the sharing in the least attractive match, using the no-rent condition. Then the division in better marriages is determined sequentially, by using the condition that along the stable matching profile each partner receives his or her marginal contribution to the marital output. The sharing rule is fully determined by the sex ratio and the respective trait distributions of the two sexes. It can be shown that a marginal increase in the ratio of women to men in the marriage market improves (or leaves unchanged) the welfare of all men, and reduces (or leaves unchanged) the welfare of all women. From (2), it is seen that an upward (downward) first-order shift in the distributions of traits is equivalent (in terms of the effects on the sharing rule) to a marginal increase (decrease) in the female–male ratio. In this regard, there is close correspondence between the impact of changes in quality (that is, the average trait) and size of the two groups that are matched in the marriage market (Browning et al. 2005, ch. 9).

Search

The process of matching in real life is characterized by scarcity of information about potential matches. Models of search add realism to the assignment model because they provide an explicit description of the sorting process that happens in real time.

Following Mortensen (1988), consider infinitely lived agents and assume that meetings are governed by a Poisson random process (these two assumptions are made to ensure a stationary environment). The total marital output is observed upon meeting and, on the assumption of transferable utility, marriage will occur whenever this marital output exceeds the *sum* of the values of continued search of the matched partners. This rule holds because it implies the existence of a division within marriage that makes both partners better off. Because meetings are random and sparse in time, those who actually meet and choose to marry enjoy a positive rent. The division of these rents between the partners is an important issue. Two considerations determine the division of the gains from marriage: outside options, reflected in the value of continued search, and the self-enforcing allocation that would emerge if the marriage continued without agreement (Wolinsky 1987). If these two considerations are combined, the sharing rule is influenced by both the value of search as single and the value of continued search during the bargaining process, including the option of leaving when an outside offer arrives. In this way, a link is created between the division of marital output gains and market conditions.

Search models explain why, despite the gains from marriage, part of the population is not married and individuals move between married and single states. The steady state proportions of the population in each state are such that the flows into and out of each state are equalized. These two flows are determined by the search strategies that individuals adopt.

Search models may have significant externalities. For instance, it may be easier to find a mate if there are many singles searching for mates. There are several possible reasons for such *increasing returns* in the matching process. One reason is that the two sexes meet in a variety of situations (work, sport, social life and so on) but many of these meetings are 'wasted' in the sense that one of the individuals is already attached and not willing to divorce. A second reason is that the establishment of more focused channels, where singles meet only singles, is costly. These will be created only if the 'size of the market' is large enough. Third, the intensity of search by unattached decreases with the proportion of attached

people in the population who are less likely to respond to an offer (Mortensen 1988). In such a case, the marriage (divorce) rates will be above (below) their efficient levels, as each person fails to consider the effect of marriage or separation on the prospects of other participants in the marriage market.

Search and Assortative Matching

The presence of frictions modifies somewhat the results on assortative matching. Following Burdett and Coles (1999), consider a case of non-transferable utility with frictions. Assume that if man m marries women f, he gets f and she gets m. There is a continuum of types with continuous distributions and meetings are generated by a Poisson process with parameter λ. Upon meeting, each partner decides whether to accept the match or to continue the search. Marriage occurs only if both partners accept each other and, by assumption, a match cannot be broken.

Each man (woman) chooses a reservation policy that determines which women (men) to accept. The reservation values for men and women, R_m and R_f, respectively, depend on the individual's own trait. Agents at the top of the distribution of each gender can be choosier because they know that they will be accepted by most people on the other side of the market. Hence, continued search is more valuable for them. Formally, let

$$\begin{aligned} R_m &= b_m + \frac{\lambda\mu_m}{r}\int_{R_m}^{\overline{f}} (f - R_m)dG_m(f), \\ R_f &= b_f + \frac{\lambda\mu_f}{r}\int_{R_f}^{\overline{m}} (f - R_f)dF_f(m) \end{aligned} \tag{4}$$

where the flow of benefits as single, b, the proportion of meetings that end in marriage, μ, and the distribution of 'offers' if marriage occurs, all depend on traits, as indicated by the m and f subscripts. The common discount factor, r, represents the cost of waiting.

In equilibrium, the reservation values of all agents must be a best response against each other, yielding a (stationary) Nash equilibrium. In particular, the 'best' woman and the 'best' man will adopt the policies

$$R_{\overline{m}} = b_{\overline{m}} + \frac{\lambda}{r}\int_{R_{\overline{m}}}^{\overline{f}} (f - R_{\overline{m}})dG(f),$$

$$R_{\overline{f}} = b_{\overline{f}} + \frac{\lambda}{r}\int_{R_{\overline{f}}}^{\overline{m}} \left(m - R_{\overline{f}}\right)dF(m).$$

Thus, the best man accepts some women who are inferior to the best woman and the best woman accepts some men who are inferior to the best man, because a bird in the hand is worth two in the bush.

The assumption that the ranking of men and women is based on a single trait introduces a strong commonality in preferences whereby all men agree on the ranking of all women and vice versa. Because all individuals of the opposite sex accept the best woman and all women accept the best man, μ is set to 1 in Eq. (5) and the distribution of offers equals the distribution of types in the population. Moreover, if the best man accepts all women with f in the range $\left[R_{\overline{m}}, \overline{f}\right]$, then all men who are inferior in quality will also accept such women. But this means that all women in the range $\left[R_{\overline{m}}, \overline{f}\right]$ are sure that all men accept them and therefore will have the *same* reservation value, $R_{\overline{f}}$, which in turn implies that all men in the range $\left[R_{\overline{f}}, \overline{m}\right]$ will have the same reservation value, $R_{\overline{m}}$.

These considerations lead to a *class structure* with a finite number of distinct classes in which individuals marry each other. Having identified the upper class, we can then examine the considerations of the top man and woman in the rest of the population. Lower-class individuals face $\mu < 1$ and a *truncated* distribution of offers because not all meetings end in marriage but, in principle, these can be calculated and then one can find the reservation values for the highest two types and all other individuals in the group forming the second class. Proceeding in this manner to the bottom, it is possible to determine all classes. This pattern is similar to the case without frictions and non-transferable utility except that, because of the need to compromise, low-and high-quality types mix within each class.

With frictions and transferable utility, there is still a tendency towards positive (negative) assortative matching based on the interaction in traits. If the traits are complements, individuals of either

sex with a higher endowment will adopt a more selective reservation policy and will be matched, on the average, with a highly endowed person of the opposite sex. However, with sufficient friction it is possible to have negative assortative matching even under complementarity. This, again, is driven by the need to compromise. With low frequency of meetings and costs of waiting, males with low *m* expect some women with high *f* to accept them. If the gain from such a match is large enough, they will reject all women with low *f* and wait until a high *f* woman arrives.

Divorce and Remarriage

Divorce is motivated by uncertainty and changing circumstances. Thus, individuals may enter a relationship and then break it if a better match is met. Or changing economic and emotional circumstances may dissipate the gains from marriage. As time passes, new information on match quality and outside options is accumulated, and each partner decides whether to dissolve the partnership. In making this choice, partners consider the expected value of each alternative, where the value of remaining married includes the option of later divorce and the value of divorcing includes the option of later remarriage. Under divorce at will, divorce occurs endogenously whenever one partner has an alternative option that the current spouse cannot, or is unwilling to, match by a redistribution of the gains from marriage.

Following divorce, the options for sharing and coordination of activities diminish. The divorced partners may have different economic prospects, especially if children are present. Asymmetries arise because the mother usually loses earning capacity as a result of having a child. To mitigate these risks, the partners have a mutual interest in signing binding contracts that stipulate post-divorce transfers. Such contracts are negotiated 'in the shadow of the law' and are legally binding. Child support payments are mandatory but the non-custodial father may augment the transfer to influence child expenditures by the custodial mother. Payments made to the custodial mother are usually fungible and, therefore, the amount that actually reaches the children depends on the mother's marital status. If she remarries, child expenditures depend on the new husband's net income, including his child-support commitments to his ex-wife. Hence, the willingness of each parent to provide child support depends on commitments of others. These interdependencies can yield *multiple equilibria*, with and without children and correspondingly low and high divorce rates (Browning et al. 2005, ch. 11).

Theory and Evidence

There is a growing body of empirical research that addresses the testable implications of the models outlined above.

1. The unitary model of the household implies that the consumption levels of husband and wife depend only on *total* family income. This, however, is rejected by the data (Lundberg et al. 1997). Nevertheless, consumption and work patterns of married couples indicate that they act efficiently (Browning and Chiappori 1994), implying that a collective model fits the data.
2. Matching models with transferable utility imply positive assortative matching based on the spouses' schooling but negative matching based on their wages (Becker 1991, ch. 10). In fact, the correlation between the education levels of married partners (about.6) is substantially higher than the correlation between their wages (about.3).
3. Because partners are matched based on their traits as observed at the time of marriage, both positive or negative *surprises* trigger divorce (Becker 1991, ch. 10). Weiss and Willis (1997) find an impact of unexpected changes in husband's and wife's incomes on the probability of divorce.
4. Unanticipated shocks are less destabilizing if partners are well matched. Anticipating that, couples would sort into marriage according to characteristics that enhance the stability of marriage. In fact, individuals with similar schooling are less likely to divorce and are more likely to marry. This pattern holds for religion and ethnicity, too (Weiss and Willis 1997).

5. Individual types congregate into locations that facilitate matching; gays in San Francisco (Black et al. 2000) or Jews in New York (Bisin et al. 2004). Such patterns suggest increasing returns in search. Higher wage variability among men induces women to search longer for their first or second husband, consistently with an optimal search strategy (Gould and Paserman 2003).
6. Marital choices and family decisions respond to aggregate marriage market conditions. Black women in the United States delay their marriage and have children out of wedlock because of a shortage of eligible black men (Willis 1999); a higher male–female ratio reduces the hours worked by wives and raises the hours worked by husbands (Chaippori et al. 2002).
7. The sharp increase in divorce in the United States and other countries during 1965–75 seems to constitute a switch across two different equilibria. A marriage market is capable of such abrupt change because of inherent positive feedbacks in matching and contracting. Explanations for the timing of the change include the appearance of the contraceptive pill, the break-up of norms and legal reforms (Michael 1988; Goldin and Katz 2002).

Marriage Markets

Andrew Foster

Abstract

The term 'marriage market' refers to the application of economic theory to the analysis of the process that determines how men and women are matched to each other through marriage and how this process influences other choices

including human capital investment and the allocation of marital surplus. The specific sub-topics in this article include a characterization of stable assignment in marriage, consideration of the effects of marriage allocations on distribution within marriage, discussion of the extent to which partners who marry have similar characteristics, and a review of results on marriage timing.

Keywords

Assortative mating; Dowries; Fertility; Human capital investment; Inequality; Marriage markets; Non-market production; Stable assignment; Transferable utility

O1

The marriage market is a term used by economists to characterize the process that determines how men and women are matched to each other through marriage. Formally the marriage market may be thought of as an allocative process that, given the preferences and endowments of two sets of individuals (men and women), yields a set of couples and unmatched individuals and a distribution of resources within each match. Marriage markets are generally distinguished from other sorting processes such as worker–firm matching by the assumption that each member of each set of individuals is matched to at most one member of the other set. However, the basic concept of the marriage market may also be applied to other cases such as polygamy or same-sex partnerships. It is also generally assumed that one's well-being within marriage is determined by the characteristics of one's partner and the distribution of resources within the marriage, but not the matches of other individuals in the marriage market conditional on these factors. The economics literature on the marriage market has built importantly on a two-part foundational article on the economics of marriage published in 1973 and 1974 (Becker, 1973, 1974). However, the phrase 'marriage market' is considerably older, with a first citation in the *Oxford English Dictionary* of 1842.

Stable Assignment

Central to the notion of a marriage market is the notion of stable assignment. A stable assignment may be characterized as a set of partner allocations and distributions of resources within marriage so that no individual of one sex would be willing to make an offer (in terms of partnership and a distribution of resources within that partnership) to an individual of the other sex which that individual strictly prefers to his or her equilibrium allocation.

An early and important divide in terms of economic models of marriage arises with respect to the question of transferable utility. Transferable utility arises when well-being within the household may be freely transferred between members of the household through a reallocation of household resources. Under these conditions the question of who marries whom can be importantly separated from the question of how resources are distributed within marriage and any stable marriage assignment can be characterized as the outcome of the maximization of a linear programme (Bergstrom, 1997).

At the other extreme from a transferable utility model is one in which there is no possibility of transferring resources within or across marriage. A key feature of such models is that there is generally a wide variety of possible stable equilibria. Gale and Shapley (1962) illustrate two such stable equilibria, by the construction of two matching algorithms based on who makes offers and who makes the decision to accept, tentatively accept, or reject those offers. Each man is at least as well off in the equilibrium in which men make offers relative to the equilibrium in which women makes offers and vice versa.

Distributive Effects

Becker's (1973) pioneering analysis of the marriage market considered, among other things, the effects of the marriage market on household distribution. Consider, for example, a simplified version of this model in which there is heterogeneity in tastes for being single, transferable utility

within marriage, and no heterogeneity across couples in total utility within marriage. The outcome of the model is a distribution parameter that characterizes the share of total marital utility going to each partner within marriage and a number of marriages, with those individuals of both sexes with the highest taste for being single remaining unmarried. Among other things the model illustrates how a rise in the female wage raises the utility of married females within marriage even when married women are not active in the labour market. The increased opportunities for women outside marriage implies that women must, at the margin, receive a higher share of marital utility in order to be willing to marry.

There is substantial debate about the importance of marriage market structure in influencing transfers between partners and their respective households of origin at the time of marriage. Of particular relevance is the evidence of a historical transition from bride-price to dowry in parts of South Asia and the very large levels of dowry relative to annual income that are sometimes observed in that region. A number of factors have been argued to play an important role in this regard, including changes in the relative sizes of female and male populations of marriageable age associated with population growth and the gap in typical ages at marriage, changes in inequality and economic opportunity, and changes in the relative merits of different forms of parental transfers in their children.

Assortative Mating

A second issue that has received significant theoretical and empirical scrutiny is the question of the extent to which the marriage market matches men and women with similar characteristics. This issue is thought to be important because of its implications for interhousehold inequality and for intergenerational transmission of inequality. If high-earning men match with high-earning women, and these high-earning couples transfer these resources to their children in the form of financial assistance and/or human capital, then inequality is likely to be more persistent across generations than would be the case otherwise. Assortative mating by religion and/or immigrant status is also thought to be both an indicator of and contributor to the process of assimilation. Finally, assortative mating on unobservable (to analysts) attributes can affect inferences about household behaviour that condition on household composition. For example, if men with a high unobservable taste for child human capital match with more educated women, then highly educated women will appear to have more educated children even if there is no direct effect.

A simple transferable utility model in which marital output is increasing in the product of male and female quality yields the prediction that there should be positive assortative mating on such attributes as intelligence, wealth and beauty. A possible exception arises with respect to market earnings capacity to the extent that, as postulated by Becker (1973), one member of the couple specializes in the production of non-market goods. Interestingly, the theoretical prediction of positive assortative mating across classes of individuals can arise within the marriage market with imperfect information (Burdett and Coles, 1997).

The evidence supports the prediction of positive assertive mating on partner attributes, although there have been changes over time in the degree to which this is observed. In particular, the degree of educational assortative mating fell between 1940 and 1960 in the United States but has increased subsequently, largely due to a decline in the share of low-education individuals marrying (Schwartz and Mare, 2005). There has also been a shift in the sign of the correlation in partner earnings from negative to positive since the 1960s (Schwartz, 2005), a pattern that has contributed to the overall increase in interhousehold inequality in income.

Marriage Timing

A third set of marriage-market issues relates to the timing of marriage, particularly for women. It is argued that early marriage can result in higher fertility, lower rates of human capital investment, and an adverse bargaining position from the

perspective of women. Boulier and Rosenzweig (1984), in an early contribution on this subject, showed how unobserved attractiveness could lead to incorrect inference about the role of education in delaying marriage and increasing spousal quality. Bergstrom and Bagnoli (1993) show how the process of uncertainty resolution with regard to the marital prospects may differentially affect the timing of marriage for men and women of different qualities. It also is the case that timing of marriage can play an important role in the equilibration of marriage markets given substantial differences in the relative numbers of eligible men and women arising from sex differences in mortality or a gap in the age at marriage for men and women for a growing population. In particular, because of how changes in the timing of marriage for sequential cohorts of eligible men and women affect the number of marriages taking place at a particular point in time, a persistent ten per cent excess in the number of eligible females relative to males can be accommodated with an increase in the female relative to male age at marriage by just one year over a decade (Foster et al. 2004).

The diversity of Jacob Marschak's education and early experience made it likely that he would approach the study of economic behaviour with more than the average breadth of interest and vision. He was born in Kiev on 23 July 1898, and studied mechanical engineering at the Kiev Institute of Technology. At the beginning of the Russian Revolution he served briefly as Minister of Labour in the Menshevik government of Georgia but was forced to escape to Germany. There he went first to the University of Berlin, where he studied economics and statistics with

L.V. Bortkiewicz, and then to the University of Heidelberg, where he received his Ph.D. in economics in 1922. His professors at Heidelberg included E. Lederer in economics, A. Weber in sociology, K. Jaspers in philosophy and G. Anschuetz in public law.

Following his doctoral studies at Heidelberg, he earned his living for the next eight years as an economic journalist and applied economist. He was economic editor for the *Frankfurter Zeitung* (1924–5), a research associate at the Research Centre for Economic Policy in Berlin (1926–8), and supervisor and editor of research for a Parliamentary Commission of Exporting Industries, at the Institute of World Economics of the University of Kiel (1928–30). Also, in 1926 he spent time in London on a travelling fellowship from the University of Heidelberg.

In 1930 he was appointed as a Privatdozent in economics at the University of Heidelberg, but three years later, once again the victim of political events, he left Germany and went to Oxford as a university lecturer. In 1935 he became Reader in Statistics and Director of the Oxford Institute of Statistics, where he remained until 1939. During this period he wrote extensively on theoretical and statistical aspects of demand analysis, a field in which he was a pioneer (Marschak 1931).

In 1939 Marschak moved to the United States, where he lived the rest of his life, teaching at the New School for Social Research (1940–42), the University of Chicago (1943–55), Yale University (1955–60), and the University of California at Los Angeles (1960–77).

During the first dozen years Marschak was an active participant in the econometric revolution that is commonly associated with the Cowles Commission for Research in Economics. This revolution was nurtured at an early and crucial stage by the seminar on econometric methods and results that Marschak organized at the National Bureau of Economic Research, while he was on the faculty of the New School for Social Research. The intensive contacts fostered in this seminar led, in particular, to three fundamental papers on the statistical estimation of systems of simultaneous equations, by Haavelmo (1943), Mann and Wald (1943), and Marschak and Andrews (1944). Two further publication landmarks in this movement were the Cowles Commission Monographs No. 10 and No. 14, to which Marschak contributed the opening chapters (Marschak 1950a, 1953).

Two other topics on which Marschak worked presaged his later work on decision and organization. First, he was, for a number of years, interested in the demand for money, and through his work and that of others the idea evolved that this demand could be better understood in the context of a more general theory of the joint demand for various assets (Marschak 1938, 1949, 1950b). Furthermore, since the ultimate values of assets are rarely known with certainty at the time they are acquired, such a general theory needed to be based on a more systematic theory of decision in the face of uncertainty than was then available.

A second topic was the subject of his first scientific publication, a contribution to the debate on the efficiency, or even viability, of socialism. A central issue in that debate was whether the centralization of economic authority in a socialist state was compatible with the decentralization of information necessary in a complex economy.

From 1950 on, Marschak's research and writing was concerned with the general area of decision, information and organization. More specifically, one can identify at least three topics to which he made substantial contributions: (1) stochastic decision, (2) the economic value of information, and (3) the theory of teams.

Stochastic Decision

In a series of articles (Marschak 1959a, 1964a; Marschak and Block 1960; Marschak and Davidson 1959b; Marschak et al. 1963a, b, 1963c, 1964b), Marschak proposed and elaborated the theory of stochastic decision and reported on a number of experiments. This work had its roots in the theory of rational economic choice or utility theory and in certain theories of psychological measurement.

Marschak developed a framework for describing the behaviour of economic decision makers who are approximately rational or consistent, or whose consistency of behaviour cannot be exactly verified through observation because of the observer's inability to control or identify all of the relevant factors in the decision-making situation.

It had long been recognized that economic decision makers did not exhibit exact consistency in their detailed choices. Economists were and remain loath to abandon the general framework of rational decision making that has appeared to be so fruitful in the analysis of the economic system as a whole, Marschak's theory provided a theoretical model that could be used for econometric studies of individual choice behaviour and that was connected in a coherent way with the general hypothesis of economic rationality. The work of Marschak and his co-authors was at first more appreciated by psychologists than by economists. His papers on this subject are still standard references in the theory of psychological scaling (Luce et al. 1963, vol. 3, ch. 19). More recently, this theory has provided the basis of statistical studies of individual choice behaviour (McFadden 1982), as well as of a new approach to the theory of economic equilibrium that takes account of the uncertainty of individual behaviour (Hildenbrand 1971; Bhattacharya and Majumdar 1973).

Economic Value of Information

Marschak was probably the first to develop a systematic theory of the economic value of information. In this development he recognized that the measurement of quantity of information used by communication engineers, and associated with the work of Wiener and Shannon, was not adequate to measure the value of information. Indeed, it was not possible to identify a single measure of information such that more is always better.

Instead, Marschak turned to the newly developed theory of statistical decision for the source of his framework. For him, the value of a particular information system – or more generally, a system of information gathering, communication and decision – was related to the particular class of economic decision problems under consideration. His theoretical analysis of the value and cost of information pointed to the importance of more empirical knowledge concerning the technology of observation, information processing, communication and decision making, although he, himself, did not do any empirical work in this field. These ideas are elaborated in a long series of papers beginning with his contribution to *Decision Processes* (Marschak 1954) and summarized in his paper 'Economics of Information Systems' (1971).

Economic Theory of Teams and Organization

In an economic or other organization, the members of the organization typically differ in (1) the actions or strategies available to them, (2) the information on which their actions can be based, and (3) their preferences among alternative outcomes and their beliefs concerning the likelihoods of alternative outcomes given any particular organization action. Marschak recognized that the difficulty of determining a solution concept in the theory of games was related to differences of type 3. However, a model of an organization in which only differences of types 1 and 2 existed, which he called a team, presented no such difficulty of solution concept, and promised to provide a useful tool for the analysis of problems of efficient use of information in organizations. Such a model provided a framework for analysing the problems of decentralization of information so central to both the theory of competition and the operation of a socialist economy. The idea of a team was introduced in Marschak (1954, 1955), and a systematic development of the theory of teams is provided in Marschak and Radner (1972).

Towards the end of his career, Marschak returned to the theoretical issues concerning conflict of interest among the members of a decentralized organization. He approached this primarily in terms of the normative problem of

devising incentives for the members of a 'team' to behave in accord with the goals of the organization. Of course, to the extent that such incentives are needed, the organization is no longer a team, in the technical sense of the term and the problem is back in the domain of the more general theory of games. It was left to others to make substantial progress on this set of problems. An important early effort in this direction was by T. Groves, who in his doctoral dissertation (1969) and his subsequent article, 'Incentives in Teams' (1973) presented – in a particular case – a solution to the problem of providing incentives to decentralized decision makers to both send truthful messages and make optimal decisions. These ideas were further developed in the contexts of the theory of public goods, the allocation of resources in a divisionalized firm and the principal–agent relationship. (For references to the literature on these developments see Groves and Ledyard 1987; Hurwicz 1979; Radner 1986.)

Besides the significance of Marschak's individual contributions to economic analysis, I would like to emphasize the cumulative significance of his life's work. Through his work ran the important message that economists must come to grips with problems of uncertainty. He led the way, not only through his own research, but through his indefatigable and successful efforts at explaining these problems to his colleagues in economics and related disciplines. His work drew from psychology, statistics and engineering, and in turn influenced research in those disciplines. Indeed, more than any other economist I know, Marschak typified the best in behavioural science.

Marshall Plan

Francisco Alvarez-Cuadrado

Abstract

The Marshall Plan transferred over US$12.5 billion to Western European countries between 1948 and 1951. This article contrasts the main views on its impact on the post-war European performance. It concludes that, although the direct impact of the plan through private and public investment was rather limited, Marshall Aid provided the recipient economies with a temporary solution for the severe dollar constraint that posed a threat to the continuation of the European miracle. Furthermore the Plan played an important role in promoting collaboration among former adversaries.

In Europe during the Second World War the productive effort of more than an entire generation was lost, with per capita income returning to the levels of the turn of the century. This fall in output reflected not only the destruction of capacity but also the disruption of channels for obtaining inputs and distributing production. The reconstruction process began right after the war, with industrial production reaching pre-war levels as soon as 1947. The weather conditions in 1947 substantially depressed agricultural yields, leading to important food and energy shortages. The substantial trade deficits of the recovering economies combined with the negative experience of international investors after the First World War lead to a 'dollar gap' which posed a threat to the continuation of the European miracle.

These were the circumstances that surrounded the development of the Marshall Plan, officially the European Recovery Program (ERP). The views on the motivations behind the ERP range from plain American imperialism (Kolko and Kolko 1972) to pure altruism; in the words of Galbraith (1998), 'the primary purpose of the Plan was compassionate good will, the notion that our former allies needed to have the help of the US'. Nonetheless most of the literature acknowledges that, beyond the concern for former allies, the political and social stability of non-communist Europe and the continuity of export markets for US products were two of the main concerns of the Truman administration.

The initial Plan proposal was presented in June 1947 by secretary of state George Marshall, asking European governments to design a coordinated aid programme to be funded by the United States. The offer included the Soviet Union and its allies, but the conditional terms on economic collaboration and disclosure of information guaranteed that the Soviet Union would never accept it. In response to the American offer the final aid recipients, Austria, Belgium, Denmark, France, West Germany, Great Britain, Greece, Iceland, Ireland, Italy, Luxembourg, the Netherlands, Norway, Sweden, Switzerland and Turkey, formed the Organization for European Economic Cooperation (OEEC) to coordinate a proposal based on national needs and consistent with American objectives on trade and economic cooperation between recipient countries. US President Truman signed the Plan into a law on 3 April 948, establishing the American-led Economic Cooperation Administration (ECA) to administer the programme.

Over the four years that followed its approval by Congress, the Plan transferred $12.5 billion of US aid to Western Europe. The allocation of funds did not follow a simple rule, although it was mainly determined by the dollar balance of payment deficits of the recipient economies, taking also into account geopolitical considerations especially in the cases of France and the United Kingdom. Marshall Aid represented 2.1 per cent of US GNP in 1948, rose to 2.4 per cent in 1949 and then fell to 1.5 per cent in the remaining two years. In terms of national income of the recipient economies, the funds ranged from 0.3 per cent per year for Sweden to 14 per cent for Austria. For the large Western European economies it represented an average yearly transfer of 2.5 per cent of GDP for France, 2.2 per cent for Italy, 1.3 per cent for the United Kingdom and 1.2 per cent for Germany.

The OEEC took the leading role in allocating funds, conditional on the approval of the ECA. The American supplier was paid in US dollars, which were debited against the ERP account corresponding to the European buyer. This buyer paid for the American imports in local currency, which was deposited by its own government in a counterpart fund. These additional resources were used for local investment projects and eventually were absorbed into the recipient's national budget.

The impact of the plan on the European recovery is not free of controversy. On the one hand, early triumphalist accounts (Jones 1955; Mayne 1970; Arkes 1972) describe the Plan as vital for the reconstruction of productive capacity, the development of the necessary institutions for cooperation among former adversaries, and the restoration of European confidence in market capitalism. In the words of Mayne (1970), Marshall Aid 'was a precondition of all later affluence and economic miracles, as well as moves toward European unity'. On the other hand, Milward (1984) discounts the importance of ERP transfers, arguing that the recovery was well under way before 1948 and the reconstruction of the damaged private and public capital stocks was almost completed. Somewhere in between, De Long and Eichengreen (1993) argue that Marshall Aid helped the recipient economies more in terms of political economy than macroeconomics. The ERP bought European governments the political space needed to avoid the attrition wars that characterized the interwar period, allowing an institutional environment conducive to growth.

Until the influential work of Milward (1984), the literature agreed on the vital importance of the ERP funds for Western European growth. According to this view Marshall Aid allowed for the reconstruction of the capital stock, the elimination of bottlenecks that obstructed production,

the public provision of infrastructures and the surge in intra-European trade. In the words of Arkes (1972), 'the plan was critical at the margins having a multiplier effect of three or four times its value'. A superficial analysis of the data suggests that this view is exaggerated. If we compute the growth rates of per capita GDP for the recipient economies, we find that in the three years that preceded the ERP, yearly growth averaged 6.5 per cent, while during the Plan it averaged 4.4 per cent, falling to four per cent between 1953 and 1956.

Eichengreen et al. (1992) argue that if the effects of the Plan worked mainly through private and public capital accumulation, there should be a significant correlation between output growth and ERP allotments as a share of GDP across recipient economies. Contrary to this view, their statistical analysis does not turn up a significant coefficient on Aid allotments. Alvarez-Cuadrado and Pintea (2008) present a two-sector neoclassical growth model with public capital to explore the direct impact of the ERP. Their numerical analysis suggests that the transfers increased the rate of private investment by less than one percentage point, leading to no more than half a percentage point increase in the growth rate of output. Since average yearly transfers represented no more than half a year's worth of post-war growth, it is not surprising that the effects of the Plan through capital accumulation are rather limited. Along similar lines, Milward (1984) argues that the outstanding performance of Western European economies would have not been very different in the absence of the Plan. He discounts the direct impact of the Plan and convincingly documents that the leverage afforded by the ERP was insufficient for the United States of America to force through its vision of the United States of Europe. In Milward's view the primary role of the ERP was limited to sustaining the flow of capital imports necessary to prolong the recovery.

In a different spirit, De Long and Eichengreen (1993) argue that political economy considerations lie behind the true impact of the Plan. Marshall Aid provided the currency needed to relax the foreign exchange constraint, giving European policy makers extra room to manoeuvre. This political space, together with aid conditionality, induced European governments to balance their budgets, restore internal financial stability, and maintain their commitment to free markets. Their counterfactual vision of Western Europe suggests a permanent influence of Communist parties, an expansion of government controls and regulations, and a resurgence of economic nationalism and isolationism.

This argument, although it has its merits, does not seem to account for the variety of institutional arrangements present in the recipient economies. For instance, two of the fastest-growing economies, France and Germany, adopted rather different growth strategies. The French economy was characterized by major involvement of the state in key economic sectors, while the German approach illustrates the growth potential of relatively free markets. In my view, although the functioning of the market mechanism was constrained in many countries as a result of war priorities, there was a tacit consensus that this was only a temporary interruption of the long European experience with free markets, and therefore the influence of the Plan was rather limited in this respect.

To sum up, the direct impact of the Plan led to no more than half of a percentage point of growth per year. Along the lines of Milward (1984), I believe the plan provided European governments the means to prolong the recovery process which began after the war. In some cases the transfers complemented export revenues, preventing a balance-of-payment crisis, while in others they only postponed its occurrence. The political economy argument is more difficult to evaluate, but given the prior European experience with free markets and the existence of a well-developed system of property rights, it is difficult fully to accept the counterfactual scenario drawn by De Long and Eichengreen (1993). Finally, the Marshall Plan played an important role by inducing British and French support for a strong Germany. Although the forces that led to the process of European integration responded more to internal political and economic developments in the European countries than to American pressure, the Marshall Plan helped promote collaboration among former adversaries.

Marshall, Alfred (1842–1924)

John K. Whitaker

Abstract

English economist Alfred Marshall, founder of the Cambridge School of economics, was a leading and internationally prominent figure in the development of economic thought between 1870 and 1920. He played a significant role in professionalizing British economics, always stressing the social importance of wider economic understanding. His influential ideas on economic theory were conveyed primarily in his *Principles of Economics* (1890). Accounts of his life, career and general views on economics are followed by a more technical treatment of his contributions to various aspects of economic analysis. Guides to his writings and to the secondary literature on him are appended.

Alfred Marshall, Professor of Political Economy at the University of Cambridge from 1885 to 1908 and founder of the Cambridge School of Economics, was born in Bermondsey, a London suburb, on 26 July 1842. He died at Balliol Croft, his Cambridge home of many years, on 13 July 1924 at the age of 81. His magnum opus, *Principles of Economics* (1890a) evolved through eight editions in his lifetime, the final edition (1920) being most commonly cited today. It was one of the most influential treatises of its era and was for many years the Bible of British economics, introducing many still familiar concepts. The Cambridge School rose to great eminence in the 1920s and 1930s. A.C. Pigou and J.M. Keynes, the most important figures in this development, were among Marshall's pupils.

Marshall's biography and career are outlined initially, after which descriptions are given of his views on the social setting, aims and methods of economics, and his intellectual debts to others. An analysis of his fundamental ideas on theories of value and distribution, which were mainly set out in *Principles*, follows, after which his contributions to monetary and international-trade theory are considered briefly. A final section provides additional documentation and general suggestions for further reading. Also, some of the more technical sections have attached to them brief 'bibliographic notes' offering suggestions for further exploration. All bibliographic references lacking an author's name are to works by Marshall, and the bibliographic details of all his cited publications can be found in the list of 'Selected works' below. The bibliographic details for all cited works written or edited by others are listed in the concluding 'Bibliography'.

Biography and Career

Marshall grew up in the London suburb of Clapham, being educated at the Merchant Taylors' School where he showed academic promise and a particular aptitude for mathematics. Eschewing the more obvious path of a closed scholarship to Oxford and a classical education, he entered St John's College, Cambridge, in 1862 on an open exhibition. There he read for the Mathematical Tripos, Cambridge University's most prestigious degree competition, emerging in 1865 in the exalted position of Second Wrangler, bettered only by the future Lord Rayleigh. This success ensured Marshall's election to a Fellowship at St John's. Supplementing his stipend by some mathematical coaching, and abandoning – doubtless because of a loss of religious conviction – half-formed earlier intentions of a clerical career, he became engrossed in the study of the philosophical foundations and moral bases for human behaviour and social organization. In 1868 he became a College Lecturer in Moral Sciences at St John's, coming to specialize in teaching political economy. By about 1870 he seems to have committed his career to developing this subject, seemingly ripe for reform, and helping to transform it into a new science of economics.

For several years he laboured persistently to develop and refine his economic ideas, and to deepen his understanding and grasp of both the existing economic literature and the economic reality that was its subject matter. In 1875 he visited the United States to probe economic conditions, and throughout his life he was tireless in his efforts to master the practicalities of the economic world. Prior to 1879 his publications were meagre. He had embarked on a book on international trade and problems of protectionism in the

mid-1870s, and before that he had worked out many of his distinctive theoretical ideas in the form of short essays, many now reproduced in Whitaker (1975). But the only part of this material to be made public was four chapters from the theoretical appendices for the proposed international-trade volume. In 1879 Henry Sidgwick had these printed for private circulation under the title *The Pure Theory of Foreign Trade: The Pure Theory of Domestic Values* (1879a). (An amplified version together with surviving portions of the text of the abandoned trade volume is also reproduced in Whitaker 1975.) The year 1879 also saw the publication of Marshall's first book, *The Economics of Industry* (1879b), written jointly with his wife Mary Paley Marshall.

Mary Paley had been one of the first group of students at Newnham Hall (later Newnham College) where Marshall, an early supporter of the informal scheme of Cambridge lectures for women, taught her political economy. Their marriage in 1877 required Marshall to give up his Cambridge position under the celibacy rules then in force. He found a new livelihood as principal of the recently established University College, Bristol, where he also became Professor of Political Economy. There *The Economics of Industry* was brought to completion and published by the house of Macmillan, which continued as Marshall's publisher thereafter. Ostensibly an elementary primer, this book contained the first general statement of Marshall's emerging theories, and a considerable sophistication lay beneath its deceptively simple surface. Together with the powerful *Pure Theory* chapters published by Sidgwick, a few copies of which circulated outside Cambridge, *The Economics of Industry* marked Marshall as a rising star in the economics firmament. With the death of W. S. Jevons in 1881, he moved into the public eye as the leader in Britain of the new scientific school of economics.

The duties of the Bristol principalship proved irksome to Marshall, especially as the college was struggling financially. He was anxious to proceed with his writing, having by 1877 conceived the plan for the book that was to become the *Principles*. His frustrations were increased by the onset in 1879 of a debilitating illness, diagnosed as kidney stones, which restricted his activities. He was persuaded to continue as principal until 1881, when he resigned both posts at the college. The next year was spent travelling, with an extended sojourn in Palermo, and it was in this year that composition of the new book began in earnest.

At Bristol, Marshall had got to know well Benjamin Jowett, the famed Master of Balliol, who was one of the governors of the struggling college. It was probably by Jowett's generosity that Marshall was able to return to Bristol in 1882 as Professor of Political Economy. And it was doubtless at Jowett's instigation that the Marshalls moved to Oxford in 1883, when a Balliol lectureship became vacant on the unexpected death of Arnold Toynbee. Marshall had considerable success as a teacher in Oxford and appeared settled in for an indefinite stay. But an 'Oxford School of Economics' was not to be. The sudden death of Henry Fawcett, who had been Professor of Political Economy at Cambridge since 1863, opened up the irresistible prospect of a return to Cambridge and a position with great potential for academic leadership. Marshall, the dominant candidate, was duly elected in December 1884, holding the chair until 1908, when he resigned to devote himself entirely to writing.

In many ways Cambridge's inviting prospects were to prove illusory. Economics was taught as part of the Historical and Moral Sciences Triposes, but neither avenue provided a supply of able interested students, nor was there much scope for advanced work. Marshall struggled for many years, with limited success, to increase the scope for economic teaching. But it was not until 1903, with the establishment of a new Tripos in Economics and Politics, that his goal was achieved. Even then, few resources were made available by the university and colleges for the teaching of economics, and the staffing of the new Tripos relied heavily on Marshall's willingness to support two young lecturers from his own pocket. The flowering of the new school came about mainly after his retirement, but the seeds were certainly planted by his efforts.

Absorbed in the struggle for his own subject, Marshall took relatively little part in general university affairs. Indeed, his rather obsessive

personality and proneness to magnify details would have made him ineffectual as a university statesman even if he had aspired in that direction. But he did play a prominent part in the successful campaign of 1896–7 against the granting of Cambridge degrees to students of the women's colleges – this despite his wife being at the time a lecturer at Newnham. He was not opposed to women's education, indeed had been a warm supporter in his early days, but was vehemently opposed to the assimilation of women into an educational system designed for men.

But the dominant fact in Marshall's life after his return to Cambridge, and certainly the aspect of greatest interest to posterity, is his long struggle to give adequate written expression to the stores of economic knowledge and understanding he had accumulated. The demands of teaching and administration left him little time or energy for sustained composition during term time and it was in the jealously guarded long vacations, usually spent away from Cambridge on the south coast of England or in the Tyrol of Austria, that the only real progress could be made. By 1887 the book commenced in 1881 had grown into a projected two-volume treatise. He hoped to complete the first volume in time for it to appear in the autumn of that year with the second volume appearing by 1889. In fact, the first volume (1890a) appeared as the *Principles of Economics, Volume One,* only in July 1890, when it was received with great and immediate acclaim and established Marshall firmly as one of the world's leading economists. The second volume never appeared. It was to have covered foreign trade, money, trade fluctuations, taxation, collectivism and aims for the future – a tall order!

Marshall struggled for the next 13 years with his intractable second volume, meanwhile spending much time on substantial, but not very substantive, recastings of the first volume in new editions of 1891, 1895 and 1898, and in preparing a digest of it to replace the earlier *Economics of Industry* which he had come to dislike intensely. (The digest, 1892, appeared under the title *Elements of the Economics of Industry, Volume One.* Like the earlier work it included material on trades unions that was never incorporated into *Principles.*) By 1903 much material had been accumulated for the second volume, but the scope was becoming unmanageable as Marshall became increasingly preoccupied with problems of trusts, trades unions, international trade, and comparative economic development, and decreasingly concerned with matters of pure theory. In that year, partly from the impetus of writing a private memorandum on trade policy for the use of the then Chancellor of the Exchequer, and partly because the tariff controversy was at full heat, Marshall was tempted into writing a short topical book on foreign trade questions, intending to publish it speedily. But this project too grew unmanageably in his hands. In 1907, the preface to the fifth edition of *Principles* (the last major rewriting) announced the abandonment of the proposed continuation and promised instead a volume, already partly in print, on 'National Industry and Trade', to be followed soon by a companion volume on 'Money, Credit and Employment' (Guillebaud 1961, vol. 2, p. 46). To reflect this change, the title of the sixth and subsequent editions of *Principles* was changed to *Principles of Economics: An Introductory Volume.* Retirement in 1908, at the age of 66, freed Marshall to concentrate on these projects, but progress continued to be slow. He appears to have suffered from recurrent dyspepsia and high blood pressure, necessitating a strict regimen and limiting his ability to work. But the more fundamental problem was that the world kept changing and the increasingly realistic and factual tone of his enquiry called for incessant recasting and revision. Nothing had been completed by the time war broke out in 1914, and then much rewriting was required to take into account the radical changes that were transforming the world economy and its post-war prospects. At last, when Marshall was 77 years old, *Industry and Trade* (1919), his second masterpiece, finally appeared. It was a magisterial, largely factual, consideration of trends in the British and international economy and of future economic prospects. But, lacking an obvious theoretical skeleton, it has not received from economists the kind of attention lavished on *Principles*, although interest in it is now beginning to stir among historians of economics.

In its final form, *Industry and Trade* was narrower in scope than had been intended earlier, while the proposed book on 'Money, Credit and Employment' still remained to be written. Over the next 4 years, by a remarkable effort, and despite rapidly waning powers, some of the mass of accumulated raw material remaining was pulled together in *Money, Credit and Commerce* (1923). This contains Marshall's fullest treatment of the theories of money and international trade, but it is an imperfect pastiche of earlier material, some dating back almost 50 years.

In the last months of his life, Marshall toyed with the occasional writings and the memoranda and evidence for governmental enquiries that he had prepared at various stages during his career, with the hope of editing them for publication in book form. This was not to be, but his plan was largely fulfilled after his death in two books sponsored by the Royal Economic Society (Pigou 1925; Keynes 1926).

Judged by what might have been, Marshall's authorial performance after 1890 was a sorry one, marked by repeated procrastination and inconstancy and by chronically over-optimistic expectations. The mantle of leadership that he had assumed on Jevons's death had proved a heavy one. Both temperamentally and by virtue of his acknowledged position as the doyen of British economists, Marshall was compelled to attempt the magisterial and to denigrate the kind of forceful direct essay of which he was eminently capable.

As Cambridge professor and unquestioned leader of British orthodox economists, Marshall could hardly avoid becoming a public figure whose pronouncements carried more than a personal weight. His consciousness of this, and of the precarious public standing of economics, as well as his own temperament, made him peculiarly reluctant to enter into public controversy, although he would on occasion fire off a letter to *The Times* on some issue of the day. He served as an expert witness for several government enquiries and was an influential member of the Royal Commission on Labour of 1890–94. As President of Section F of the British Association in 1890 he took the formal lead in the movement to found the British (later Royal) Economic Association, but he was not a prime mover. Indeed, he was not a clubbable or organizational man and relied on others to further whatever goals he desired for economics and the economics profession at large. But neither was he a recluse. Balliol Croft received a continuing stream of visitors, ranging from working class leaders to distinguished foreign economists, while students or young colleagues were always welcomed and offered generous advice mixed with exhortation.

Although able students interested in economics were in short supply, Marshall did over the years teach and influence several students who were to make contributions to the subject. From the early Cambridge period H.S. Foxwell, H.H. Cunynghame, J.N. Keynes and J.S. Nicholson might be mentioned. The Oxford period brought L.L.F.R. Price and E.C.K. Gonner, while the period as Professor in Cambridge produced, among others, A. Berry, A.W. Flux, C.P. Sanger, A.L. Bowley, S.J. Chapman, A.C. Pigou, J.H. Clapham, D.H. Macgregor, C.R. Fay, and, last but not least, J.M. Keynes.

The undoubted fact of Marshall's professional leadership of British economics calls for some explanation. He was far from suited to such a role by temperament, and his fussiness and inflexibility could be irritating. For example, Sidgwick, J.N. Keynes, and Foxwell, the most important of his early allies in Cambridge, were all eventually alienated. Marshall's success can be attributed partly to sheer persistence. As in the case of the new Tripos, he had a clear idea of what he wanted to accomplish and worried away at it until he exhausted the opposition and was allowed to have his way. But it must also have been due to the lack of any alternative. The relevant question is not 'Why Marshall?' but 'Who else?' Economics was rapidly evolving as a profession around the turn of the 20th century, creating a leadership vacuum. Leadership was unlikely to emanate from outside Oxford, Cambridge or London, but F.Y. Edgeworth at Oxford was perhaps the last man capable of meeting the need, while E. Cannan at the new London School of Economics, although more suited than Marshall to the hurly-burly of professional politics, was too

much the perennial critic and iconoclast to fill the bill. Moreover, whatever Marshall's foibles, the sheer power of his intellectual vision, his international standing as Britain's leading economic thinker, and his ability to inspire an impressive flow of budding scholars, all conspired to make him the only feasible contender.

Marshall's Views on the Social Setting, Aims and Methods of Economics

Marshall saw economics as concerned with those aspects of human behaviour open to pecuniary influences and sufficiently regular and ubiquitous to permit statements of broad scope and some persistence. While maintaining, especially in earlier work, that some heeded moral imperatives might be impervious to pecuniary considerations, he conceded that most behaviour lay within the ambit of the measuring rod of money. On the other hand, he emphasized that motivation was not merely a matter of pursuing pecuniary self-interest, even if broadly conceived to include interests of family and friends. He was anxious to lay the ghost of *homo economicus* and emphasized the human desires to obtain social approbation or distinction and to enjoy the pleasures of skilful activity. He saw actors as diverse as captains of industry and sculptors driven more by the joys of creative activity and the striving for the regard of peers than by the desire for material acquisition.

As well as not being pecuniary maximizers in any narrow sense, individuals were for the most part seen as imperfect optimizers. The working classes, especially, often lacked the knowledge and foresight to judge their long-term interests. Marshall's actors were not imbued with complete knowledge of their environment but had to acquire knowledge slowly, and often painfully, through experience. Nor were they endowed with fixed desires and an intrinsic, unchanging character. Indeed, character and preferences evolved as individuals were exposed to new possibilities and chose to enter into new activities. The workplace, in particular, was an important moulder of character. Self-improvement and character development induced by environmental changes, planned or unplanned, both figured largely in Marshall's world view. He believed that social institutions, such as land tenancy practices, were pliable and ultimately moulded themselves into conformity with the individual interests involved, rather than presenting a permanent constraint on mutually desired accommodations. (For this he was taken to task by his most vehement critic, W. Cunningham, who denied the applicability of modern economic theory to medieval practices – see Cunningham 1892.) But institutional change must be slow, slower even than changes in individual character and wants, because informal customs and tacit agreements are hard to change. Thus, while the institutions and informal understandings and prohibitions that constrain and mould economic behaviour might ultimately be endogenous they will often be ill adapted to current circumstances and thereby act as an independent constraint on the pursuit of mutually desired accommodations. Institutions, in the broad sense, are important and not always socially rational constraints on individual action.

Marshall was impelled to economics because 'the study of the causes of poverty is the study of the causes of the degradation of a large part of mankind' (1920, p. 3). For the bulk of the population, mired in poor living and working conditions, little progress in habits, aspirations and self-esteem could be expected without prior improvement in economic conditions. Such improvement was socially important not so much for its own sake, at least once the pangs of immediate want were assuaged, but because of its instrumental role in permitting and stimulating improvement in the quality and character of the population. What Marshall really valued was not improvement in the standard of living but the enhancement of the standard of life that this improvement made possible. And he entertained little doubt about what constituted a qualitative improvement here, even though – or perhaps because – his values may seem quite parochial and culture-bound.

Economic improvement required appropriate institutions, incentives and attitudes, and would be threatened by wide-scale government intrusions into economic affairs, although some forced

income redistribution could be tolerated. But even if economic conditions were improved, the full yield of social betterment would be garnered only if enlarged consumption were turned to ennobling and horizonexpanding channels (rather than, say, to strong drink), involved a due consumption of beneficial leisure, and was accompanied by healthier and less stultifying conditions of working and town life. The government had a guiding role to play here. But even more important would be the assistance and example of employers and the upper and middle classes, who must first rid themselves of a frequent propensity to showy and ostentatious consumption and excessive materialism. The working-class leaders and skilled artisans who had already raised their own standard of life had an important leadership role too. Voluntary individual efforts to assist the rise of the underprivileged must rest on an adequate understanding of economic consequences. For this, as well as to secure an informed electorate, the diffusion of sound economic knowledge was an essential and integral element in the process of socio-economic transformation. Economics thus was itself a noble activity of high importance for the future of mankind.

The broad view of the economy suggested by the foregoing is of a complex evolutionary process of combined economic, social and individual change in which each individual's abilities, character, preferences and knowledge develop jointly, along with social institutions, markets and the technologies of production and communication. The pursuit of self-interest, broadly conceived, is ubiquitous in directing this evolutionary process, but is subject to inertia, ignorance and limited foresight, not to mention individual mutability.

Unfortunately, Marshall was able to bring little formal analysis to bear on this general 'biological' vision of the economy and could only evoke it descriptively. It might be true that 'the Mecca of the economist lies in economic biology rather than in economic dynamics' (1920, p. xiv). Nevertheless, the only available analytical tools were those of classical mechanics, tools that Marshall's early mathematical training had equipped him to employ skillfully. In fact, chief reliance had to be put on that branch of classical mechanics dealing with statics. Dynamics, beyond a few qualitative applications, required more precise information than was likely to be available. Perforce then, much of Marshall's formal analysis, like that of W.S. Jevons or Léon Walras, was based on simple assumptions of individual optimization and market equilibrium, taking preferences, technology and market institutions for granted. Such provisional or tentative 'statical' treatments could often be valuable. Indeed Marshall viewed them as indispensable for the correct analysis of many questions. But he was always anxious to stress that the analysis was preliminary, and perhaps of only transitory validity. This awareness made him impatient of overelaboration, so that, for example, he showed no interest at all in pushing the statical approach to its logical conclusion in the general equilibrium analysis of the stationary state. For him, equilibrium analysis was an indispensable but rough and ready instrument that needed to be employed with due caution and a continuing awareness of its limitations in the face of a complex ever-evolving reality. It was only a tool and did not itself constitute concrete knowledge.

Marshall had no great profundity as a philosopher of science and had little patience with metaphysics: 'in a sense … he held no views on method' (Coase 1975, p. 27). Marshall's discussions of methodology largely reflect the philosophical presuppositions of his day. His method was in the general deductive tradition of John Stuart Mill, but he sought to emphasize the relativity of particular theories, as contrasted with the universality of the general theoretical 'organon' or economists' toolbox. Anxious to present a public image of the unity of economics in the face of the Methodenstreit among economists in the late 19th century, he attempted to maintain an uneasy balance on method, decrying extended chains of deductive reasoning but denying the possibility of purely inductive inference unguided by a coherent conceptual framework. Economics had room for specialists in both deductive and inductive methods, but both must ultimately be co-workers. Assumptions must be selected with close regard to the facts of the case and potential disturbing causes must be kept prominently in mind and due allowance made for them.

J.N. Keynes described Marshall's analytical method as 'deductive political economy guided by observation' (1891, p. 217n) and Keynes's chapter 'On the Deductive Method in Political Economy' (1891, pp. 204–35) is perhaps as good a rationalization of Marshall's method as one can find.

Intellectual Debts

The intellectual background to Marshall's work in economics was established in the 1860s, partly in his stringent mathematical training, but perhaps more importantly in the heady mixture of utilitarianism, evolutionism and German idealism which he eagerly imbibed in the years immediately following his graduation. He seems to have started on economics from J.S. Mill's *Principles of Political Economy* (1848), moving on to the classic works of Smith and Ricardo. At a fairly early stage, probably around 1868, he discovered Cournot's *Récherches* (1838), which provided examples of the application of mathematics to economic questions. Acquaintance with J.H. von Thünen's work, which influenced Marshall's distribution theory, must have come somewhat later, in the early to mid-1870s. During the 1870s and early 1880s Marshall also read widely on economic development and socialism, including much literature in German, the only foreign language he mastered thoroughly. After that, his reading seems to have been concentrated mainly on factual and practical matters. Once his own theoretical views had crystallized, he appears to have been reluctant to do more than attempt to explain and clarify them to others, and to have taken remarkably little interest in new theoretical issues or in the theoretical ideas of others.

In many ways, the list of Marshall's denials of theoretical indebtedness is more remarkable than that of his acknowledgments. He claimed to have developed his ideas on consumer surplus before learning of anticipations by J. Dupuit and H. Fleeming Jenkin. The grudging attitude to W.S. Jevons's marginal utility theory shown in his review (1872) of Jevons (1871), although subsequently relaxed, was never replaced by any acknowledgement of indebtedness. He showed little or no interest in the work of Walras, gave meagre credit to Carl Menger, whose work must have become known to him by the early 1880s, patronized Pantaleoni and Böhm- Bawerk, largely ignored Pareto, and so on. Even in the case of Edgeworth, one of his few intimates, Marshall felt that undoubted theoretical powers were guided by an unreliable judgement and refused to follow Edgeworth's subtle elaborations far. In fact, the only major theorist of the day to command Marshall's entire admiration and respect was J.B. Clark, and even here there was no acknowledgement of serious indebtedness. This tendency to denigrate the work of his contemporaries was matched by an equally strong tendency to overvalue the achievements of the British Classical School led by A. Smith, D. Ricardo and J.S. Mill. For one reason or another – perhaps a personality quirk, perhaps an effort to boost the public esteem of economics – Marshall was prone to exaggerate the intellectual continuity and maturity of his subject – see O'Brien (1990) on this.

A growing interest in wider intellectual influences on Marshall in his formative years 1865–70 has been sparked by the publication and analysis of his early philosophical manuscripts (Raffaelli 1994, 2003), especially a paper entitled 'Ye Machine' that outlines a mechanism capable of learning new routines from experience, thus freeing its limited learning ability to gradually establish new and higher level routines, and so on. It appears that Marshall's ambitions in these early years lay in the area of 'psychology' or perhaps better in the 'philosophy of mind'. Whether the world lost more than economics gained from his switch to economics remains an open and perhaps insoluble question. But it does appear that the pattern of a sequential routinizing of new methods, continually leading to new levels of individual or organizational complexity, continued to play a significant part in Marshall's economic thought. More generally it is clear that he read philosophical literature widely in his formative years: Kant, Hegel, H. Spencer, and others. But whether and how these sources influenced his economic thought remains uncertain, partly because evidence is slight or absent.

Demand Theory

So far the discussion has remained on a very general level, dealing with broad aspects of Marshall's life and work. At this point there begins a much more detailed and technical consideration of various aspects of his theoretical contributions, commencing with his demand theory. Marshall's treatment of the theory of demand is sketchy and incomplete, concentrating on the demand for a single commodity, or commodity group, against a loosely defined background. A utility-maximizing individual's utility is defined by $u(x) + w(y)$ where x is the individual's consumption of the particular good X, while y is the individual's expenditure on all other goods. This expenditure is measured in money of constant purchasing power: that is, deflated by a general price index. How this index is defined and whether, as seems appropriate, the price of X is excluded from it, is left unclear. Such money can be treated as a composite good, Y, and y can be regarded as the amount of this composite good consumed. If m is the individual's initial endowment of Y, then $y = m$ whenever $x = 0$, while if X can be freely purchased at a fixed price of p units of Y per unit of X then x and y must satisfy the constraint $px + y = m$. Marshall assumes that the utility functions $u(x)$ and $w(y)$ have positive but diminishing marginal utility so that $u'(x) > 0 > u''(x)$ and $w'(y) > 0 > w''(y)$, where single and double primes are used to denote first and second derivatives. The maximum expenditure, e, that the individual is willing to make to secure x units of X is implicitly defined as a function e(x, m) by $u(x) + w(m - e) - w(m) = 0$. Providing that x and y are both positive, the rate at which e increases with x is $u'(x)/w'(m - e)$ by the implicit function theorem. This ratio would be the demand price for the xth unit of X if all previous units had been acquired at their corresponding demand prices: that is, if the individual had faced perfect price discrimination in exchanging Y for X. Alternatively, if the individual had been able to obtain any amount of X at fixed per unit price, p, the resulting demand function $x(p, m)$ for X would be implicitly defined (given x and y are both positive) by the first-order condition $u'(x) - pw'(m - px) = 0$. Partial differentiation of $x(p, m)$ shows that x falls as p increases, while an increase in m increases both x and y: thus, the Giffen possibility of an increase in p increasing the quantity of X demanded is excluded. But an increase in p may lower or raise the value of px, so that demand for X may be price elastic or price inelastic at a given p.

The possibility of buying at a fixed price rather than facing perfect price discrimination creates a consumer surplus of $e(x(p, m), m) - px(p, \text{m})$. This is the additional amount that could have been extracted by perfect price discrimination for all units up to the price-taking optimal one. That this surplus is positive follows from the fact that every infra-marginal unit of X acquired creates a surplus utility when the individual faces a fixed price (since $u'(x) > pw'(m - px)$ for each such x) but no surplus when the individual is faced with perfect price discrimination.

Marshall's mathematical notes (1920, pp. 838–42) on his general case are obscure and puzzling. Doubtless he felt this case was too dependent on unobservables to be of much practical value. He therefore emphasized the special case in which the marginal utility of money is treated as a constant. The rationale offered is that an individual's 'expenditure on any one thing ... is only a small part of his whole expenditure' (1920, p. 842). This simplifies $e = e(x, m)$ above to $e = u(x)/w'(m)$ while $x(p, m)$ is now defined implicitly by $u'(x)/w'(m) = \text{p}$. At the x value defined by the latter equation, consumer surplus arising from the ability to buy any amount of X at the per-unit price p can be expressed in utility terms as $u(x) - xu'(x)$ or in money terms as $u(x)/w'(m) - xu'(x)/W(m)$. These formulae are exactly analogous to the standard formula for Ricardian land rent, with the first term the output obtained on a piece of land from the application of x doses of variable input, each dose remunerated at the common marginal product. Partly because of this analogy, Marshall used the term 'consumer rent' rather than 'consumer surplus' prior to 1898.

Although priority must go to Dupuit, Marshall's simple concept of consumer surplus based on the assumption of a constant marginal

utility of money has been influential. But he was well aware of the complications arising from variation in the marginal utility of money: 'Strictly speaking we ought to take account of the fact that if he spent less on tea the marginal utility of money to him would be less than it is, and he would get an element of consumers' surplus from buying other things at prices which now yield him no such rent' (1920, p. 842). Although such influences may be 'of the second order of smallness' they raise the more disquieting issue of assessing the overall welfare effects of changes that affect many markets simultaneously. On this Marshall had little to say: 'the task of adding together the total utilities of all commodities, so as to obtain the aggregate of the total utility of all wealth, is beyond the range of any but the most elaborate mathematical formulae' (1920, p. 131n.). It was a task he chose not to pursue. Apart from generalizing for the possibility that a certain quantity of good X might be indispensable, Marshall elected not to develop his demand theory further, or even to generalize it to incorporate utility functions that were not additively separable (1920, p. 845). It is clear that each commodity in turn might take the spotlighted role of good X and that in certain circumstances simultaneous consumer surpluses for several goods might be added (1920, p. 842). An unpublished early manuscript note from the 1870s on the theory of taxation (Whitaker 1975, vol. 2, pp. 285–305) had advanced matters considerably further by working formally with the maximization of utility under a budget constraint, but this lead was not followed up in print and some of its lessons for welfare economics were apparently forgotten. *Principles* gave a clear intuitive account of the consumer's overall optimization problem (1920, pp. 117–23), but failed to connect it to the resulting interrelated set of demand functions for the various goods consumed. Indeed, it is clear that for positive purposes Marshall was willing to treat market demand functions in a quite pragmatic way, admitting, for example, close substitutes or complements and the Giffen exception, all inconsistent with the simple formal theory set out above. In judging this, it must be borne in mind that consistency and generality of 'statical' analysis were not Marshall's real goal. Rather, 'fragmentary statical hypotheses are used as temporary auxiliaries to dynamical – or rather biological – conceptions' (1920, p. xv).

The market demand for a good that is offered to all actual or potential buyers at the same given price is of course obtained as a function of that price by summing the amounts demanded at that price by all the consumers. A sufficient but not necessary condition for market demand to fall as price increases is that each individual's demand decreases. The now familiar concept of market demand elasticity – proportional quantity change divided by proportional price change – was first introduced by Marshall, although several authors had come close to the idea previously. It appeared without flourish in (1885c), and appeared more prominently in *Principles.* But Marshall himself made relatively little use of it.

Bibliographic note: Marshall's treatment of demand is essentially contained in (1920, pp. 92–137, 838–43). An influential, although controversial, interpretation of Marshall's demand theory is given by Friedman (1949). Biswas (1977) gives another alternative to the orthodox reading provided by Stigler (1950) that is largely adopted here. An excellent overview is Aldrich (1996). On consumer surplus see Chipman (1990).

Production and Long-Period Competitive Supply

In deriving the long-period supply curve of a commodity in *Principles,* Marshall envisages production as organized by firms, typically family businesses. Each firm strives to minimize its production costs, substituting one productive factor or production method for another according to the 'Principle of Substitution'. In its simpler forms this involves marginalist adjustment to bring relative marginal value products into line with relative marginal costs. But more generally, the Principle of Substitution is akin to a natural selection process, being 'a special and limited application of the law of survival of the fittest'

(1920, p. 597). Marshall's firms do not have costless access to a common production function, but must grope and experiment their way to cost-reducing modifications. The long-period supply curve is defined for a given state of general scientific and technical knowledge. But each firm must explore this to some extent anew.

Although the distinction is not entirely clear – distinctions seldom are for Marshall – two polar cases may be distinguished within his theory of long-period competitive supply. These will be referred to as the 'agricultural' and the 'industrial' cases. The former is much the more straightforward and involves an industry in which production is relatively simple, internal economies of scale are minimal, and the product is homogeneous and easily marketed. The optimal firm size is small, and management is sufficiently routine to need no exceptional ability to keep a firm operating efficiently. As the overall market expands, new firms may be added, but changing composition of the population of firms is not an essential feature of this case.

The long-period supply price per unit of output at which such an industry can supply any quantity of output must just cover the cost of maintaining that level of output indefinitely. That is, it must just suffice to pay all the inputs (including management) needed to produce that level of output in a cost-minimizing way at rates that just ensure that the requisite input quantities will continue to be forthcoming indefinitely. In the case of skilled workers, in particular, the rate must just suffice to induce parents to apprentice new workers to the industry at a rate exactly offsetting the attrition through retirement and other causes. Similarly, the return to fixed capital must just suffice to induce replacement of the existing stock of fixed assets, while the return to management must keep up the necessary replacement flow of managers. On the other hand, the return to land services must just suffice to prevent these services from migrating elsewhere, replacement not being necessary. As the level of industry output being considered is increased, the supply price will probably rise, mainly because of the need to pay a higher return to land so as to attract a greater supply from other uses, but perhaps also because of the need to pay more for rare natural talents that, like land, must be attracted in greater quantity from other uses, not being capable of replication through education and training. Such a tendency for long-period supply price to rise with output may be mitigated though seldom eliminated by substitution against inputs whose supply price is rising, and by possible external economies that increase each firm's efficiency by influences that depend, not on its own output, but on the entire industry's output. A tendency for supply price to rise with output will imply that infra-marginal units of those inputs whose supply prices are rising receive rents, since all units will be remunerated at the rate necessary to induce continuing supply of the marginal unit. In the absence of external economies (or diseconomies) the total rent or producer surplus generated will be the 'triangular' area above the supply curve. That is, it will be

$$R = xg(x) - \int_0^x g(v)\mathrm{d}v$$

where $g(x)$ is the supply price of output quantity x, an increasing function of x. This result does not apply in the presence of external economies. In later editions of the *Principles,* Marshall introduced the device of the 'particular expenses curve' (1920, pp. 810–12) to display rent in such a case, but this *ex post* construction does not give an independent basis for determining rent.

It that the long-period supply curve of an industry depends on the general economic background against which the industry is assumed to operate. As is the case with demand, Marshall does not consider this background in detail. He assumes prices to be expressed in money of constant purchasing power and recognizes on occasion that there may be close interrelations between two industries (for example, they may compete for the same specialized land). He also recognizes that 'a theoretically perfect long period must give time enough to enable not only the factors of production of the commodity to be adjusted to the demand, but also for the factors of production of those factors of production to be adjusted and so on' (1920, p. 379n.), and that this leads ultimately to the assumption of a stationary state. But

he is not willing to follow this route far and is content in general to take the supply conditions of the factors of production for granted when analyzing long-period price determination.

In the 'manufacturing' case, to which we now turn, the product is differentiated, marketing is difficult, and each firm must build up and retain goodwill and a customer connection for its own specialized product. There are substantial internal economies of scale in production and successful management calls for business ability of a high and rare character. In this environment, a family business may be built up by an exceptional founder, but this build-up must be slow because of the difficulty of establishing a market and perhaps also because of constraints on financing. And when the founder passes on, his successors are unlikely to have equal talents or even the lesser talents required to prevent the firm's business from languishing. By the third generation of succession, the firm is likely to expire. Even a joint stock company (a case added rather as an afterthought) is likely to ossify into bureaucratic stagnation, and presumably the same is true of family businesses that rely on paid managers. Thus, the typical firm in the manufacturing case passes through a finite life cycle, and the industry is comprised of a population of such firms at various phases of the life cycle, some in the early expanding phase, others in decline.

The long-period supply price at which such an industry can supply a specified level of output must now be regarded as an index of the prices of all the different firms' products. It must meet all the conditions required in the agricultural case. Thus, the price must allow for a continuing replacement flow of the various types of workers (including managers) and fixed assets, as well as the retention of the necessary 'land' services. But now there must also be a surplus sufficient to induce are placement flow of new firms – a supply of 'business organization' that will just suffice to replace the expiring firms and keep the age distribution of firms constant.

Industry equilibrium does not require each firm to be in an unchanging equilibrium any more than the trees in the proverbial forest. A new firm will be established if the prospective earnings over the expected life cycle appear to justify the cost and trouble involved. The firm's initial earnings are likely to be negative as it slowly builds up its technical expertise and market connections, but these early losses can be regarded as investments to be recouped in the later stages of the firm's prospective life cycle.

It is here that Marshall's 'representative firm' enters the picture. It is best regarded as a parable that avoids the need to consider the entire distribution of firms. By definition, the long-period supply price of any level of industry output is the average cost of the representative firm at that level of output. Industry-level magnitudes may then be regarded as if they were generated by a fixed number of unchanging representative firms rather than by the actual heterogeneous body of ever-changing firms. In other words, the manufacturing case may be treated as if it were an agricultural case populated by representative firms only. Such arguments add nothing conceptually and are prone to confuse, although it might be noted that Marshall believed an acute well-informed observer could select an actual firm that was close to being representative in this sense.

The average cost and size of the representative firm will change as industry output changes. There are two main reasons for this. A larger industry output is likely to generate more external economies, lowering the costs of every firm. But more importantly, the larger industry demand is, the easier it will be for a new firm to build up a market, and so the larger the size to which firms will grow before they begin to decline. This will bring about greater access on average to unexhausted internal economies of scale, again leading to lower costs on average. For both these reasons, long-period supply price is likely to decline as a larger industry output is considered, even though the opportunity cost of obtaining greater supplies of land services and rare natural talents may rise. Again, the particular expenses curve may be used to display the producer surpluses or rents accruing to such scarce factors at any given level of industry output, but the relationship of this family of curves to the long-period supply curve is tenuous and complex. Rent obviously cannot be represented by a 'welfare triangle' above the supply curve when the latter is falling.

The conception of competition in Marshall's manufacturing case is much closer to later ideas of imperfect or monopolistic competition than to modern notions of perfect competition. Products are differentiated and firms are not price takers, but face at any time downward-sloping demand curves in their special markets. Even if the difficulties of rapidly building up a firm's internal organization can be overcome, the resulting enlarged output cannot be sold at a price covering cost – even granted substantial scale economies in production – without going through the slow process of building up a clientele and shifting the firm's particular demand curve. The time this takes is assumed to be considerable relative to the duration of the firm's initial vitality. But in some cases the difficulties of rapid expansion may be overcome. They may not have been very severe, as when different firms' products are highly substitutable, or the firm's founder may have unusual genius. In such cases the industry will pass into a monopoly or be dominated by a few, strategically interacting firms, or 'conditional monopolies' as Marshall termed them.

Marshall's reconciliation of persisting competition with increasing returns and falling supply price is complex and problematic, but it does not depend in any essential way on scale economies being external to the firm. The concept of external economies is one of his significant contributions, although his treatment of it can hardly be called pellucid. But it was added more for verisimilitude than because it was theoretically essential to the structure of his theory.

The issues surrounding Marshall's representative firm, and the problem of reconciling the persistence of competition with the presence of unexhausted internal economies of scale, continue to receive attention among historians of economic thought but no definitive reading has yet been attained, or perhaps ever will be. The account given above is well supported by Marshall's text, but as is often the case with Marshall, elements of ambiguity and vagueness remain.

Bibliographic note: Marshall's treatment of long-period competitive supply is to be found in (1920, pp. 314–22, 337–80, 455–61, 805–12) and (1919, pp. 178–96). The earliest version, dating from the early 1870s is reproduced in Whitaker (1975, vol. 1, pp. 119–59) and see also (1879a). Key early commentaries and criticisms of Marshall's theory of supply are Sraffa (1926), Robbins (1928), Robertson et al. (1930), Viner (1931), Frisch (1950), Hague (1958) and Newman (1960).

Price Determination and Period Analysis

The long-period supply curve for any good indicates for each market quantity the least price at which that quantity will continue to be supplied indefinitely. The long-period equilibrium price and quantity are determined by the intersection of this supply curve with the market demand curve, assumed to be negatively sloped, that indicates the highest uniform price at which any total quantity can be sold. In the agricultural case, equilibrium will be unique as the supply curve slopes positively. But in the manufacturing case, the supply curve, as well as the demand curve, may have negative slope, so that multiple equilibria can occur. Equilibrium is adjudged locally stable if demand price is above (below) supply price at a quantity just below (above) the equilibrium quantity. The intuitive justification for this is that the actual price of any available quantity is determined by the demand price, while quantity produced tends to increase (through both expansion of existing firms and entry of new firms) whenever an excess of market price over supply price promises high profits, while it tends to decrease in the opposite case.

This stability argument is sketchy and, in any case, there still remains the question of exactly how a new long-period equilibrium is attained following some change, such as a permanent shift in the demand curve. One possibility would be to consider explicitly the adjustment process through time, but Marshall preferred to approach the problem by another route – his period analysis, one of his most memorable and lasting contributions. (His passing claim (1920, p. 808) that the long- period supply curve may not be reversible, supply price depending upon past-peak output as well as current output, is something of an

exception to this generalization. It appears to rest on some restriction of the degree of downward supply adjustment, and so not to involve a true long-period analysis, or else to invoke a kind of learning by doing that once attained is not readily lost.)

Period analysis is Marshall's most explicit and self-conscious application of the comparative-static, partial-equilibrium method with which his name will always be associated. As he observed,

> the most important among the many uses of this method is to classify forces with reference to the time which they require for their work; and to impound in *Caeteris Paribus* those forces which are of minor importance relatively to the particular time we have in view. (Guillebaud 1961, vol. 2, p. 67)

Which forces or variables are to be hypothetically frozen or impounded, and which are to be determined by the requirements of equilibrium (an equilibrium contingent upon the contents of the *ceteris paribus* pound, of course), should be determined pragmatically in each case with the aim of focusing on the features deemed dominant in that case. As a general rule, those forces should be impounded which move very slowly, or else bounce around very rapidly, relative to the length of 'the particular time we have in view'. This is well illustrated by Marshall's example of a fish market, where the focus may be on the determinants of price over a few days, a few months, or several years, or even decades (1920, pp. 369–71). As an expositional matter, however, and also to embody distinctions of wide (but not universal) applicability, Marshall emphasized three broad cases. Temporary or market equilibrium analysis proceeded on the assumption of a fixed stock of output already available or in the pipeline. Short-period normal equilibrium analysis permitted output to be varied, but not the stock of productive 'appliances' available to produce that output. 'Appliances' must be taken here to cover skilled labour and business organization as well as fixed capital assets, so that the existing set of firms is to be taken as given. Finally, long-period normal equilibrium, which has already been considered, allows the stock of appliances, as well as the level of output, to be freely varied. In this case equilibrium incorporates the conditions necessary for inducing an exact replacement flow of each kind of appliance, including a replacement flow of new firms in the manufacturing case.

Temporary equilibrium for a perishable commodity is simply a matter of selling off the existing stock. Marshall recognizes the possibility of 'false trading' – sales at a non-equilibrium price – but argues that (*a*) this will not affect the eventual price if the marginal utility of money is constant, and (*b*) price will quickly settle close to the uniform price that would just clear the market if used in all transactions. With a storable good there is the further speculative possibility of holding back supply for future sale, and this gives expected future cost of production an indirect role in influencing current market price. Cost of production already incurred is an irrelevant bygone, however.

In short-period normal equilibrium, output is adapted to demand within the constraints set by the fixed supply of available 'appliances'. High demand will raise equilibrium output, but only within the limits possible by working existing appliances more intensively or pulling in versatile unspecialized labour and land from elsewhere. Low demand will lead to low utilization of appliances, perhaps idleness of some, and migration of unspecialized inputs to elsewhere. In the agricultural case a firm will change output until marginal prime or variable cost equals market price. In the manufacturing case, a fear of spoiling the future market or invoking retaliation from competitors tends to make a firm's output more responsive to variation in market price, and hence to make market price less responsive to demand shifts. Otherwise, the two cases are similar, both involving a fixed population of firms and a rising supply curve.

The return received by an appliance will often exceed the minimum necessary to induce its operation at the chosen intensity (its prime cost) and this excess is a 'quasi rent'. To the extent that land and rare natural talents are immobile in the short period, or less mobile in the short period than the long, their returns too will often have a quasi-rent element. Otherwise, they will receive only

differential rents, though often at rates differing from their long-period values. It should be stressed that the concepts of quasi-rent and differential rent are relative to a specific use. The prime cost necessary to retain an input in this use may itself include rent or quasi-rent when viewed in the context of a more inclusive set of alternative uses. Thus, from the viewpoint of all possible uses in the economy, the return to any factor in fixed supply is entirely a rent or quasi-rent (the latter if fixity is only short-period).

Marshall paid little attention to the possibility that forces similar to those constraining the adjustment of supply when time is limited might also operate on the side of demand. Thus the same considerations underlie the market demand curve whether it is coupled with a temporary, short-period or long-period supply curve. In each case, market equilibrium price and quantity are determined by the intersection of the appropriate demand and supply curve. The stability of temporary equilibrium is directly asserted. The stability of short-period equilibrium depends on the same quantity-adjustment argument invoked for long-period equilibrium, but since the short-period supply curve is always positively sloped, uniqueness and stability are assured.

The theory of short-period normal equilibrium was designed as a tool for analysing unemployment and economic fluctuations in the never-completed second volume of *Principles*. But it also has use in explaining adjustment to a permanent disturbance. Suppose, for instance, that an industry is in long-period equilibrium when a permanent shift in demand occurs. The immediate or short-period effects can be analysed by freezing output and stocks of appliances at their initial levels. Insight into the actual adjustment through time can then be obtained by appropriately changing the output level assumed in the temporary equilibrium, so that movement of temporary equilibrium towards short-period equilibrium can be traced out as output, but not stocks of appliances, adjusts. Similarly, the levels assumed for the stocks of appliances in this short-period equilibrium can be allowed to change and the movement of short-period equilibrium towards long-period equilibrium traced out. Such arguments are now a staple of elementary pedagogy. They clearly require additional assumptions about the adjustment of output and the way in which investment or disinvestment in appliances proceeds, and are only a poor and ambiguous substitute for an explicit dynamic analysis. But such 'statical' procedures, although imperfect, may, in Marshall's words, be 'the first step towards a provisional and partial solution in problems so complex that a complete dynamical solution is beyond our attainment' (Pigou 1925, p. 312).

Marshall's period analysis, and more generally his partial-equilibrium approach to price determination, was designed in large part as a usable tool for the analysis of concrete issues. Its longevity amply testifies to its usefulness in this respect. But it was also meant to serve the more doctrinal purpose of clarifying the respective roles utility and cost of production play in determining value. The aim was to show that the greater the scope for supply adjustment permitted in the definition of equilibrium, the more dominant the supply side influence on price becomes. This doctrinal goal helps to account for the rather heavy weight given to long-period analysis in *Principles*. For, as Marshall recognized, its value as a tool of applied analysis is seriously qualified by the fact that 'violence is required for keeping broad forces in the pound of Caeteris Paribus during, say, a whole generation, on the ground that they have only an indirect bearing on the question in hand' (1920, p. 379n). That is, there is no good ground for assuming that background forces such as technology and tastes will remain constant for the length of time required for long-period equilibrium to be practically relevant. For concrete analysis of problems of such long duration it will often be necessary to transcend the period analysis, with its reliance on statical equilibrium, and undertake directly an analysis of secular change, of which Book 6, Ch. 12 of *Principles* on the 'General Influence of Economic Progress' (1920, pp. 668–88) offers the main example, but not a very impressive one.

In emphasizing the role that cost of production plays in the determination of long-period value, Marshall was not content to rest on money costs of production but sought to go behind these costs to

the real costs –the efforts and abstinences – for which in a non-coercive economy the money costs are recompense. In doing so he purported to follow Ricardian tradition, but is more plausibly viewed as attempting to place the newer subjective value theories in broader (but still subjective) focus. Just as the price paid by a consumer serves as a measure of marginal utility, with a consumer surplus gained on infra-marginal units, so the unit price received by a worker or saver measures the real cost or disutility at the margin, with a producer surplus on the inframarginal units of effort or abstinence. But, as Marshall recognized, the parallel holds imperfectly in the long period when workers must be regarded as produced means of production as well as final consumers and cost bearers. In particular, parental sacrifice for raising and training offspring obtains little or no direct pecuniary reward.

Bibliographic note: Marshall's treatment of period analysis is concentrated in (1920, pp. 363–80) but see Whitaker (1975, vol. I, pp. 119–59) for the earliest version. For commentary and exposition see especially Viner (1931), Opie (1931), Frisch (1950) and Whitaker (1982). On temporary equilibrium see (1920, pp. 331–6, 791–3, 844–5) and Walker (1969). On short-period normal value see Gee (1983).

Normal Value and Normal Profit

Implicit in the preceding discussion are Marshall's conceptions of normal value and normal profit. Normal value is defined as the value that would result 'if the economic conditions under view had time to work out undisturbed their full effect' (1920, p. vii). It is contrasted with market value, which is 'the actual value at any time' (1920, p. 349). Normal value is hypothetical, resting on a *ceteris paribus* condition, its role being to indicate underlying tendencies. The normal value of a commodity may approximate its average value over periods sufficiently long for the 'fitful and irregular causes' (1920, pp. 349–50) that dominate market value to cancel out, but this should not be presupposed automatically outside a hypothetical stationary state.

The distinction between normal and market value is closely related to the distinction between natural and market value found in the work of Smith and the classical economists. In 1879 Marshall had identified normal value with 'the results which competition would bring about in the long run' (1879b, p. vii), but in *Principles* he switched to the view that 'Normal does not mean Competitive' (1920, p. 347) and admitted any kind of regular influence so long as it was sufficiently persistent. The economic forces hypothetically permitted to achieve full mutual accommodation could now be chosen appropriately for each case. In particular, the distinction between short-period and long-period normal (or 'sub-normal' and 'true- normal' in earlier editions) was emphasized.

Profit was viewed by Marshall as the residual income accruing to a firm's owner, a return on the investment of the owner's own capital and recompense for the pains of exercising 'business power' in planning, supervision and control. Normal profit is essentially an opportunity cost, the minimum return necessary to secure the owner's inputs to their current use, or rather to accomplish this for an owner of normal ability. Marshall presumes that there is a large and elastic supply of versatile actual or potential owner managers of normal ability. In long-period equilibrium each of these must just receive the same normal rates of return on investment and exercise of business power whatever the line of business. However, those who are exceptional may do better, essentially by exerting greater business power.

These common rates of normal return are simultaneously determined, along with the normal returns to other kinds of effort and abstinence, by Marshall's macroeconomic theory of the long-period determination of factor incomes (see below). Although it is the case that profits are a residual, rather than a contractually agreed amount like other incomes, this difference is immaterial in long-period equilibrium. In particular, a long-period equilibrium analogy between ordinary wages and the normal earnings of business power is stressed. Normal profit is a necessary element in the costs that underlie the long-period normal supply curve, but actual profit is a quasi-rent or producer surplus for shorter periods.

Normal profits are a return to 'business power in command of capital' and compensate for three distinct elements: 'the supply of capital, the supply of the business power to manage it, and the supply of the organization by which the two are brought together and made effective for production' (1920, p. 596). The combined compensation of the latter two components comprises 'gross earnings of management', the return to the second component being 'net earnings of management'. In long-period equilibrium, the normal return to the first element is imputed at the market interest rate on default-free loans, and that to the second component at the rate paid to hired managers performing comparable tasks. The residual third element, the return to 'organization', is most straightforwardly interpreted as an extra return on owned capital equivalent to the premium for default risk, or 'personal risk', that would have to be paid on borrowed capital. In the manufacturing case, the annual level of normal profit for each firm in an industry must be interpreted as the annualized equivalent of the expected stream of returns that is just sufficient to induce an individual of normal ability to found a firm in the industry rather than divert energies and capital elsewhere. Normal ability here is defined relative to other potential founders of firms, a group already exceptional relative to the population as a whole. By construction, such normal profits must be earned by the representative firm.

Bibliographic note: The most pertinent commentary is Frisch (1950). For Marshall's views on normal value see (1879b, pp. v–vii, 65–71, 146–9; 1920, pp. vii, 33–6, 337–50, 363–80). For his views on normal profit see (1879b, pp. 135–45; 1920, pp. 73–4, 291–313, 596–628). For the role of 'personal risk' see Guillebaud (1961, vol. 2, p. 672).

Welfare Economics

To serve as a tool of welfare economics, monetary measures of consumer surplus, producer surplus and rent must be aggregated over individuals. But how are the resulting sums to be interpreted? Marshall's very limited and proximate attempts at formal welfare arguments are carried out within a utilitarian framework, for which the goal is maximizing aggregate utility. He implies that interpersonal utility comparisons are possible in principle and that utility functions will be similar for all members of any group that is homogeneous in terms of mental, physical and social attributes. Within such a group, the marginal utility of money will be the same for two individuals having the same income, and lower for the richer of two individuals with differing incomes, on the assumption in each case that both individuals face the same trading opportunities. A postulated government action may impose gains and losses on various individuals that can be measured and aggregated in money- equivalent terms. But how can these measures be translated into statements about aggregate gains and losses of utility? Marshall emphasizes two special cases. First, if the gains and losses are both proportionately distributed over income classes in exactly the same way, then net aggregate gain (positive or negative) in money will serve as an ordinal index for the net aggregate gain in utility. A corollary of this is that if two alternative actions affecting the same group have the same relative distributions of gains and losses over income classes then the alternative yielding the greater net aggregate gain in money must have the greater net aggregate gain in utility. Second, if some change makes for a zero net aggregate change in money terms, but the gains accrue to individuals of lower income than those bearing the costs, then the aggregate net utility gain must be positive – a warrant for certain redistributive policies. In other cases he sees that careful assessments of the marginal utility of money to the various injured and benefited groups would be needed, assessments that could be used to transform monetary gains and losses into utility measures. He toys (1920, pp. 135, 842–3) with using the Bernoulli hypothesis on the relation between wealth and utility as a basis for such calculations, but gives little indication as to how assessments might be made in practice.

Marshall's best known and most successful foray into formal welfare analysis was his proof that total welfare might be increased by using the proceeds of a tax on an 'agricultural' industry to subsidize a 'manufacturing' industry.

All comparisons involved long-period equilibria and relied on the validity of aggregated money-equivalent measures of gains and losses. He demonstrated that the gain in consumer surplus in the expanded decreasing-cost manufacturing industry might exceed the combined loss in consumer and producer surplus in the contracted increasing-cost agricultural industry. No formal account was taken of a possible gain in producer surplus in the manufacturing industry as this merely makes the argument hold *a fortiori.* The crucial point in this argument, as Marshall recognized, is that producers are not harmed by 'a fall in price which results from improvements in industrial organization' (1920, p. 472). It is immaterial whether the improved organization of the enlarged manufacturing industry is due to external economies or to internal economies resulting from an increase in the size of the representative firm. Contrary to much subsequent opinion, Marshall's tax-subsidy argument is not necessarily dependent upon external economies.

Another significant, but overlooked, welfare analysis provided by Marshall was that of a monopolistic public enterprise in a situation where taxation involves an excess burden (1920, pp. 487–93, 857–8). In the absence of this excess burden Marshall proposes that the enterprise seek to maximize 'total benefit', the sum of net profit and consumer surplus. This implies marginal cost pricing, since the area below the demand curve and above the marginal cost curve is maximized when the two curves intersect. But, given that taxation involves an excess burden, it may be desirable to augment tax receipts from monopoly revenue if the sacrifice of consumer surplus is small. Marshall proposes the alternative goal of maximizing 'compromise benefit', the sum of consumer surplus and monopoly revenue when the latter is in effect multiplied by the marginal cost of raising a unit of government revenue from other sources. Maximization of compromise benefit leads to the setting of what has come to be termed a 'Ramsey price'.

The two examples of welfare analysis just described proceed within a partial equilibrium framework, treating each industry as negligible compared to the entire economy and regarding the marginal utility of money as approximately constant to each individual. Marshall's rather fragmentary remarks on optimal tax systems, income redistribution and the 'doctrine of maximum satisfaction' cannot be restricted in this way, and so raise serious unresolved analytical difficulties. On the other hand, his tax-subsidy argument was a valid counterexample to arguments that competition must lead to a social optimum, or that optimal indirect tax systems must involve uniform tax rates. It must also be borne in mind that utilitarian welfare economics was for Marshall only a first step towards a more evolutionary analysis of possible modes of improving the physical quality and the values and activities of mankind.

Bibliographic note: Marshall's treatment of welfare economics is to be found in (1920, pp. 18–19, 124–37, 462–76, 487–93). Ellis and Fellner (1943) is a good statement of the standard interpretation of the Marshall–Pigou tax-subsidy argument, emphasizing external effects. See also Bharadwaj (1972). On Marshall's treatment of compromise benefit see Whitaker (1986, pp. 186–8). Myint (1948) gives a useful general perspective on Marshall's welfare theory. Albon (1989) offers an intriguing insight into Marshall's attempt to apply welfare analysis to issues surrounding the British Post Office monopoly.

Interrelated Markets and Distribution Theory

Marshall was anxious to emphasize the interdependence of markets and introduced his treatment of joint and composite demand and supply largely for this purpose. A group of goods is jointly supplied if all are outputs of a single productive activity and jointly demanded if all are inputs. On the other hand, a particular good is compositely supplied or demanded if it is provided or acquired by several distinct productive activities. Marshall's formal treatment of joint demand and supply proceeded on the general assumption that the products involved were consumed or produced in fixed proportions, as did his related analysis of the 'derived demand' for any one of several jointly demanded inputs – 'derived' since the demand for such inputs is derived from

the demand for their joint product. The derived demand curve for a specific input can be constructed conceptually by supposing that its supply is perfectly elastic at an arbitrary price and that the markets for the output and all the inputs (including the specific input) adjust to equate quantity demanded to quantity supplied in each market. This gives a price quantity combination on the derived demand curve for the specific input. Other such combinations can be obtained by varying the arbitrarily chosen price and repeating the exercise, and so on. Marshall laid down four rules for inelasticity of derived demand. These were that the input should have no good substitutes, that the product it helps make should be inelastically demanded, that the input should account for only a small part of production costs, and that cooperating inputs should be inelastically supplied. Fixity of input ratios guaranteed the first condition, but the more general case was asserted rather than proven. The advantage of working with the derived demand curve for an input is that it permits a more transparent analysis of the effects of changes in the supply conditions of the singled-out input.

The prime example of joint demand is the demand for productive inputs, and Marshall's analysis of market interdependence was carried through more fully in this specific connection, the role of substitution among inputs receiving full acknowledgement. The principle of substitution ensured that input usage tended to be adjusted by firms so as to minimize the total production cost of any level of output. Thus, the value of the marginal product of an input (or the 'net product' as Marshall termed it) tended under competition to equal the unit price of the input. There has been some confusion about the relation between 'net product' and marginal product because the former allows usage of other inputs to adjust consequentially when the chosen input is increased while the latter does not. But, provided that the initial situation is cost-minimizing, the adjustment of other inputs (if small) has no effect on the change in output – an application of the envelope theorem. Marshall recognizes this explicitly (1920, p. 409n) and there is no good reason for refusing to classify him as a marginal productivity theorist.

Interdependence among input markets was further highlighted in the analysis of the competition of several industries for an input that is in temporarily or permanently fixed overall supply. A peculiarity of this last analysis was the insistence on excluding from the marginal cost of any industry the cost of bidding such fixed resources away from other uses. This is a perfectly legitimate application of the general envelope theorem: provided resource use is optimally adjusted, the marginal cost of increasing output will be the same whatever input or sub-group of inputs is increased. But Marshall's insistence on asymmetry where there is really symmetry can be accounted for only by his desire to legitimize, and extend to quasirent, the classical doctrine that rent is price determined rather than a pricedetermining element of cost.

Marshall's vision of market interdependence culminates in his treatment of income distribution, where he seeks to bring out the extents to which the interests of different factors of production are harmonious or conflicting. Distribution is determined by the interaction of the demands and supplies for the various inputs, the demands being essentially joint demands. Marginal productivity is a theory of input demand, not a complete theory of distribution, because the supplies of the various inputs cannot be viewed as fixed, at least in the long period. Indeed, in the long period the dominant influences on the prices of factors other than land are exerted by their supply conditions. The costs that then have to be met must ensure that various kinds of labour and capital continue to be replaced in their existing uses and quantities.

From an overall view 'The net aggregate of all the commodities produced is itself the true source from which flow the demand prices for all these commodities, and therefore for the agents of production used in making them' (1920, p. 536). This aggregate, 'the national dividend', is distributed among the factors of production. It is at once the

> aggregate net product of, and the sole source of payment for, all the agents of production within the country: it is divided up into earnings of labour; interest of capital; and lastly the producer's surplus, or rent, of land and of other differential advantages for production. It constitutes the whole of them, and

> the whole of it is distributed among them; and the larger it is, the larger, other things being equal, will be the share of each of them. (1920, p. 536)

The share going to any class of inputs will depend upon the need people have for its services: 'not the *total* need, but the *marginal* need' (p. 536, italics original). But a complicating influence for distribution theory, although one 'more full of hope for the future of the human race than any that is known to us' lies in the fact that 'highly paid labour is generally efficient and therefore not dear labour' (p. 510). Influenced by F.A. Walker, Marshall was a strong proponent of the 'economy of high wages' argument that high wages increase labour efficiency, not perhaps immediately, but cumulatively over time and perhaps over generations: effects that transcend simple theorizing in terms of static equilibrium.

All the different productive factors cooperating in production have a common interest in increasing the size of the pie to be shared, the national dividend or income, but each factor has a selfish interest in restrictive practices that increase its own share, even if they reduce the size of the pie slightly. A prime question of social policy for Marshall is how these divergent incentives can be reconciled: how combined action by various groups, such as unions, can be prevented from assuming forms that, while perhaps individually beneficial to any one group in isolation, are certainly mutually harmful if undertaken by all.

Marshall here enters into macroeconomic forms of argument, and it is indeed true that he did toy with the formal specification of macroeconomic models of growth and distribution (see Whitaker, 1975, vol. 2, pp. 305–16). But, with this exception, it should be emphasized that his treatment of market interdependence fell far short of a full theory of general equilibrium on Walrasian lines. Even when formalizing market interdependence in the mathematical appendix to *Principles* (1920, pp. 846–56), he simply treated the demand or supply of each commodity as a function of nothing but the price of the commodity itself. The links between the generation of income in factor markets and the expenditure of that income in product markets were left quite vague. Again, it must be recalled that the development of comprehensive fully articulated equilibrium theories was not Marshall's aim.

Bibliographic note: The key sections for Marshall's treatment of interrelated markets and distribution theory are (1920, pp. 381–54, 504–45, 660–67, 846–56). For general commentaries on Marshall's distribution theory see Stigler (1941), H.M. Robertson (1970), Whitaker (1974, 1988). On Marshall's treatment of labour supply see Walker (1974, 1975), Matthews (1990). On the economy of high wages see Petridis (1996).

Monopoly and Combination

Marshall's analysis of price and output determination by a profit-maximizing monopolist, and of the effects of taxing such a monopolist, followed the lead of Cournot. The concept of marginal revenue was implicit in the mathematical statement, but Marshall's chosen vehicle was geometrical. Curves of average revenue and cost, and of their difference, average net revenue, y, (all functions of the quantity sold, x) were superimposed on a grid of iso-profit hyperbolae of form $xy = constant$. Profit was maximized when the average net revenue curve touched the highest such iso-profit curve. Weighting consumer surplus into the maximand, as well as net revenue, gave rise to the welfare analysis of 'compromise benefit' already mentioned.

Monopoly analysis was applied to trades unions, with the use of the concept of the derived demand for an input. A union controlling a labour input for which derived demand is inelastic can certainly raise wages – not only the wage rate but the total wages received – although at the price of unemployment of some members. Whether such a monopolistic restriction can be sustained for long is more doubtful, as there will be pressures both to enter the union and to evade its grasp by the relocation or reorganization of production.

A more problematic question was whether 'labour's disadvantage in bargaining' meant that combined action by workers could raise wages, even without any restriction of labour supply. Marshall believed that it did, but emphasized that the result might be less capital accumulation

by non-workers, an outcome that could harm workers eventually.

The extremes of monopoly and competition were both covered by the theory of normal value, even though the competition might be more akin to later concepts of imperfect or monopolistic competition than to any ideal form of perfect competition. But 'normal action falls into the background, when Trusts are striving for the mastery of a large market' (1920, p. xiv). The incidents, tactics and alliances of oligopolistic conflict defied reduction to a simple general theory. They were to have been considered in the uncompleted second volume of *Principles* and were to some extent covered by *Industry and Trade.* The latter's treatment of entry-limiting behaviour by a 'conditional monopolist', who dominates the market but does not control entry, is of considerable interest in the light of much recent work on this class of problems.

Bibliographic note: Marshall's treatment of monopoly theory is to be found in (1879b, pp. 180–86; 1920, pp. 477–95, 856–8). For his views on trusts and conditional monopolies see (1890b; 1919, pp. 395–635, especially 395–422). For his views on trades unions see (1879b, pp. 187–213; 1892, pp. 362–402; 1920, pp. 689–722) and Petridis (1973). On 'labour's disadvantage in bargaining' see Hicks (1930). Liebhafsky (1955) summarizes the relevant arguments of *Industry and Trade.*

Monetary Theory

Marshall was in full command of previous British discussions of monetary issues, but not himself a major contributor to the development of monetary theory. His evidence before royal commissions in 1887 and 1899 showed an impressive mastery of monetary analysis, both domestic and international, and was minutely examined by successive generations of Cambridge students, serving for many years virtually as a textbook. But it was not until 1923, with the appearance of *Money Credit and Commerce*, that Marshall put forward his monetary views in a systematic way. By then these had not the novelty, nor he the vigour, to advance contemporary discussion.

Marshall's most important contribution to monetary theory was to place the overall demand for money in the context of individual choices as to the fraction of one's wealth to keep on hand as ready cash. This approach, set out clearly in a manuscript of the early 1870s (Whitaker 1975, Vol. I, pp. 164–77), was developed by Marshall's Cambridge successors, especially A.C. Pigou and F. Lavington, into what is termed the 'Cambridge k' approach. It laid the background for the treatment of the demand for money in J.M. Keynes (1936). On international monetary theory, Marshall espoused a form of purchasing power parity.

Marshall's name is particularly associated with his proposals for 'symmetalism', the use of a fixed-weight combination of gold and silver as the monetary base, and for indexed contracts based on a 'tabular standard of value', or price index, to be maintained by the government. The former was offered as an improvement on fixed-ratio bimetallism, of which he was never more than a lukewarm adherent.

Marshall had interesting, if fragmentary, insights into business fluctuations and general unemployment, which he viewed as temporary disequilibrium consequences of credit market dislocations. These spilled over into general coordination failures, with unemployment in one market spreading to others by reducing demand in cumulative fashion – the germ at least of the multiplier concept. On the other hand, Say's Law was maintained as an equilibrium truth of great importance. He saw the remedies for cyclical unemployment in the 'continuous adjustment of means to ends, in such a way that credit can be based on the solid foundation of fairly accurate forecasts', and in curbs on reckless inflations of credit that are 'the chief cause of all economic malaise' (1920, p. 710).

Bibliographic note: Marshall's monetary evidence is reproduced in J.M. Keynes (1926, pp. 3–195, 265–326). Other sources for his monetary views are Whitaker (1975, vol. 1, pp. 164–77), and Marshall (1887; 1923, pp. 12–97, 140–54, 225–33, 264–320). The standard treatment of Marshall's monetary views is Eshag (1963). For Marshall's views on business fluctuations see his

(1879b, pp. 150–57; 1885a; 1892, pp. 400–3; 1920, pp. 710–11; 1923, pp. 234–63). Also see Wolfe (1956), Laidler (1990).

International Trade

Marshall's major contribution to international trade theory was his well-known geometrical analysis of the equilibrium and stability of two-country trade by means of intersecting offer curves. Each country's offer curve indicated the number of 'bales' of home goods it was prepared to exchange for a specified number of bales of foreign goods, demand being elastic or inelastic as an increase in the latter caused the former to increase or decrease. Possibilities of multiple and unstable offer-curve intersections were noted. The offer curves themselves were taken as data, although complex readjustments of production and consumption underlay them. The need for a separate theory of international trade was justified, in classical vein, by the supposed international immobility of factors of production that remain mobile domestically.

The main purpose of this theoretical apparatus was to examine the effects of tariffs. A country might gain by selfishly exploiting its monopoly power through restricting trade, and would certainly gain if trading equilibrium occurred on an inelastic portion of the foreign offer curve. But Marshall came to doubt increasingly the transferability of this result to a multi-country case, although admitting that it might apply to an export tax on an exceptional commodity (like British steam coal) lacking close substitutes and incapable of being produced elsewhere.

A related attempt to construct a theoretical measure of the 'net benefit' a country gains from foreign trade, analogous to the measures of consumer and producer surplus, was not entirely satisfactory as the partial equilibrium context had clearly been transcended.

On matters of concrete trade policy for Britain, Marshall was a firm but cautious adherent of free trade, even unilateral free trade, but became increasingly concerned with the prospects for Britain's position in the world economy. The discussion in *Industry and Trade* of the links between foreign competition and domestic industrial organization and structure reflected this concern.

Bibliographic note: For Marshall's treatment of the theory of international trade by offer curves see Whitaker (1975, vol. 1, pp. 260–79; vol. 2, pp. 111–81), Marshall (1923, pp. 155–224, 330–60). For the net benefit measure see Whitaker (1975, vol. 1, pp. 379–81) and Marshall (1923, pp. 338–40). Commentaries on Marshall's theory are to be found in Viner (1937, pp. 527–92), Chipman (1965), Johnson and Bhagwati (1960) and Creedy (1990). For Marshall's views on trade policy and trends see Marshall (1919, pp. 1–177, 681–784; 1923, pp. 98–139, 201–24) and J.M. Keynes (1926, pp. 367–420).

A Brief Survey of Marshall's Writings with Suggestions for Further Reading

The first editions of Marshall's five books were (1879b), (1890a), (1892), (1919), (1923). *Economics of Industry* (1879b) had a new edition in 1881 and was reprinted with minor changes several times up to 1892. It is an important source for Marshall's views on distribution theory, trades unions and business fluctuations. His magnum opus, *Principles* (1890a), had new editions in 1891, 1895, 1898, 1907, 1910, 1916 and 1920. The title was changed to its final form (as in (1920)) in the fifth edition. *Principles* is the basic source for Marshall's views on the theories of value and distribution as well as his broader views on economics and social welfare. Since the rewritings between editions were substantial, the ninth variorum edition, edited by C.W. Guillebaud, Marshall's nephew (Guillebaud 1961), is essential for serious study. The first of its two volumes is a facsimile of the eighth edition of 1920. The second volume contains deleted passages from earlier editions, editorial notes, and various supporting documents. Users of the differently paginated Macmillan paperback edition of the eighth edition should note that all page references to the eighth edition given above must be located by using the table of correspondences appended to the paperback version.

Elements of the Economics of Industry (1892) had new editions in 1896 and 1899 and frequent reprintings. The last preface is dated 1907. It is essentially an abridgement of *Principles,* designed to replace *Economics of Industry,* a book that Marshall had come to despise, quite unjustifiably. *Elements* contains Marshall's fullest treatment of trades unions. *Industry and Trade* (1919) had new editions in 1919, 1920 and 1923 but only the first of these involved significant changes. Its three books deal with 'Some origins of present problems of industry and trade', 'Dominant tendencies of business organization', and 'Monopolistic tendencies: their relations to public well-being'. It adopts a largely historical and comparative approach and focuses on contemporary issues. Nevertheless, it contains many passages and insights of permanent interest and warrants closer attention by economists than it has received until recently. *Money Credit and Commerce* (1923) had only one edition and conveys Marshall's views on money, international trade and business fluctuations. Although blemished, it should not be dismissed.

An almost comprehensive annotated list of Marshall's occasional writings is found in Pigou (1925, pp. 500–8), which also reprints many of the texts of these writings. Guillebaud (1961) reproduces further occasional pieces. The 'Pure Theory' chapters (1879a), privately printed by Sidgwick, were first published in reprint form in 1930. A corrected and amplified version is included in Whitaker (1975). The two volumes of the latter also reproduce Marshall's unpublished early manuscripts, mainly from the 1870s, including several manuscript chapters from the abandoned volume on foreign trade. Marshall's important contributions to official enquiries are collected in J.M. Keynes (1926), a book that is supplemented by Groenewegen (1996).

The literature on Marshall's life and thought is too extensive to allow for more than a highlighting of some significant contributions. The splendid memorial essay by J.M. Keynes (1924) is not to be missed, although outdated on some points, nor is the charming memoir by Marshall's wife (Marshall 1944). Pigou (1925) includes fascinating vignettes by several of Marshall's colleagues and friends and Guillebaud (1971) gives a nephew's reminiscences. A major scholarly biography (Groenewegen 1995) covers Marshall's life and thought exhaustively, while a comprehensive three-volume edition of Marshall's correspondence (Whitaker 1996) provides much new information. Additional primary material on Marshall is provided in Raffaelli et al. (1995), where notes on Marshall's 1873 lectures to women students are reproduced, and Raffaelli (1994), where Marshall's essays on philosophical and psychological manuscripts from the late 1860s are reproduced and analyzed. See also Harrison (1963). Newspaper reports on public lectures Marshall gave during his years in Bristol are reproduced in Coase and Stigler (1969), Whitaker (1972) and Butler (1995).

Valuable overall assessments of Marshall are provided by Cannan (1924), Schumpeter (1941), Viner (1941), Shove (1942) and O'Brien (1981). Maloney (1985) studies Marshall's involvement in the professionalization of British economics. An extensive body of detailed analysis and criticism of Marshall's thought, mainly conducted in academic journals, continues to expand, with growing tributaries from Italy and Japan in particular. Wood (1982, 1996) assembles in eight volumes a somewhat miscellaneous collection of 239 pieces on Marshall, but standard bibliographic aids such as EconLit are recommended for a comprehensive search. The 1990 centenary of the publication of *Principles* produced two books of essays on Marshall (Whitaker 1990, McWilliams-Tullberg 1990) and several symposia on Marshall in economics journals. Samples of recent research can be found in Arena and Quéré (2003). On Marshall's social and behavioural views see Parsons (1931, 1932), Whitaker (1977) and Chasse (1984). For Marshall's views on socialism and trades unions see, respectively, McWilliams-Tullberg (1975) and Petridis (1973).

British economist, born in Ufford (Nottinghamshire) on 24 October 1850; died in Cambridge 7 March 1944. Great-granddaughter of the great theologian William Paley, she was brought up in a strictly evangelical faith in Ufford, her father's vicarage. Thomas Paley, had taken a good degree in mathematics (33rd wrangler) in 1833 at Cambridge, and had been, for a period, a fellow of St John's College. Mary had one elder sister and two younger brothers.

In 1871, with a scholarship, she went up to Cambridge to complete her education with studies at university level. Under the whimsical chaperon Anne J. Clough (sister of the poet), and the teaching of a handful of young voluntary dons committed to the cause of higher education of women (among them Henry Sidgwick and Alfred Marshall), she took the Moral Sciences Tripos. She graduated, albeit informally, in 1874 (the first woman to achieve such a distinction in Cambridge) but the board of examiners (W.S. Jevons was among them) was so bitterly divided that in the certificate they recorded, very unusually, that she had received two votes for a first class and two for a second.

Shortly after her degree Mary Paley began to teach and to tutor female students in the newly opened Newnham Hall. In 1876, on request, she began to write a small economic textbook for Extension Lectures, that eventually became *The Economics of Industry* (1879). In the same year she became engaged to Alfred Marshall. They married in Ufford in July 1877. From that date onwards, till the death of Alfred Marshall in 1924, her life was essentially devoted, first in Bristol,

where they settled after marriage, then in Oxford (1883–4) and finally in Cambridge, to helping him in his scientific work and to saving him from all the normal nuisances of life.

For several decades Mary Paley Marshall taught and tutored female students of economics in Newnham college. A member of many associations (Charity Organization Society, Ethical Society, and so on) she participated in the founding group of the British Economic Association. After 1924 she became the first librarian of the newly founded Marshall Library, which she visited regularly until her 90th year. In 1928 the University of Bristol awarded her an honorary degree. She was a gifted amateur water colour painter and her posthumous Memoir, *What I Remember* (1947), shows glimpses of literary talent. Mary was not buried beside Alfred, but her ashes were scattered in the garden of her house.

Mary Paley Marshall's claims to be considered as an economist by herself are, strictly speaking, unassessable. Personally she signed only a few short notes in the early issues of the *Economic Journal,* which show a clear mind, a good style and a balanced judgement, but no more. Her only title to fame resides in the green-covered *Economics of Industry,* co-authored with Alfred Marshall. This small textbook, reprinted many times and translated into several foreign languages, was rated very highly by contemporaries. J.M. Keynes went so far as to say: 'It was, in fact, an extremely good book; nothing more serviceable for its purpose was produced for many years, if ever.' From the viewpoint of the development of economic analysis the book is relevant as a sort of half-way house between the *Principles* of J.S. Mill and the *Principles* of A. Marshall. Despite some hints to the contrary by J.M. Keynes, the respective positions (teacher and pupil) and ages (Alfred was older by eight years) suggest that Mary Paley's contribution was only secondary and subordinate.

Worthy of mention is the help she afforded Alfred Marshall in preparing and amending all his works. In a letter to John Neville Keynes, there is a hint of a substantial collaboration: 'My wife and I', writes Alfred Marshall, alluding to an article by J.L. Laughlin (*Quarterly Journal of Economics,* 1887), 'find it very hard to see Laughlin's points & perhaps we underrate the strength of his attack.'

Had it not been for the suffocating influence of Alfred, Mary Paley, with her clear mind, earnestness and strong will, would have become herself, we can confidently guess, an economist of repute and not, as is the case, a minor figure in the shadow of Alfred Marshall.

Marshall–Lerner Condition

Murray C. Kemp

In the comparative-statical calculations of the simplest two-commodity barter theory of international trade, the outcomes invariably depend on the magnitude of the sum of the two import-demand elasticities, one relating to the country under study (the 'home' country) and the other to the rest of the world (collectively, the 'foreign' country); in particular, the response of a variable to a disturbance will be in one direction if the sum of elasticities is less than minus 1 and in the opposite direction if the sum is greater than minus 1. On the other hand, for some dynamic or 'disequilibrium' models of international trade it is a necessary and sufficient condition of local stability that the same sum of elasticities be less than minus 1. Let us define Δ as one plus the sum of the two elasticities of import demand. Then the so-called Marshall–Lerner condition requires that Δ be negative. Evidently the condition provides a link between the comparative-statics of international trade and some forms of trade dynamics. That such a link exists is, of course, the essence of Samuelson's correspondence principle.

Proceeding to a more detailed account of the Marshall–Lerner condition, let us suppose that the home country imports the first commodity, the foreign country the second; and let us denote by p the world price of the second commodity in terms of the first and by α and α^* parameters of the home and foreign economies, respectively. Then, in the absence of trade impediments and autonomous international transfers, we may write the general-equilibrium or *mutatis mutandis* home import-demand function as $\varphi(1/p, \alpha)$, the foreign import-demand function as $\varphi^*(p, \alpha^*)$ and the condition of world equilibrium as

$$\varphi(1/p, \alpha) - p\varphi^*(p, \alpha^*) = 0. \tag{1}$$

Suppose now that an initial equilibrium is disturbed by small changes in α and α^*. Differentiating (1) totally we obtain

$$\left(p^{-2}\varphi_{1/p} + \varphi^* + p\varphi_p^*\right) \mathrm{d}p = \varphi_\alpha \mathrm{d}\alpha - p\varphi_{\alpha*}^* \mathrm{d}\alpha^*$$

or, equivalently,

$$\Delta \mathrm{d}p \equiv (1 + \xi + \xi*)\mathrm{d}p = \left(\phi_\alpha \mathrm{d}\alpha - p\phi_\alpha^* \mathrm{d}\alpha^*\right)/\phi^* \tag{2}$$

where the subscripts indicate partial derivatives and where $\xi \equiv \varphi_{1/p}/(p\varphi)$ and $\xi^* \equiv p\varphi_p^*/\varphi^*$ are the price elasticities of home and foreign import demand, respectively.

On the other hand, we may consider the dynamic tâtonnement defined by the differential equation

$$\dot{p} \equiv \mathrm{d}p/\mathrm{d}t = f[\varphi^*(p, \alpha^*) - \varphi(1/p, \alpha)/p] \tag{3}$$

where f is a differentiable sign-preserving function of the world excess demand for the second commodity and t denotes time. Evidently (3) is a dynamic extension of (1). For the local stability of p at an equilibrium value it is necessary and sufficient that $\mathrm{d}f/\mathrm{d}p$ be negative in a sufficiently small neighbourhood of the equilibrium value. Now a little calculation shows that $\mathrm{d}f/\mathrm{d}p = f'\,\Delta\varphi^*/p$, where the prime indicates differentiation; moreover, since f is differentiable and sign-preserving, f' is necessarily positive sufficiently near the equilibrium value of p. For local stability, therefore, it is necessary and sufficient that Δ be negative.

By way of illustration we may consider the traditional 'transfer problem'. Identifying $\alpha = \alpha^*$ with the amount transferred from the foreign to the home country, in terms of the numeraire, Eq. (1) reduces to

$$\varphi(1/p, \alpha) - p\varphi^*(p, \alpha^*) - \alpha = 0.$$

and, if α is initially zero, Eq. (2) reduces to

$$\Delta \mathrm{d}p = \left(\varphi_\alpha - 1 + p\varphi_\alpha^*\right) \mathrm{d}\alpha/\varphi^*.$$

Evidently φ_α and $1 - p\varphi_\alpha^*$ are home and foreign marginal propensities to consume the first commodity. Thus, in stable systems, the terms of trade move in favour of the recipient of a small payment if and only if that country's marginal propensity to consume the imported commodity is less than the foreign country's marginal propensity to consume the same commodity.

The home and foreign economies have been specified in terms of the functions φ and φ^* only. Whether in any particular context the Marshall–Lerner condition is satisfied depends

on the structure imposed on φ and φ^* by the context. Evidently the appropriate structure will be quite different for economies with and without chronic unemployment and, more generally, for economies with and without internal market-clearing. It will also be quite different for rural and industrial economies, for growing and declining economies and for rich and poor economies.

While the inequality $\Delta < 0$ is now widely known as the Marshall–Lerner condition, the label is inappropriate in a context of dynamic analysis. For Alfred Marshall developed a quite different stability condition (see Marshall 1879, II; 1923, Appendix J; Samuelson 1947, pp. 266–7; Amano 1968; Kemp 1964, pp. 89–90); and Abba Lerner was not at all concerned with disequilibrium dynamics (see Lerner 1944).

Martin Stuart ('Marty') Feldstein (1939–)

Charles Yuji Horioka

Abstract

Martin Stuart ('Marty') Feldstein, currently George F. Baker Professor of Economics at Harvard University and President Emeritus of the National Bureau of Economic Research, Inc. (NBER), is an American economist who has made important contributions to public finance, macroeconomics, international economics, social insurance, health economics, the economics of national security, and many other fields of economics, trained a large number of prominent economists, served as President of the National Bureau of Economic Research for some 30 years, and served as President Ronald Reagan's chief economic advisor.

Introduction

Martin Stuart ('Marty') Feldstein was born in New York City on 25 November 1939. He graduated *summa cum laude* from Harvard College with a major in economics in 1961, and even though he was admitted by the Harvard Medical School, he opted to study at the University of Oxford on a Fulbright scholarship. He received a B. Litt. in 1963 and a Ph.D. in 1967, both in economics, from Oxford, but combined his interest in medicine and economics by writing a doctoral dissertation about how hospital costs could be reduced in a

government-run health system (the UK's National Health Service). He was a Fellow of Nuffield College, Oxford, from 1964 until 1967, before returning to the USA and to his alma mater. He became an Assistant Professor of Economics at Harvard University in 1967, and only 2 years later, at the age of 28, he was granted tenure and promoted to full professor, becoming one of the youngest full professors in Harvard's history.

Feldstein was an immensely popular teacher, teaching the introductory course in economics (which attracted as many as 1000 students) for 21 years, as well as graduate courses in macroeconomics, public finance, the economics of national security etc. He trained a huge cadre of students, such as Jeffrey D. Sachs and Lawrence H. Summers, who have gone on to pursue illustrious careers in academia and government.

Feldstein spent virtually his entire career at Harvard and is currently George F. Baker Professor of Economics there, but in addition to being an academic, Feldstein served as President of the National Bureau of Economic Research (NBER) for some 30 years from 1977 until 2008 (except in 1982–84), building it up to its current status as the premier US-based economic research organisation.

Feldstein has received honorary doctorates from several universities and is an Honorary Fellow of Nuffield College Oxford, a Corresponding Fellow of the British Academy, and a Fellow of the Econometric Society and the National Association for Business Economics.

Moreover, Feldstein has also made important contributions to economic policymaking as Chair of President Ronald Reagan's Council of Economic Advisors from 1982 until 1984, a member of President George W. Bush's Foreign Intelligence Advisory Board from 2007 until 2009, and a member of President Barack Obama's Economic Recovery Advisory Board from 2009 until 2011.

Feldstein currently serves on the Board of Directors of the Council on Foreign Relations, the Trilateral Commission, the Group of 30 (a Washington-based financial advisory body) and the National Committee on United States–China Relations. He also serves on the Council of Academic Advisors of the American Enterprise Institute and was formerly on the Boards of Directors of a number of major corporations including AIG, Eli Lilly and JP Morgan.

Well known for his ability to explain economic concepts clearly, Feldstein also frequently writes op-ed pieces for the *Wall Street Journal* and other newspapers and makes policy proposals about a variety of economic issues. In past years, he regularly co-authored such pieces with his economist wife Kathleen, who received a Ph.D. from the Massachusetts Institute of Technology (MIT).

With respect to Feldstein's research, he started out as a specialist in health economics, the field of his doctoral dissertation, but his interests gradually broadened to include social insurance more generally, public finance, macroeconomics, international economics, the European Monetary Union, the Chinese economy and the economics of national security, among others. Feldstein has written close to 400 scholarly articles on a broad range of topics, many of which show, via careful theoretical and empirical analysis, that government tax and transfer policies have important impacts on the economic behaviour of households and firms – in other words that households and firms respond to incentives and disincentives – and that the impact of tax and transfer policies cannot be gauged accurately unless one takes account of the behavioural responses that they induce.

In recognition of his impressive research achievements, in 1977 Feldstein was awarded the John Bates Clark Medal of the American Economic Association (AEA), which at the time was awarded every 2 years to the economist under the age of 40 who was judged to have made the greatest contribution to economic science, and he was elected President of the American Economic Association in 2004.

In 2007 Feldstein received the Bradley Prize from the Lynde and Harry Bradley Foundation; in 2011 he was included in the 50 Most Influential ranking of *Bloomberg Markets* magazine because, despite being a Republican himself, his staunch advocacy of scaling back tax expenditures (government spending through the tax code – i.e. tax exemptions, deductions or credits to select groups or specific activities) incurred the wrath of Republicans but garnered the widespread support

of Democrats [see Homan (2011) for more details]; and in 2012 he received the SIEPR Prize for Contributions to Economic Policy from the Stanford Institute for Economic Policy Research (SIEPR) of Stanford University.

Social Insurance

Feldstein has made significant contributions to a broad range of fields in economics, but one area in which he has truly revolutionised the thinking of economists and policymakers alike is in the area of social insurance [see Feldstein (2005b) for a useful overview]. Feldstein showed that, while existing social insurance programmes protect individuals from a variety of risks, they also distort individuals' behaviour in a variety of ways, thereby lowering saving, economic growth and welfare. For example, unemployment insurance protects individuals from the loss of income during unemployment spells, but at the same time causes individuals to search for new jobs for too long, induces them to save less and encourages them to take jobs that have a greater likelihood of seasonal and/or cyclical layoffs. Social security (public old-age pensions) protects individuals from poverty during old age and longevity risk, but at the same time induces individuals to reduce their saving and to retire too early. Health insurance protects individuals from the risk of being unable to afford needed medical care, but at the same time induces them to consume too much health care, to take inadequate precautions with their health and to save too little because they know that they will not have to bear the full cost of health care themselves.

Feldstein has done extensive research to show that social insurance programmes have indeed distorted individuals' behaviour in the expected ways. For example, Feldstein (1976b, 1978a) shows that unemployment insurance substantially increases the amount of temporary layoff unemployment, while Feldstein and Poterba (1984) show that the higher the replacement rate of unemployment benefits, the higher the reservation wage of unemployed workers, meaning that the longer will be the duration of unemployment.

Turning to Feldstein's work on the impact of social security [see Feldstein and Liebman (2002b) for a useful overview], Feldstein (1974), a very well-known article, analyses theoretically and empirically the impact of social security on household consumption and saving behaviour. As Feldstein notes, there are at least two offsetting ways in which a social security system can affect household saving. On the one hand, the introduction of a social security system will cause households to not feel as much need to save for retirement as they did before the introduction of such a system (the wealth replacement effect). On the other hand, the introduction of a social security system will induce households to retire earlier, lengthen their retirement span, and make it necessary for them to save more than before (the induced retirement effect). Thus, it is not clear *a priori* whether the introduction of a social security system will induce households to save more or less than before. However, Feldstein has shown, using a variety of data, that the wealth displacement effect dominates the induced retirement effect, as a result of which the net effect of the public pension system is to lower household saving and capital accumulation. For example, Feldstein (1974, 1982c, 1996b) shows, using time-series data for the USA, that social security has substantially increased personal consumption (and by implication has substantially reduced personal saving). [Leimar and Lesnoy (1982) pointed out that there was a programming error in the program used to calculate the social security wealth variable used in Feldstein (1974), but Feldstein (1982c) showed that correcting the error does not change the basic result, and moreover, Feldstein (1974) remains of seminal importance, even though the empirical results have been debated, because it focused attention on social security crowd-out issues.] Similarly, Feldstein (1977, 1980) estimates the magnitudes of both the wealth displacement effect and the induced retirement effect using cross-country data and shows that the former is larger in absolute

magnitude than the latter, as a result of which social security reduces private saving, on balance.

Turning to Feldstein's work on health insurance [see Feldstein (1995c) for a useful overview], Feldstein (1970) finds that the price of physicians' services rose much faster than the consumer price index after the introduction of Medicare and Medicaid in 1966, suggesting that these health insurance programmes increased the demand for physicians' services, thereby bidding up the price. Similarly, Feldstein (1973) estimates a demand function for health care using time series data on individual states of the USA and finds that health insurance has a significant impact on the demand for health care.

Moreover, after establishing that social insurance programmes have indeed distorted the behaviour of individuals as theory would predict, Feldstein has then gone on to make recommendations about how to reform these programmes so that they continue to protect individuals from the risks they are designed to protect them from, while at the same alleviating the distortions they cause, including the reductions in saving that they cause. For example, Feldstein proposes reforming the current unemployment insurance system by making benefits taxable (as they are now, due in large part to Feldstein's own efforts), reducing replacement rates and/or (better yet) introducing a more fundamental reform involving the introduction of unemployment insurance saving accounts earmarked to pay benefits when unemployment occurs [see, for example, Feldstein and Altman (2007)].

Similarly, Feldstein proposes a transition from the current pay-as-you-go social security system to a mixed system with a substantial investment-based (funded) component [see, for example, Feldstein (1995a, f, 1996a, 1997b, 1998, 2005c, 2009a), Feldstein and Samwick (1997, 1998a, b, 2002), Feldstein and Ranguelova (2001) and Feldstein and Liebman (2002a)]. Economists have traditionally felt that it is difficult, if not impossible, to make the transition from a pay-as-you-go social security system to a mixed system or a fully funded system because one generation will have to bear a so-called 'double burden', financing the social security benefits of its parents' generation as well as its own benefits, but Feldstein shows in the aforementioned papers that this is not an insurmountable problem.

Finally, Feldstein proposes a transition from the current pay-as-you-go comprehensive low-deductible low-coinsurance Medicare system (the US federal health care programme for those over the age of 65) to a health savings account (HSA) system that creates strong incentives to choose high deductibles and high coinsurance [see, for example, Feldstein (1971, 1999a), Feldstein and Gruber (1995) and Feldstein and Samwick (1997)]. Tax-advantaged health savings accounts have been available to taxpayers who have a high-deductible health plan (HDHP) since 2003, and these accounts could provide a model for Medicare reform.

A related paper (Feldstein 1995b) pertains to college scholarships, which are not a form of social insurance narrowly defined, but which have similar distortive effects on individual behaviour. Feldstein (1995b) shows that college scholarships are beneficial in that they enable the children of low-income families to attend college, but distortive in that expected parental contributions are higher and the amounts of financial assistance lower if parental assets are higher. This implies a hefty 'education tax rate' on saving and strongly discourages parents from saving.

Public Finance

Another major contribution Feldstein has made to economics is in the area of public finance. Feldstein has shown in a long series of papers that taxes distort the behaviour of households and firms, causing substantial deadweight losses, and that one needs to take full account of the behavioural response of households and firms to tax changes when estimating their impact. For example, Feldstein (1995a, d, 1999b) estimated the impact of the Tax Reform Act of 1986 using the compensated elasticity of taxable income with respect to changes in tax rates, which allows one

to take account of the fact that tax changes would affect not only labour supply, but also the forms of compensation, the investment of assets and the extent of spending on tax-deductible activities [see Feldstein and Feenberg (1996) for a similar analysis of the 1993 tax rate increases].

Feldstein has also argued that tax policies have had the effect of depressing saving and investment, thereby causing a substantial deadweight loss and lowering economic growth [see Feldstein (1995e) for a useful survey]. We have already discussed the saving-depressing effects of various social insurance programmes, but the tax system also has the effect of depressing saving. The combination of the corporate income tax and personal income taxes on interest, dividends and capital gains creates a substantial wedge between the pre-tax marginal product of capital and the net return received by individual savers (i.e. it raises the effective tax rate on capital income), which depresses saving, investment and economic growth.

Feldstein (1976a, 1978b, c, 1995e) points out that, when doing a welfare analysis, the deadweight loss arising from the current tax system must be compared to the deadweight loss of the tax system that replaces it, and Feldstein (1995e) shows that a shift from the current income tax to a consumption tax or a labour income tax will increase national saving and reduce the deadweight loss of the overall tax system.

Feldstein has also analysed the distortionary effects of specific taxes. For example, Feldstein and Yitzhaki (1978) show that capital gains taxes have discouraged the sale of equities and reduced tax revenue via the lock-in effect and that cutting the capital gains tax would *increase* tax revenues by encouraging investors to realise their capital gains.

As another example, Feldstein (1981) shows that the use of the 'historic cost' method of depreciation for tax purposes implies that higher inflation rates reduce the real value of future depreciation deductions and therefore raise the real net cost of investment, that the rise in the real net cost of investment can be substantial at recent inflation rates, and that allowing accelerated depreciation and valuing depreciation at replacement cost for tax purposes are alternate ways of alleviating the biases caused by the use of 'historical cost' depreciation.

As yet another example, Feldstein has written a series of papers on the impact of tax breaks for charitable contributions on the amount of charitable giving [see, for example, Feldstein and Clotfelter (1976)]. These papers find that the elasticity of charitable giving with respect to the price or net cost of giving is slightly greater than one, which implies that any reduction in price will increase the total contributions received by charitable organisations by more than the reduction in tax revenue.

Moreover, Feldstein has also shown that the distortions caused by the tax system are exacerbated by the interaction between an unindexed tax system and high inflation [see Feldstein (1983b) for a collection of a number of his papers on this topic]. For example, inflation increases households' nominal incomes and pushes them into higher and higher tax brackets, thereby raising their marginal tax rates (a phenomenon called 'bracket creep'). Similarly, Feldstein (1983b, 1995e) has shown that inflation distorts the measurement of capital income and raises the effective tax rate on the return to saving. For example, because nominal interest income and nominal capital gains (the nominal increase in asset values) are taxed at the personal level, interest income and capital gains are overstated and overtaxed when there is inflation. Furthermore, because depreciation is understated and inventory profits are overstated when there is inflation, corporate income is overstated and overtaxed (although the fact that nominal interest payments can be deducted from profits works in the opposite direction). For example, Feldstein and Summers (1978) show that, on balance, the high rates of inflation in the USA in the 1970s raised the effective tax rate on corporate income substantially, and Feldstein (1982a) shows that this, in turn, has substantially reduced business investment in the USA since the late 1960s. Moreover, Feldstein (1982b) shows that the interaction between the tax code and inflation has distorted not only the size of the capital stock, but also the allocation of capital between business capital and housing capital, leading to too little of the former and too much of the latter.

The Feldstein–Horioka Paradox or Puzzle

One of Feldstein's best known papers is Feldstein and Horioka (1980), his joint paper with Charles Yuji Horioka on international capital mobility [see also Feldstein (1983a) and Feldstein and Bacchetta (1991)]. In this paper, the authors regress the domestic investment rate on the domestic saving rate using cross-section data on OECD member countries for the 1960–74 period and find that the coefficient of the domestic saving rate (subsequently referred to as the 'saving retention coefficient') is significantly different from zero but not significantly different from one. If capital markets are fully integrated and capital flows freely across national borders in search of the highest return, this coefficient should be zero (at least in the case of small economies). The fact that it is not significantly different from one suggests (in the absence of legal and other restrictions on international capital flows) that 'home bias' is strong and that people strongly prefer to invest their saving in their home country. This result generated considerable interest and surprise, because many economists had assumed that capital had become perfectly mobile internationally, and it came to be known as the 'Feldstein–Horioka puzzle or paradox'. It spawned a voluminous literature trying to verify and/or explain the result [see Coakley et al. (1998) and Apergis and Tsoumas (2009) for surveys of this literature], was included in Obstfeld and Rogoff's (2001) list of the 'six major puzzles in international macroeconomics', is covered in many, if not most, textbooks in macroeconomics and international economics, and is one of the most frequently cited papers in international economics.

The findings of this paper are important for a number of reasons. First, they shed light on the true nature of the world capital market and on the extent to which capital markets are integrated. Second, they confirm that it is appropriate, at least as a first approximation, to study income distribution in general and tax incidence in particular using models that ignore international capital mobility. Third, they imply that the national return on domestic saving is approximately equal to the pre-tax domestic marginal product of capital, since such saving increases the domestic capital stock rather than either flowing abroad or replacing foreign investment at home.

The Economics of the European Monetary Union

A related topic on which Feldstein has also made an important contribution is the impact of the introduction of the European Monetary Union (EMU) and the euro. Feldstein did extensive research on this topic both before and after the introduction of the EMU and the euro, and has shown convincingly that the disadvantages of implementing a monetary union among a very heterogeneous group of countries have far outweighed the advantages thereof, and that the experiment was a dismal failure [see, for example, Feldstein (1997a, 2005a, 2012)].

The Economics of National Security

In recent years, Feldstein has become increasingly interested in the economics of national security, a topic of growing importance due to the rapid rise in terrorism and military conflicts. In addition to conducting research on various topics relating to national security, Feldstein has been advising graduate students on topics relating to national security; started a new graduate course on the Economics of National Security at Harvard shortly after the 11 September 2001 attacks; heads the Working Group on the Economics of National Security at the National Bureau of Economic Research; and founded the Economics of National Security Association (ENSA) in 2013.

To cite two examples of Feldstein's work in this area, Feldstein (2008) proposes ways of reforming the institutions for domestic counterterrorism (CT) in the USA and of strengthening cooperation among the CT activities of the USA and its allies, while Feldstein (2009b) draws lessons from the 1930s to make recommendations concerning economic and national security policies for the USA today, one of which is to increase the scale and funding of the Federal Bureau of Investigation

(FBI) and the Department of Homeland Security to prepare for the threats of domestic terrorism and cyber attacks that did not exist in the 1930s.

Economics Education

As an academic, Feldstein has made a substantial contribution not only to economics research but also to economics education. Perhaps most importantly, he has trained numerous prominent economists who went on to occupy the top echelons of academia and government, among them Alan J. Auerbach (Robert D. Burch Professor of Economics and Law; Director of the Burch Center for Tax Policy and Public Finance; formerly Chair of the Economics Department, University of California, Berkeley; and formerly Deputy Chief of Staff of the U.S. Joint Committee on Taxation), Raj Chetty (professor at Harvard University; a 2012 MacArthur Fellow; and recipient of the 2013 John Bates Clark Medal), David T. Ellwood (professor and Dean of the John F. Kennedy School of Government at Harvard University and formerly Assistant Secretary for Planning and Evaluation at the U.S. Department of Health and Human Services), Douglas W. Elmendorf (Director of the Congressional Budget Office; formerly Deputy Assistant Secretary for Economic Policy at the US Department of the Treasury; and formerly Senior Fellow at the Brookings Institution), Charles Yuji Horioka (Research Professor at the Asian Growth Research Institute in Kitakyushu City, Japan; previously Vea Family Professor of Technology and Evolutionary Economics Centennial at the University of the Philippines, Diliman; and recipient of the 2001 Japanese Economic Association-Nakahara Prize), R. Glenn Hubbard (professor and Dean of the Business School at Columbia University; formerly Deputy Assistant Secretary for Tax Analysis at the US Department of the Treasury; and formerly Chairperson of the President's Council of Economic Advisors), Steven N. Kaplan (Neubauer Family Distinguished Service Professor of Entrepreneurship and Finance at the University of Chicago and one of the top twelve Business School professors in the country according to *Business Week*), Jeffrey B. Liebman (Malcolm Wiener Professor of Public Policy, John F. Kennedy School of Government, Harvard University, and formerly Acting Deputy Director for Policy in the US Office of Management and Budget), Lawrence B. Lindsey (Chief Executive Officer of the Lindsey Group; formerly Director of the National Economic Council; and formerly member of the Board of Governors of the Federal Reserve System), Jose Piñera (Distinguished Senior Fellow at the Cato Institute; formerly Chile's Secretary of Labor and Social Security and Secretary of Mining; and architect of Chile's private pension system), James M. Poterba (professor and formerly Head of the Economics Department at the Massachusetts Institute of Technology; Feldstein's successor as President of the National Bureau of Economic Research; and formerly a member of the President's Advisory Panel on Federal Tax Reform), Harvey S. Rosen (professor and formerly Chair of the Economics Department at Princeton University; formerly Deputy Assistant Secretary for Tax Analysis at the US Department of the Treasury; and formerly member and Chairperson of the President's Council of Economic Advisors), Jeffrey D. Sachs (Professor and Director of the Earth Institute at Columbia University; formerly Professor at Harvard University; advisor to many Latin American and post-Communist economies; and Special Adviser to two successive United Nations Secretaries-General on the Millennium Development Goals), Andrew A. Samwick (Sandra L. and Arthur L. Irving ′72a, P′10 Professor of Economics; Director of the Nelson A. Rockefeller Center for Public Policy and the Social Sciences, Dartmouth College; and formerly Chief Economist of the President's Council of Economic Advisors), Joel Slemrod (Professor, Economics Department Chair and Director of the Office of Tax Policy Research at the University of Michigan, Ann Arbor; and a member of the Congressional Budget Office Panel of Economic Advisers), Lawrence H. Summers (Professor and formerly President of Harvard University; recipient of the 1993 John Bates Clark Medal; and formerly Secretary of the Treasury, Chief Economist of the World Bank and Chairperson of the President's

National Economic Council); and this is a very incomplete list.

Furthermore, Feldstein taught the introductory course in economics at Harvard for 21 years (from 1984 until 2005), and this course was the most popular course on campus when he was teaching it, with more than 1000 students enrolled in it in some years.

The National Bureau of Economic Research

Feldstein contributed significantly to the development of the field of economics by serving as the President of the National Bureau of Economic Research, Inc. (NBER), the US's leading non-profit, non-partisan economic research organisation, for some 30 years. He became President in 1977 at the tender age of 37, and served in this capacity until he retired in 2008 (except from 1982 to 1984, when he was Chairperson of the Council of Economic Advisors under President Reagan). The NBER expanded and prospered enormously during his many years at the helm and now counts more than 1300 leading scholars from throughout North America as Research Associates. Moreover, Feldstein organised the NBER into Research Programs (of which there are now 20) and Working Groups (of which there are now 15), created the NBER Working Paper series (dubbed 'yellow jackets' because of their distinctive yellow covers), inaugurated the NBER Summer Institute (a three-week gathering of applied economists that now draws 2400 participants a year), moved the headquarters to a modern office building near the Harvard campus in the direction of MIT, and fostered ties with the Centre for Economic Policy Research (its European counterpart), the Chinese Academy of Sciences etc. [see Warsh (2008) for more details]. One indication of the NBER's prominence is that 24 Nobel Prize winners in Economics and 13 past Chairs of the President's Council of Economic Advisers have been researchers at the NBER.

Feldstein is still active at the NBER as President Emeritus and Director of the Working Group on the Economics of National Security. Moreover, to honour Feldstein's outstanding tenure as President, the NBER inaugurated the Martin Feldstein Lecture, an annual lecture by an outstanding economist, in 2009.

Economic Policymaking

In addition, Feldstein has been deeply involved in economic policymaking for much of his career. In 1982–84, he served for 2 years as Chairperson of the Council of Economic Advisors under President Reagan and spoke out strongly about the dangers of ballooning federal government deficits, even though this led to conflicts with other members of the Reagan Administration and his advice was not always heeded. Feldstein has continued speaking out about the dangers of ballooning government deficits, and in recent years his staunch advocacy of scaling back tax expenditures as a way of trimming federal government deficits has incurred the wrath of Republicans, who are against any increases in tax revenues, but has garnered the widespread support of Democrats.

With respect to other policies upon which Feldstein has had an influence, he was instrumental in cutting the capital gains tax [see Loungani (2004)] and making unemployment compensation benefits taxable, and has long been an avid advocate of social security reform, was instrumental in implementing a tax reform that made social security benefits taxable in the case of high-income households in 1983, and was one of the main driving forces behind former President George W. Bush's initiative of partial privatisation of the social security system in 2005. President Bush's initiative ultimately failed, but much earlier (in 1980), one of Feldstein's disciples, Jose Piñera, successfully privatised Chile's pension system and converted it into a fully funded system based on personal retirement accounts as Secretary of Labor and Social Security.

Thus Feldstein has made remarkable contributions not only to the development of the field of economics, but also to the conduct of economic policy as a researcher, research administrator, policy advisor, educator and journalist.

Martin, Henry (Died 1721)

Douglas Vickers

Henry Martin (Martyn), eldest son of Edward Martyn of Upham, Wiltshire, owes his place in the history of economics to his participation in the debates surrounding the Treaty of Commerce between England and France proposed at Utrecht in 1713. He did not pursue the legal career for which he had been educated, but he accepted, as a reward for his contributions to the trade debates, an appointment as Inspector-General of Exports and Imports. He died at Blackheath in March 1721.

Martin was the principal author (together with Joshua Gee, among many others) of the periodical *The British Merchant, or Commerce Preserved* which appeared twice a week between August 1713 and July 1714. It strenuously argued the case for continued protectionism and the support of the British manufacturing trades against the free-trade and reciprocal tariff clauses of the proposed Treaty, and it was undoubtedly due to Martin's writing that the Treaty was ultimately rejected.

Martin was also influential in the publication of the *Spectator*, and appears to have written issue No. 180 and to have contributed heavily to, or written, Nos. 200 and 232. These contributions

present the popular argument that the 'riches [of the state] must increase or decrease in proportion to the number and riches of the people'. Increased population would lead to increased consumption expenditures and would increase land values and thereby taxation revenue. Arguing that 'the wages of labourers make the greatest part of the price of everything', it was claimed that lower wages would reduce manufacturing prices and 'increase foreign markets'. Employment would be provided for a larger number of workers, particularly if, in the manner of William Petty's example of watch making, output volumes were increased by a division of labour and specialization of production (*Spectator* No. 232). For these reasons it was argued that the poor should be employed rather than made the object of indiscriminate charity.

Harriet Martineau, the best-selling popularizer of classical political economy, was born in Norwich, England, on 12 June 1802, the sixth of eight children of Thomas Martineau, a Unitarian textile manufacturer, and Elizabeth Rankin Martineau. She was educated at home, except that from 1813 to 1815 she studied French, Latin, and English composition at a school run by the Reverend Isaac Perry. Her early writings were religious, beginning with an article on 'Female Writers on Practical Divinity' for the *Monthly Repository*. After her father's death in 1826, she became engaged, but her fiancé died before they could be married. She remained single for the rest of her life. Investment losses in 1829 forced her to support herself by writing: William Johnson Fox's *Monthly Review* hired her as a book reviewer for 15 pounds a year, and when the Central Unitarian Association offered prizes for essays to convert Catholics, Jews, and Muslims, Martineau won all three prizes, for 15 guineas each. These prizes enabled her to visit her brother in Dublin in 1831. While there, she planned the series *Illustrations of Political Economy*, stories that would expound (especially to the working classes) the principles of classical political economy, to which she had been introduced by Jane Marcet's *Conversations on Political Economy* (1816) and James Mill's *Elements of Political Economy* (1821). The first of the 34 tales of political economy, of the Poor Laws, and of taxation was published in February 1832 by Charles Fox (brother of William Fox), and distributed by the Society for the Diffusion of Useful Knowledge. By 10 February, the first printing of 1,500 copies had all been sold, and a second printing of 5,000 copies ordered.

The success of *Illustrations of Political Economy* (1832–4, 2004a) made Martineau a celebrity: Henry Brougham, the Lord Chancellor, provided her with private papers on the impending reform of the Poor Law, while Robert Owen attempted, without success, to convert her to socialism. Although poor health interrupted her work several times, Harriet Martineau refused offers of government pensions from Lord Grey in 1835, Lord Melbourne in 1841, and W.E. Gladstone in 1873, lest her independence be compromised. Instead, her friends raised funds for an annuity

for her in 1843, and, when her health permitted she worked with great diligence, writing more than 1,600 articles for the *Daily News* from 1852 to 1866. Although her income was modest, she was a philanthropist, founding a building society among other charitable projects.

Harriet Martineau disclaimed originality for *Illustrations of Political Economy*, insisting that its purpose was didactic, making established principles better known. Her presentation of the principles was original, and her work stood out for its recognition of women as rational economic agents (1985). In her *Illustrations*, Martineau upheld laissez-faire and property rights. In later life, Martineau endorsed married women's property rights, condemned slavery as an illegitimate form of property, gave qualified support to workers' cooperatives, and accepted the need for state intervention in certain very limited circumstances. Her lectures at working men's institutions stressed education rather than state intervention as the remedy for most social ills. Her subsequent writings on America and slavery (1837, 2002) demonstrated that she was an adept economic analyst, not just a popularizer. For example, Martineau recognized the limited demand for the services of prostitutes in the South as evidence of the sexual exploitation of slaves, and identified the inability of slaveholders to make credible long-term commitments to their slaves as a source of inefficiency in slave agriculture (Levy 2003). Martineau's *Society in America* (1837) emphasized the incompatibility of slavery and of the legal, political, and economic position of American women (lacking votes and, if married, property rights) with America's founding rhetoric of liberty. Her study of the United States was accompanied by her *How to Observe Morals and Manners* (1838), a methodological manual on comparative sociology and ethnography. In 1853, Martineau published a translation and abridgement of the pioneer sociologist Auguste Comte's *Philosophie positive*, an adaptation that pleased Comte so much that he had it translated back into French.

In 1855, anticipating death from heart disease, Martineau wrote her autobiography for posthumous publication (1877), but she lived until 27 June 1876.

Martingales

Alan F. Karr

JEL Classifications
C0

A martingale is a mathematical model of a fair game, or of some other process that is incrementally random noise. The term, which also denotes part of a horse's harness or a ship's rigging, refers in addition to a gambling system in which every losing bet is doubled; it was introduced into probability theory by J.L. Doob. Among stochastic processes, martingales have particular constancy properties with respect to conditioning. The time parameter may be either discrete or continuous, but since the latter is more important in economic applications, we concentrate on it.

Suppose that on a basic probability space there is defined a *history* $\mathscr{H} = (\mathscr{H}_t)_{t\geq 0}$ representing observable events as a function of time. For each t, $(\mathscr{H}_t)$ is the σ-algebra comprising events determined by observations over the interval $[0, t]$, so that $(\mathscr{H}_s) \subseteq (\mathscr{H}_t)$ when $s \leq t$. Then a stochastic process $M = (M_t)_{t\geq 0}$ is a *martingale* with respect to this history if

(a) For each t, M_t is $\mathscr{H}_t$ measurable (i.e., the state of the process at t is observable over $[0, t]$);
(b) $E[|M_t|] < \infty$ for each t;
(c) The 'martingale property' holds: whenever $s \leq t$,

$$E[M_t|\,\mathscr{H}_s] = M_s. \tag{1}$$

When no history is specified, it is usually understood that $\mathscr{H}_t = \sigma(M_s; s \leq t)$. One specific consequence is that $E[M_t] = E[M_0]$ for each t, so that a martingale is constant in the mean.

Written as

$$E[M_t - M_s|\ \mathscr{H}_s] = 0, s \leq t,$$

the martingale property implies that the optimal (in the sense of minimum mean squared error, or MMSE) predictor of a future increment of a martingale is zero. Thus, a martingale is indeed a mathematical idealization of a fair game. In some ways this property is clearest in differential form: assuming that the differential dM_t, which always extends *forward* in time from t, can be defined, then M is a martingale provided that

$$E[dM_t|\,\mathscr{H}_t] = 0 \tag{2}$$

for each t. Thus, a martingale can be interpreted as a 'noise' process, in which the MMSE prediction of the differential dM_t is simply zero; in many applications this interpretation becomes quite literal. Martingales are also analogous to the residuals in a regression problem, where what remains unexplained by the model should reduce, ideally, to chance variation.

One can also define *supermartingales*, for which (1) becomes

$$E[M_t|\,\mathscr{H}_t] \leq M_s, \tag{3}$$

and *submartingales*, in which the sense of the inequality in (3) is reversed. A supermartingale represents a less-than-fair game.

All martingales are in some sense convex combinations of (generalizations of) two key examples, namely the Wiener and Poisson processes. If (W_t) is a Wiener process (Brownian motion), then the processes W_t and $W_t^2 - t$ are both martingales; in fact, these properties characterize the Wiener process. In discrete time, martingales generalize sums of independent, mean zero random variables; the Wiener process, which has independent

and stationary increments, is a continuous time counterpart of these partial sum processes.

If (N_t) is a point process (or counting process), with N_t the number of events occurring in $[0, t]$, then under quite general assumptions there exists a nonnegative, predictable (a technical term, which in practice means left-continuous) random process (λ_t), the stochastic intensity of N, such that the process $M_t = N_t - \int_0^t \lambda_s ds$ is a martingale. Since $\lambda_t dt = E[dN_t | \mathscr{H}_t]$, M represents the new information realized as a function of time and, because of this and applications in statistics and state estimation, is known as the innovation martingale. For a Poisson process, which like the Wiener process has independent and stationary increments, the stochastic intensity is deterministic and equal to the rate of the process.

Square integrable martingales are especially important. A martingale M is *square integrable* if $\sup_t E\left[M_t^2\right] < \infty$, and in this case there exists a predictable process $\langle M \rangle$, the *predictable variation* of M, such that $M_t^2 - \langle M \rangle_t$ is a martingale. That the predictable variation is incrementally a conditional variance is confirmed by the differential relationship

$$\begin{aligned} d\langle M \rangle_t &= E[(dM_t - E dM_t | \mathscr{H}_t])^2 | \mathscr{H}_t] \\ &= E\left[(dM_t)^2 | \mathscr{H}_t\right]. \end{aligned}$$

Here the second equality holds because M is a martingale.

For the Wiener process $\langle W \rangle_t \equiv t$ in particular, the predictable variation is deterministic, a property characteristic of processes with independent increments. For a point process N with stochastic intensity λ, the predictable variation of the innovation martingale $dM_t = dN_t - \lambda_t dt$ is given by $d\langle M \rangle_t = \lambda_t dt$, which implies that a point process is locally and conditionally Poisson, in the sense that the incremental conditional mean and variance coincide.

Existence of the predictable variation is proved via the Doob-Meyer decomposition theorem, a cornerstone of the theory. The principal theoretical results pertaining to martingales fall into three classes: inequalities, convergence theorems and optimal sampling theorems.

So-called maximal inequalities, which provide upper bounds for probabilities of the form $P\{sup_{s \le t} |M_s| > c\}$, are not only of inherent interest, but also the key tools for proving convergence theorems. Moreover, these inequalities form the basis of a profound connection between martingales and classical mathematical analysis.

Under various assumptions, given a martingale M there exists a random variable M_∞ such that $M_t \to M_\infty$ almost surely as $t \to \infty$. Convergence obtains both almost surely and in L^1 if M is uniformly integrable, and in this case $M_t = E[M_\infty | \mathscr{H}_t]$ for each t. Not all martingles converge, however; those that fail to converge include, for example, the Wiener process and most innovation martingales.

Optional sampling theorems require the further concept of a stopping time. A random time T (a random variable with values in $[0, \infty]$, interpreted as the time at which some event occurs – with $T = \infty$ corresponding to its not occurring) is a *stopping time* of the history $\mathscr{H}$ if $\{T \le t\} \epsilon \mathscr{H}_t$ for each t. Intuitively, whether a stopping time has occurred by t can be determined from observations over $[0, t]$, and does not require prescient knowledge of the future. The rule by which a gambler quits a game must be a stopping time. Associated with a stopping time T is a σ-algebra $\mathscr{H}_t$ representing events determined by observations over the random time interval $[0, T]$ in the same way that for deterministic t, $\mathscr{H}_t$ corresponds to the interval $[0, t]$.

Martingale property extends from deterministic times to stopping times, and imply in particular that an unfair game cannot be made fair by means of a stopping time. More precisely, if M is a martingale and S and T are stopping times with $S \le T$, then under broad – albeit not universal – conditions,

$$E[M_T | \mathscr{H}_s] \le M_s. \tag{4}$$

With $S = 0$ in (4), taking expectations yields $E[M_T] = E[M_0]$. The corresponding result for supermartingales,

$$E[M_T|\mathscr{H}_s] \leq M_s, \tag{5}$$

demonstrates that an unfair game cannot be made fair via a stopping time, and dooms gambling systems without infinite resources to eventual failure.

Significant applications of martingales include mathematical statistics (likelihood ratio processes are martingales), queueing theory, filtering and prediction (for example, in signal processing) and economics.

A common feature of these applications is that they involve a random system 'driven' by a martingale in precisely the same manner that a dynamical system is driven by a forcing function. Given a (square integrable) martingale M and a predictable process C fulfilling integrability restrictions, the stochastic integral process

$$(C * M)_t = \int_0^t C_s dM_s$$

is itself a martingale, for which M acts as driving term. (Since M may change state discontinuously, whether endpoints are included in the interval of integration must be specified; in this case, the integral is over the closed interval $[0, t]$.) Construction of stochastic integrals is a difficult, subtle problem: none of the conventional definitions can be applied pathwise (typically the sample paths of M are not of bounded variation), and instead one must employ sophisticated probability theory. The predictable variations satisfy

$$d\langle C * M\rangle_t = C_t^2 d\langle M\rangle_t.$$

Economic applications include, e.g., models of securities prices.

In applications, the inclusion of a 'dt'-integral is often desirable or necessary, leading to *semimartingales,* which are random processes Z of the form

$$Z_t = \int_0^t A_s ds + \int_0^t C_s dM_s, \tag{6}$$

where M is a martingale, C is a predictable process and A fulfills a technical property known as progressive measurability. (Integrability conditions must be satisfied as well.) The differential version of (6) is

$$dZ_t = A_t dt + C_t dM_t. \tag{7}$$

If the processes A and C, rather than specified exogenously, are functionals of Z, then (7) becomes a stochastic differential equation

$$dZ_t = \mu(Z_t)dt + \sigma(Z_t)dM_t, \tag{8}$$

or, more generally,

$$dZ_t = \mu(Z_s; s \leq t)dt + \sigma(Z_s; s \leq t)dM_t. \tag{9}$$

These equations can be solved – however, not using pathwise methods – under a variety of assumptions, but essentially only when the driving term is a martingale. For example, if the martingale is the Wiener process, solutions to (8) and (9) are known as diffusions and Itō processes, respectively, and the resultant theory as the Itō calculus, after its principal inventor, K. Itō. Alternatively, if M is the innovation martingale associated with a point process N then, inter alia, solutions to (8) can be used to construct recursive methods for filtering to extract signals from noise.

Ernest Mandel

Abstract

This article summarizes the methodology and economics of Karl Marx. After a brief account of his life, it deals with his historical materialism, and then his labour theory of value, his theories of rent, money, surplus value, and crises, his account of the laws of motion of the capitalism mode of production, and his and Engels's conception of the economy of post-capitalist societies.

Keywords

Accumulation of capital; Asiatic mode of production; Böhm-Bawerk, E. von; Bukharin, N.; Capitalist mode of production; Class; Commodity theory of money; Communism; Concentration (centralization) of capital; Constant and variable capital; Credit cycles; Economic crisis; Economic laws; Economic science; Engels, F.; Exploitation; Feudalism; Hilferding, R.; Historical materialism; Ideology; Invisible hand; Iron law of wages; Labour power; Labour theory of value; Land rent; Lassalle, F.; Laws of motion of capitalism; Lenin, V.; Market value; Marx, K.; Mobility of capital; Modes of production; Monopoly; Organic composition of capital; Overproduction; Paper money; Post-capitalist society; Prices of production; Proletariat; Rate of profit; Rent; Reserve army of labour; Ricardo, D.; Social polarization; Socialism; Sraffa, P.; Surplus value; Technological change; Trade unions; Transformation problem; Underconsumptionism

Karl Marx was born on 5 May 1818, the son of the lawyer Heinrich Marx and Henriette Pressburg. His father was descended from an old family of Jewish rabbis, but was himself a liberal admirer of the Enlightenment and not religious. He converted to Protestantism a few years before Karl was born to escape restrictions still imposed upon Jews in Prussia. His mother was of Dutch-Jewish origin.

Life and Work

Karl Marx studied at the *Friedrich-Wilhelm Gymnasium* in Trier, and at the universities of Bonn and Berlin. His doctoral thesis, *Differenz der demokritischen und epikurischen Naturphilosophie*, was accepted at the University of Jena on 15 April 1841. In 1843 he married Jenny von Westphalen, daughter of Baron von Westphalen, a high Prussian government official.

Marx's university studies covered many fields, but centred around philosophy and religion. He frequented the circle of the more radical followers of the great philosopher Hegel, befriended one of their main representatives, Bruno Bauer, and was especially influenced by the publication in 1841 of Ludwig Feuerbach's *Das Wesen des Christentums* (The Nature of Christianity). He had intended to teach philosophy at the university, but that quickly proved to be unrealistic. He then turned towards journalism, both to propagandize his ideas and to gain a livelihood. He became editor of the *Rheinische Zeitung,* a liberal newspaper of Cologne, in May 1942. His interest turned more and more to political and social questions, which he treated in an increasingly radical way. The paper was banned by the Prussian authorities a year later.

Karl Marx then planned to publish a magazine called *Deutsch-Französische Jahrbücher* in Paris, in order to escape Prussian censorship and to be more closely linked and identified with the real struggles for political and social emancipation which, at that time, were centred around France. He emigrated to Paris with his wife and met there his lifelong friend Friedrich Engels.

Marx had become critical of Hegel's philosophical political system, a criticism which would lead to his first major work, Zur Kritik

des *Hegelschen Rechtsphilosophie* (A Critique of Hegel's Philosophy of Right). Intensively studying history and political economy during his stay in Paris, he became strongly influenced by socialist and working-class circles in the French capital. With his 'Paris Manuscripts' (*Oekonomisch-philosophische Manuskripte,* 1844), he definitely became a communist, i.e. a proponent of collective ownership of the means of production.

He was expelled from France at the beginning of 1845 through pressure from the Prussian embassy and migrated to Brussels. His definite turn towards historical materialism (see below) would occur with his manuscript *Die Deutsche Ideologie* (1845–6) culminating in the eleven *Theses on Feuerbach,* written together with Engels but never published during his lifetime.

This led also to a polemical break with the most influential French socialist of that period, Proudhon, expressed in the only book Marx would write in French, *Misère de la Philosophie* (1846).

Simultaneously he became more and more involved in practical socialist politics, and started to work with the Communist League, which asked Engels and himself to draft their declaration of principle. This is the origin of the *Communist Manifesto* (1848), *Manifest der Kommunistischen Partei* (1848).

As soon as the revolution of 1848 broke out, he was in turn expelled from Belgium and went first to France, then, from April 1848 on, to Cologne. His political activity during the German revolution of 1848 centred around the publication of the daily paper *Neue Rheinische Zeitung*, which enjoyed wide popular support. After the victory of the Prussian counter-revolution, the paper was banned in May 1849 and Marx was expelled from Prussia. He never succeeded in recovering his citizenship. Marx emigrated to London, where he would stay, with short interruptions, till the end of his life. For fifteen years, his time would be mainly taken up with economic studies, which would lead to the publication first of *Zur Kritik der Politischen Oekonomie* (1859) and later of *Das Kapital,* Vol. I (1867). He spent long hours at the British Museum, studying the writings of all the major economists, as well as the government Blue Books, Hansard and many other contemporary sources on social and economic conditions in Britain and the world. His reading also covered technology, ethnology and anthropology, besides political economy and economic history; many notebooks were filled with excerpts from the books he read.

But while the activity was mainly studious, he never completely abandoned practical politics. He first hoped that the Communist League would be kept alive, thanks to a revival of revolution. When this did not occur, he progressively dropped out of emigré politics, but not without writing a scathing indictment of French counter-revolution in *Der 18. Brumaire des Louis Bonaparte* (1852), which was in a certain sense the balance sheet of his political activity and an analysis of the 1848–52 cycle of revolution and counter-revolution. He would befriend British trade-union leaders and gradually attempt to draw them towards international working class interests and politics. These efforts culminated in the creation of the International Working Men's Association (1864) – the so-called First International – in which Marx and Engels would play a leading role, politically as well as organizationally.

It was not only his political interest and revolutionary passion that prevented Marx from becoming an economist pure and simple. It was also the pressure of material necessity. Contrary to his hope, he never succeeded in earning enough money from his scientific writings to sustain himself and his growing family. He had to turn to journalism to make a living. He had initial, be it modest, success in this field, when he became European correspondent of the *New York Daily Tribune* in the summer of 1851. But he never had a regular income from that collaboration, and it ended after ten years.

So the years of his London exile were mainly years of great material deprivation and moral suffering. Marx suffered greatly from the fact that he could not provide a minimum of normal living conditions for his wife and children, whom he loved deeply. Bad lodgings in cholera-stricken Soho, insufficient food and medical care, led to a chronic deterioration of his wife's and his own health and to the death of several of their children; that of his oldest son Edgar in 1855 struck him an

especially heavy blow. Of his seven children, only three daughters survived, Jenny, Laura and Eleanor (Tussy). All three were very gifted and would play a significant role in the international labour movement, Eleanor in Britain, Jenny and Laura in France (where they married the socialist leaders Longuet and Lafargue).

During this long period of material misery, Marx survived thanks to the financial and moral support of his friend Friedrich Engels, whose devotion to him stands as an exceptional example of friendship in the history of science and politics. Things started to improve when Marx came into his mother's inheritance; when the first independent working-class parties (followers of Lassalle on the one hand, of Marx and Engels on the other) developed in Germany, creating a broader market for his writings; when the IWMA became influential in several European countries, and when Engels' financial conditions improved to the point where he would sustain the Marx family on a more regular basis.

The period 1865–71 was one in which Marx's concentration on economic studies and on the drafting of *Das Kapital* was interrupted more and more by current political commitments to the IWMA, culminating in his impassioned defence of the Paris Commune (*Der Bürgerkrieg in Frankreich [The Civil War in France]* 1871). But the satisfaction of being able to participate a second time in a real revolution – be it only vicariously – was troubled by the deep divisions inside the IMWA, which led to the split with the anarchists grouped around Michael Bakunin.

Marx did not succeed in finishing a final version of *Das Kapital* vols II and III, which were published posthumously, after extensive editing, by Engels. It remains controversial whether he intended to add two more volumes to these, according to an initial plan. More than 25 years after the death of Marx, Karl Kautsky edited what is often called vol. IV of *Das Kapital,* his extensive critique of other economists: *Theorien über den Mehrwert (Theories of Surplus Value).*

Marx's final years were increasingly marked by bad health, in spite of slightly improved living conditions. Bad health was probably the main reason why the final version of vols II and III of *Capital* could not be finished. Although he wrote a strong critique of the Programme which was adopted by the unification congress (1878) of German social democracy *(Kritik Des Gothaer Program),* he was heartened by the creation of that united working-class party in his native land, by the spread of socialist organizations throughout Europe, and by the growing influence of his ideas in the socialist movement. His wife fell ill in 1880 and died the next year. This came as a deadly blow to Karl Marx, who did not survive her for long. He himself died in London on 14 March 1883.

Historical Materialism

Outside his specific economic theories, Marx's main contribution to the social sciences has been his theory of historical materialism. Its starting point is anthropological. Human beings cannot survive without social organization. Social organization is based upon social labour and social communication. Social labour always occurs within a given framework of specific, historically determined, social relations of production. These social relations of production determine in the last analysis all other social relations, including those of social communication. It is social existence which determines social consciousness and not the other way around.

Historical materialism posits that relations of production which become stabilized and reproduce themselves are structures which can no longer be changed gradually, piecemeal. They are modes of production. To use Hegel's dialectical language, which was largely adopted (and adapted) by Marx: they can only change qualitatively through a complete social upheaval, a social revolution or counter-revolution. Quantitative changes can occur within modes of production, but they do not modify the basic structure. In each mode of production, a given set of relations of production constitutes the basis (infrastructure) on which is erected a complex superstructure, encompassing the state and the law (except in classless society), ideology, religion, philosophy, the arts, morality etc.

Relations of production are the sum total of social relations which human beings establish among themselves in the production of their material lives. They are therefore not limited to what actually happens at the point of production. Humankind could not survive, i.e. produce, if there did not exist specific forms of circulation of goods, e.g. between producing units (circulation of tools and raw materials) and between producing units and consumers. A priori allocation of goods determines other relations of production than does allocation of goods through the market. Partial commodity production (what Marx calls 'simple commodity production' or 'petty commodity production' – 'einfache Warenproduktion') also implies other relations of production than does generalized commodity production.

Except in the case of classless societies, modes of production, centred around prevailing relations of production, are embodied in specific class relations which, in the last analysis, overdetermine relations between individuals.

Historical materialism does not deny the individual's free will, his attempts to make choices concerning his existence according to his individual passions, his interests as he understands them, his convictions, his moral options etc. What historical materialism does state is: (1) that these choices are strongly predetermined by the social framework (education, prevailing ideology and moral 'values', variants of behaviour limited by material conditions etc); (2) that the outcome of the collision of millions of different passions, interests and options is essentially a phenomenon of social logic and not of individual psychology. Here, class interests are predominant.

There is no example in history of a ruling class not trying to defend its class rule, or of an exploited class not trying to limit (and occasionally eliminate) the exploitation it suffers. So outside classless society, the class struggle is a permanent feature of human society. In fact, one of the key theses of historical materialism is that 'the history of humankind is the history of class struggles' (Marx, *Communist Manifesto,* 1848).

The immediate object of class struggle is economic and material. It is a struggle for the division of the social product between the direct producers (the productive, exploited class) and those who appropriate what Marx calls the social surplus product, the residuum of the social product once the producers and their offspring are fed (in the large sense of the word; i.e. the sum total of the consumer goods consumed by that class) and the initial stock of tools and raw materials is reproduced (including the restoration of initial fertility of the soil). The ruling class functions as ruling class essentially through the appropriation of the social surplus product. By getting possession of the social surplus product, it acquires the means to foster and maintain most of the superstructural activities mentioned above; and by doing so, it can largely determine their function – to maintain and reproduce the given social structure, the given mode of production – and their contents.

We say 'largely determine' and not 'completely determine'. First, there is an 'immanent dialectical', i.e. an autonomous movement, of each specific superstructural sphere of activity. Each generation of scientists, artists, philosophers, theologists, lawyers and politicians finds a given *corpus* of ideas, forms, rules, techniques, ways of thinking, to which it is initiated through education and current practice, etc. It is not forced to simply continue and reproduce these elements. It can transform them, modify them, change their interconnections, even negate them. Again: historical materialism does not deny that there is a specific history of science, a history of art, a history of philosophy, a history of political and moral ideas, a history of religion etc., which all follow their own logic. It tries to *explain* why a certain number of scientific, artistic, philosophical, ideological, juridical changes or even revolutions occur at a given time and in given countries, quite different from other ones which occurred some centuries earlier elsewhere. The nexus of these 'revolutions' with given historical periods is a nexus of class interests.

Second, each social formation (i.e. a given country in a given epoch) while being characterized by predominant relations of production (i.e. a given mode or production at a certain phase of its development) includes different relations of production which are largely remnants of the past, but

also sometimes nuclei of future modes of production. Thus there exists not only the ruling class and the exploited class characteristic of that prevailing mode of production (capitalists and wage earners under capitalism). There also exist remnants of social classes which were predominant when other relations of production prevailed and which, while having lost their hegemony, still manage to survive in the interstices of the new society. This is for example the case with petty commodity producers (peasants, handicraftsmen, small merchants), semifeudal landowners, and even slave-owners, in many already predominantly capitalist social formations throughout the 19th and part of the 20th centuries. Each of these social classes has its own ideology, its own religious and moral values, which are intertwined with the ideology of the hegemonic ruling class, without becoming completely absorbed by that.

Third, even after a given ruling class (e.g. the feudal or semi-feudal nobility) has disappeared as a ruling class, its ideology can survive through sheer force of social inertia and routine (custom). The survival of traditional *ancien régime* catholic ideology in France during a large part of the 19th century, in spite of the sweeping social, political and ideological changes ushered in by the French revolution, is an illustration of that rule.

Finally, Marx's statement that the ruling ideology of each epoch is the ideology of the ruling class – another basic tenet of historical materialism – does not express more than it actually says. It implies that other ideologies can exist side by side with that ruling ideology without being hegemonic. To cite the most important of these occurrences: exploited and (or) oppressed social classes can develop their own ideology, which will start to challenge the prevailing hegemonic one. In fact, an ideological class struggle accompanies and sometimes even precedes the political class struggle properly speaking. Religious and philosophical struggles preceding the classical bourgeois revolutions; the first socialist critiques of bourgeois society preceding the constitution of the first working-class parties and revolutions, are examples of that type.

The class struggle has been up to now the great motor of history. Human beings make their own history. No mode of production can be replaced by another one without deliberate actions by large social forces, i.e., without social revolutions (or counter-revolutions). Whether these revolutions or counter-revolutions actually lead to the long-term implementation of deliberate projects of social reorganization is another matter altogether. Very often, their outcome is to a large extent different from the intention of the main actors.

Human beings act consciously, but they can act with false consciousness. They do not necessarily understand why they want to realize certain social and (or) political plans, why they want to maintain or to change economic or juridical institutions; and especially, they rarely understand in a scientific sense the laws of social change, the material and social preconditions for successfully conserving or changing such institutions. Indeed, Marx claims that only with the discovery of the main tenets of historical materialism have we made a significant step forward towards understanding these laws, without being able to predict 'all' future developments of society.

Social change, social revolutions and counter-revolutions are furthermore occurring within determined material constraints. The level of development of the productive forces – essentially tools and human skills, including their effects upon the fertility of the soil – limits the possibilities of institutional change. Slave labour has shown itself to be largely incompatible with the factory system based upon contemporary machines. Socialism would not be durably built upon the basis of the wooden plough and the potter's wheel. A social revolution generally widens the scope for the development of the productive forces and leads to social progress in most fields of human activity in a momentous way. Likewise, an epoch of deep social crisis is ushered in when there is a growing conflict between the prevailing mode of production (i.e. the existing social order) on the one hand, and the further development of the productive forces on the other. Such a social crisis will then manifest itself on all major fields and social activity: politics, ideology, morals and law, as well as in the realm of the economic life properly speaking.

Historical materialism thereby provides a measuring stick for human progress: the growth of the productive forces, measurable through the growth of the average productivity of labour, and the number, longevity and skill of the human species. This measuring stick in no way abstracts from the natural preconditions for human survival and human growth (in the broadest sense of the concept). Nor does it abstract from the conditional and partial character of such progress, in terms of social organization and individual alienation.

In the last analysis, the division of society into antagonistic social classes reflects, from the point of view of historical materialism, an inevitable limitation of human freedom. For Marx and Engels, the real measuring rod of human freedom, i.e. of human wealth, is not 'productive labour'; this only creates the material pre-condition for that freedom. The real measuring rod is leisure time, not in the sense of 'time for doing nothing' but in the sense of time freed from the iron necessity to produce and reproduce material livelihood, and therefore disposable for all-round and free development of the individual talents, wishes, capacities, potentialities, of each human being.

As long as society is too poor, as long as goods and services satisfying basic needs are too scarce, only part of society can be freed from the necessity to devote most of its life to 'work for a livelihood' (i.e. of forced labour, in the anthropological/sociological sense of the word, that is in relation to desires, aspirations and talents, not to a juridical status of bonded labour). That is essentially what represents the freedom of the ruling classes and their hangers-on, who are 'being paid to think', to create, to invent, to administer, because they have become free from the obligation to bake their own bread, weave their own clothes and build their own houses.

Once the productive forces are developed far enough to guarantee all human beings satisfaction of their basic needs by 'productive labour' limited to a minor fraction of lifetime (the half work-day or less), then the material need of the division of society in classes disappears. Then, there remains no objective basis for part of society to monopolize administration, access to information, knowledge, intellectual labour. For that reason, historical materialism explains both the reasons why class societies and class struggles arose in history, and why they will disappear in the future in a classless society of democratically self-administering associated producers.

Historical materialism therefore contains an attempt at explaining the origin, the functions, and the future withering away of the state as a specific institution, as well as an attempt to explain politics and political activity in general, as an expression of social conflicts centred around different social interest (mainly, but not only, those of different social classes; important fractions of classes, as well as non-class social groupings, also come into play).

For Marx and Engels, the state is not existent with human society as such, or with 'organized society' or even with 'civilized society' in the abstract; neither is it the result of any voluntarily concluded 'social contract' between individuals. That state is the sum total of apparatuses, i.e. special groups of people separate and apart from the rest (majority) of society, that appropriate to themselves functions of a repressive or integrative nature which were initially exercised by all citizens. This process of alienation occurs in conjunction with the emergence of social classes. The state is an instrument for fostering, conserving and reproducing a given class structure, and not a neutral arbiter between antagonistic class interests.

The emergence of a classless society is therefore closely intertwined, for adherents to historical materialism, with the process of withering away of the state, i. e. of gradual devolution to the whole of society (self-management, self-administration) of all specific functions today exercised by special apparatuses, i.e. of the dissolution of these apparatuses. Marx and Engels visualized the dictatorship of the proletariat, the last form of the state and of political class rule, as an instrument for assuring the transition from class society to classless society. It should itself be a state of a special kind, organizing its own gradual disappearance.

We said above that, from the point of view of historical materialism, the immediate object of class struggle is the division of the social product

between different social classes. Even the political class struggle in the final analysis serves that main purpose; but it also covers a much broader field of social conflicts. As all state activities have some bearing upon the relative stability or instability of a given social formation, and the class rule to which it is submitted, the class struggle can extend to all fields of politics, from foreign policy to educational problems and religious conflicts. This has of course to be proven through painstaking analysis, and not proclaimed as an axiom or a revealed truth. When conducted successfully, such exercises in class analysis and class definition of political, social and even literary struggles become impressive works of historical explanation, as for example Marx's *Class Struggles in France 1848–50*, Engels' *The German Peasant War*, Franz Mehring's *Die Lessing-Legende*, Trotsky's *History of the Russian Revolution*, etc.

Marx's Economic Theory: General Approach and Influence

A general appraisal of Marx's method of economic analysis is called for prior to an outline of his main economic theories (theses and hypotheses).

Marx is distinct from most important economists of the 19th and 20th centuries in that he does not consider himself at all an 'economist' pure and simple.

The idea that 'economic science' as a special science completely separate from sociology, history, anthropology etc. cannot exist, underlies most of his economic analysis. Indeed, historical materialism is an attempt at unifying all social sciences, if not all sciences about humankind, into a single 'science of society'.

For sure, within the framework of this general 'science of society', economic phenomena could and should be submitted to analysis as specific phenomena. So economic theory, economical science, have a definite autonomy after all; but is only a partial and relative one.

Probably the best formula for characterizing Marx's economic theory would be to call it an endeavour to explain the social economy. This would be true in a double sense. For Marx, there are no eternal economic laws, valid in every epoch of human prehistory and history. Each mode of production has its own specific economic laws, which lose their relevance once the general social framework has fundamentally changed. For Marx likewise, there are no economic laws separate and apart from specific relations between human beings, in the primary (but not only, as already summarized) social relations of production. All attempts to reduce economic problems to purely material, objective ones, to relations between things, or between things and human beings, would be considered by Marx as manifestations of mystification, of false consciousness, expressing itself through the attempted reification of human relations. Behind relations between things, economic science should try to discover the specific relations between human beings which they hide. Real economic science has therefore also a demystifying function compared to vulgar 'economics', which takes a certain number of 'things' for granted without asking the question: Are they really only what they appear to be? From where do they originate? What explains these appearances? What lies behind them? Where do they lead? How could they (will they) disappear? *Problemblindheit,* the refusal to see that facts are generally more problematic than they appear at first sight, is certainly not a reproach one could address to Marx's economic thought.

Marx's economic analysis is therefore characterized by a strong ground current of *historical relativism,* with a strong recourse to the genetical and evolutionary method of thinking (that is why the parallel with Darwin has often been made, sometimes in an excessive way). The formula 'genetic structuralism' has also been used in relation to Marx's general approach to economic analysis. Be that as it may, one could state that Marx's economic theory is essentially geared to the discovery of specific 'laws of motion' for successive modes of production. While his theoretical effort has been mainly centred around the discovery of these laws of motion for capitalist society, his work contains indications of such laws – different ones, to be sure – for precapitalist and post-capitalist social formations too.

The main link between Marx's sociology and anthropology on the one hand, and his economic analysis on the other, lies in the key role of social labour as the basic anthropological feature underlying all forms of social organization. Social labour can be organized in quite different forms, thereby giving rise to quite different economic phenomena ('facts'). Basically different forms of social labour organization lead to basically different sets of economic institutions and dynamics, following basically different logics (obeying basically different 'laws of motion').

All human societies must assure the satisfaction of a certain number of basic needs, in order to survive and reproduce themselves. This leads to the necessity of establishing some sort of equilibrium between socially recognized needs, i.e. current consumption and current production. But this abstract banality does not tell us anything about the concrete way in which social labour is organized in order to achieve that goal.

Society can recognize all individual labour as *immediately social labour.* Indeed, it does so in innumerable primitive tribal and village communities, as it does in the contemporary *kibbutz.* Directly social labour can be organized in a despotic or in a democratic way, through custom and superstition as well as through an attempt at applying advanced science to economic organization; but it will always be immediately recognized social labour, in as much as it is based upon *a prior* assignment of the producers to their specific work (again: irrespective of the form this assignation takes, whether it is voluntary or compulsory, despotic or simply through custom etc.).

But when social decision-taking about work assignation (and resource allocation closely tied to it) is fragmented into different units operating independently from each other – as a result of private control (property) of the means of production, in the economic and not necessarily the juridical sense of the word – then social labour in turn is fragmented into private labours which are not automatically recognized as socially necessary ones (whose expenditure is not automatically compensated by society). Then the private producers have to exchange parts or all of their products in order to satisfy some or all of their basic needs. Then these products become commodities. The economy becomes a (partial or generalized) market economy. Only by measuring the results of the sale of his products can the producer (or owner) ascertain what part of his private labour expenditure has been recognized (compensated) as social labour, and what part has not.

Even if we operate with such simple analytical tools as 'directly social labour', 'private labour', 'socially recognized social labour', we have to make quite an effort at abstracting from immediately apparent phenomena in order to understand their relevance for economic analysis. This is true for all scientific analysis, in natural as well as in social sciences. Marx's economic analysis, as presented in his main books, has not been extremely popular reading; but then, there are not yet so many scientists in these circumstances. This has nothing to do with any innate obscurity of the author, but rather with the nature of scientific analysis as such.

The relatively limited number of readers of Marx's economic writings (the first English paperback edition of *Das Kapital* appeared only in 1974!) is clearly tied to Marx's scientific rigour, his effort at a systematic and all-sided analysis of the phenomena of the capitalist economy.

But while his economic analysis lacked popularity, his political and historical projections became more and more influential. With the rise of independent working-class mass parties, an increasing number of these proclaimed themselves as being guided or influenced by Marx, at least in the epoch of the Second and the Third Internationals, roughly the half century from 1890 till 1940. Beginning with the Russian revolution of 1917, a growing number of governments and of states claimed to base their policies and constitutions on concepts developed by Marx. (Whether this was legitimate or not is another question.) But the fact itself testifies to Marx's great influence on contemporary social and political developments, evolutionary and revolutionary alike.

Likewise, his diffused influence on social science, including academic economic theory, goes far beyond general acceptance or even substantial knowledge of his main writings. Some key ideas of historical materialism and of economic analysis

which permeate his work – e.g. that economic interests to a large extent influence, if not determine, political struggles; that historic evolution is linked to important changes in material conditions; that economic crises ('the business cycle') are unavoidable under conditions of capitalist market economy – have become near-platitudes. It is sufficient to notice how major economists and historians strongly denied their validity throughout the 19th century and at least until the 1920s, to understand how deep has been Marx's influence on contemporary social science in general.

Marx's Labour Theory of Value

As an economist, Marx is generally situated in the continuity of the great classical school of Adam Smith and Ricardo. He obviously owes a lot to Ricardo, and conducts a current dialogue with that master in most of his mature economic writings.

Marx inherited the labour theory of value from the classical school. Here the continuity is even more pronounced; but there is also a radical break. For Ricardo, labour is essentially a numeraire, which enables a common computation of labour and capital as basic elements of production costs. For Marx, labour is value. Value is nothing but that fragment of the total labour potential existing in a given society in a certain period (e.g. a year or a month) which is used for the output of a given commodity, at the average social productivity of labour existing then and there, divided by the total number of these commodities produced, and expressed in hours (or minutes), days, weeks, months of labour.

Value is therefore essentially a social, objective and historically relative category. It is social because it is determined by the overall result of the fluctuating efforts of each individual producer (under capitalism: of each individual firm or factory). It is objective because it is given, once the production of a given commodity is finished and is thus independent from personal (or collective) valuations of customers on the market place; and it is historically relative because it changes with each important change (progress or regression) of the average productivity of labour in a given branch of output, including in agriculture and transportation.

This does not imply that Marx's concept of value is in any way completely detached from consumption. It only means that the feedback of consumers' behaviour and wishes upon value is always mediated through changes in allocation of labour inputs in production, labour seen as subdivided into living labour and dead (dated) labour, i.e. tools and raw materials. The market emits signals to which the producing units react. Value changes after these reactions, not before them. Market price changes can of course occur prior to changes in value. In fact, changes in market prices are among the key signals which can lead to changes in labour allocation between different branches of production, i.e. to changes in labour quantities necessary to produce given commodities. But then, for Marx, values determine prices only basically and in the medium-term sense of the word. This determination only appears clearly as an explication of *medium and long-term price movements.* In the shorter run, prices fluctuate around values as axes. Marx never intended to negate the operation of market laws, of the law of supply and demand, in determining these short-term fluctuations.

The 'law of value' is but Marx's version of Adam Smith's 'invisible hand'. In a society dominated by private labour, private producers and private ownership of productive inputs, it is this 'law of value', an objective economic law operating behind the backs of all people, all 'agents' involved in production and consumption, which, in the final analysis, regulates the economy, determines what is produced and how it is produced (and therefore also what can be consumed). The 'law of value' regulates the exchange between commodities, according to the quantities of socially necessary abstract labour they embody (the quantity of such labour spent in their production). Through regulating the exchange between commodities, the 'law of value' also regulates, after some interval, the distribution of society's labour potential and of society's non-living productive resources between different branches of production. Again, the analogy with Smith's 'invisible hand' is striking.

Marx's critique of the 'invisible hand' concept does not dwell essentially on the analysis of how a market economy actually operates. It would above all insist that this operation is not eternal, not immanent in 'human nature', but created by specific historical circumstances, a product of a special way of social organization, and due to disappear at some stage of historical evolution as it appeared during a previous stage. And it would also stress that this 'invisible hand' leads neither to the maximum of economic growth nor to the optimum of human wellbeing for the greatest number of individuals, i.e. it would stress the heavy economic and social price humankind had to pay, and is still currently paying, for the undeniable progress the market economy produced at a given stage of historical evolution.

The formula 'quantities of abstract human labour' refers to labour seen strictly as a fraction of the total labour potential of a given society at a given time, say a labour potential of 2 billion hours a year (1 million potential producers supposedly capable of working each 2000 hours a year). It therefore implies making abstraction of the specific trade or occupation of a given male or female producer, the product of a day's work of a weaver not being worth less or more than that of a peasant, a miner, a housebuilder, a milliner or a seamstress. At the basis of that concept of 'abstract human labour' lies a social condition, a specific set of social relations of production, in which small independent producers are essentially equal. Without that equality, social division of labour, and therefore satisfaction of basic consumers' needs, would be seriously endangered under that specific organizational set-up of the economy. Such an equality between small commodity owners and producers is later transformed into an equality between owners of capital under the capitalist mode of production.

But the concept of homogeneity of productive human labour, underlying that of 'abstract human labour' as the essence of value, does not imply a negation of the difference between skilled and unskilled labour. Again: a negation of that difference would lead to breakdown of the necessary division of labour, as would any basic heterogeneity of labour inputs in different branches of output. It would then not pay to acquire skills: most of them would disappear. So Marx's labour theory of value, in an internally coherent way, leads to the conclusion that one hour of skilled labour represents more value than one hour of unskilled labour, say represents the equivalent of 1.5 hours of unskilled labour. The difference would result from the imputation of the labour it costs to acquire the given skill. While an unskilled labourer would have a labour potential of 120,000 hours during his adult life, a skilled labourer would only have a labour potential of 80,000 hours, 40,000 hours being used for acquiring, maintaining and developing his skill. Only if one hour of skilled labour embodies the same value of 1.5 hours of unskilled labour, will the equality of all 'economic agents' be maintained under these circumstances, i.e. will it 'pay' economically to acquire a skill.

Marx himself never extensively dwelled on this solution of the so-called *reduction problem.* This remains indeed one of the most obscure parts of his general economic theory. It has led to some, generally rather mild, controversy. Much more heat has been generated by another facet of Marx's labour theory of value, the so-called *transformation problem.* Indeed, from Böhm-Bawerk writing a century ago till the recent contributions of Sraffa (1960) and Steedman (1977), the way Marx dealt with the transformation of values into 'prices of production' in *Capital* Vol. III has been considered by many of his critics as the main problem of his 'system', including being a reason to reject the labour theory of value out of hand.

The problem arises out of the obvious modification in the functioning of a market economy when *capitalist* commodity production substitutes itself for *simple* commodity production. In simple commodity production, with generally stable technology and stable (or easily reproduceable) tools, living labour is the only variable of the quantity and subdivision of social production. The mobility of labour is the only dynamic factor in the economy. As Engels pointed out in his Addendum to *Capital* Vol. III (Marx, *g*, pp. 1034–7) in such an economy, commodities would be exchanged at prices which would be immediately proportional to values, to the labour inputs they embody.

But under the capitalist mode of production, this is no longer the case. Economic decision-taking is not in the hands of the direct producers. It is in the hands of the capitalist entrepreneurs in the wider sense of the word (bankers – distributors of credit – playing a key role in that decision-taking, besides entrepreneurs in the productive sector properly speaking). Investment decisions, i.e. decisions for creating, expanding, reducing or closing enterprises, determine economic life. It is the *mobility of capital* and not the mobility of labour which becomes the motive force of the economy. Mobility of labour becomes essentially an epiphenomenon of the mobility of capital.

Capitalist production is production for profit. Mobility of capital is determined by existing or expected profit differentials. Capital leaves branches (countries, regions) with lower profits (or profit expectations) and flows towards branches (countries, regions) with higher ones. These movements lead to an equalization of the rate of profit between different branches of production. But approximately equal returns on all invested capital (at least under conditions of prevailing 'free competition') coexist with unequal proportions of inputs of labour in these different branches. So there is a disparity between the direct value of a commodity and its 'price of production', that 'price of production' being defined by Marx as the sum of production costs (costs of fixed capital and raw materials plus wages) and the average rate of profit multiplied with the capital spent in the given production.

The so-called 'transformation problem' relates to the question of whether a relation can nevertheless be established between value and these ' prices of production', what is the degree of coherence (or incoherence) of the relation with the 'law of value' (the labour theory of value in general), and what is the correct quantitative way to express that relation, if it exists.

We shall leave aside here the last aspect of the problem, to which extensive analysis has recently been devoted (Mandel and Freeman 1984). From Marx's point of view, there is no incoherence between the formation of 'prices of production' and the labour theory of value. Nor is it true that he came upon that alleged difficulty when he started to prepare *Capital* III, i.e. to deal with capitalist competition, as several critics have argued (see e.g. Joan Robinson 1942). In fact, his solution of the transformation problem is already present in the *Grundrisse* (Marx, *d*), before he even started to draft *Capital* Vol. I.

The sum total of value produced in a given country during a given span of time (e.g. one year) is determined by the sum total of labour-inputs. Competition and movements of capital cannot change that quantity. The sum total of values equals the sum total of 'prices of production'. The only effect of capital competition and capital mobility is to *redistribute* that given sum – and this through a redistribution of surplus value (see below) – between different capitals, to the benefit of some and at the expense of others.

Now this redistribution does not occur in a haphazard or arbitrary way. Essentially value (surplus-value) is transferred from technically less advanced branches to technologically more advanced branches. And here the concept of 'quantities of socially necessary labour' comes into its own, under the conditions of constant revolutions of productive technology that characterize the capitalist mode of production. Branches with lower than average technology (organic composition of capital, see below) can be considered as wasting socially necessary labour. Part of the labour spent in production in their realm is therefore not compensated by society. Branches with higher than average technology (organic composition of capital) can be considered to be economizing social labour; their labour inputs can therefore be considered as more intensive than average, embodying more value. In this way, the transfer of value (surplus-value) between different branches, far from being in contradiction with the law of value, is precisely the way it operates and should operate under conditions of 'capitalist equality', given the pressure of rapid technological change.

As to the logical inconsistency often supposedly to be found in Marx's method of solving the 'transformation problem' – first advanced by von Bortkiewicz (1907) – it is based upon a misunderstanding in our opinion. It is alleged that in his 'transformation schemas' (or tables) (Marx, *g*, pp. 255–6) Marx calculates inputs in 'values'

and outputs in 'prices of production', thereby omitting the feedback effect of the latter on the former. But that feedback effect is unrealistic and unnecessary, once one recognizes that inputs are essentially data. Movements of capital posterior to the purchase of machinery or raw materials, including ups and downs of prices of finished products produced with these raw materials, cannot lead to a change in prices and therefore of profits of the said machinery and raw materials, on sales which have already occurred. What critics present as an inconsistency between 'values' and 'prices of production' is simply a recognition of *two different time-frameworks* (cycles) in which the equalization of the rate of profit has been achieved, a first one for inputs, and a second, later one for outputs.

Marx's Theory of Rent

The labour theory of value defines value as the socially necessary quantity of labour determined by the average productivity of labour of each given sector of production. But these values are not mathematically fixed data. They are simply the expression of a *process* going on in real life, under capitalist commodity production. So this average is only ascertained in the course of a certain time-span. There is a lot of logical argument and empirical evidence to advance the hypothesis that the normal time-span for essentially modifying the value of commodities is the business cycle, from one crisis of over-production (recession) to the next one.

Before technological progress and (or) better (more 'rational') labour organization etc. determines a more than marginal change (in general: decline) in the value of a commodity, and the crisis eliminates less efficient firms, there will be a coexistence of firms with various 'individual values' of a given commodity in a given branch of output, even assuming a single market price. So, in his step-for-step approach towards explaining the immediate phenomena (facts of economic life) like prices and profits, by their essence, Marx introduces at this point of his analysis a new mediating concept, that of *market value* (Marx, *g*, ch. 10). The market value of a commodity is the 'individual value' of the firm, or a group of firms, in a given branch of production, around which the market price will fluctuate. That 'market value' is not necessarily the mathematical (weighted) average of labour expenditure of all firms of that branch. It can be below, equal or above that average, for a certain period (generally less than the duration of the business cycle, at least under 'free competition'), according to whether social demand is saturated, just covered or to an important extent not covered by current output plus existing stocks. In these three cases respectively, the more (most) efficient firms, the firms of average efficiency, or even firms with labour productivity below average, will determine the market value of that given commodity.

This implies that the more efficient firms enjoy *surplus profits* (profits over and above the average profit) in case 2 and 3 and that a certain number of firms work at less than average profit in all three cases, but especially in case 1.

The mobility of capital, i.e. normal capitalist competition, generally eliminates such situations after a certain lapse of time. But when that mobility of capital is impeded for long periods by either unavoidable scarcity (natural conditions not renewable or non-substitutable, like land and mineral deposits) or through the operation of institutional obstacles (private property of land and mineral resources forbidding access to available capital, except in exchange for payments over and above average profit), these surplus profits can be frozen and maintained for decades. They thus become *rents,* of which *ground rent* and *mineral rent* are the most obvious examples in Marx's time, extensively analysed in *Capital* vol. III (Marx, *g*, part 6).

Marx's theory of rent is the most difficult part of his economic theory, the one which has witnessed fewer comments and developments, by followers and critics alike, than other major parts of his 'system'. But it is not obscure. And in contrast to Ricardo's or Rodbertus's theories of rent, it represents a straightforward application of the labour theory of value. It does not imply any emergence of ' supplementary' value (surplus value, profits) in the market, in the process of

circulation of commodities, which is anathema to Marx and to all consistent upholders of the labour theory of value. Nor does it in any way suggest that land or mineral deposits 'create' value.

It simply means that in agriculture and mining less productive labour (as in the general case analysed above) determines the market value of food or minerals, and that therefore more efficient farms and mines enjoy surplus profits which Marx calls differential (land and mining) rent. It also means that as long as productivity of labour in agriculture is generally below the average of the economy as a whole (or more correctly: that the organic composition of capital, the expenditure in machinery and raw materials as against wages, is inferior in agriculture to that of industry and transportation), the sum-total of surplus-value produced in agriculture will accrue to landowners + capitalist farmers taken together, and will not enter the general process of (re)distribution of profit throughout the economy as a whole.

This creates the basis for a supplementary form of rent, over and above differential rent, rent which Marx calls absolute land rent. This is, incidentally, the basis for a long-term separation of capitalist landowners from entrepreneurs in farming or animal husbandry, distinct from feudal or semi-feudal landowners or great landowners under conditions of predominantly petty commodity production, or in the Asiatic mode of production, with free peasants.

The validity of Marx's theory of land and mining rents has been confirmed by historical evidence, especially in the 20th century. Not only has history substantiated Marx's prediction that, in spite of the obstacle of land and mining rent, mechanization would end up by penetrating food and raw materials production too, as it has for a long time dominated industry and transportation, thereby causing a growing decline of differential rent (this has occurred increasingly in agriculture in the last 25–50 years, first in North America, and then in Western Europe and even elsewhere). It has also demonstrated that once the structural scarcity of food disappears, the institutional obstacle (private property) loses most of its efficiency as a brake upon the mobility of capital. Therefore the participation of surplus-value produced in agriculture in the general process of profit equalization throughout the economy cannot be prevented any more. Thereby absolute rent tends to wither away and, with it, the separation of land ownership from entrepreneurial farming and animal husbandry. It is true that farmers can then fall under the sway of the banks, but they do so as private owners of their land which becomes mortgaged, not as share-croppers or entrepreneurs renting land from separate owners.

On the other hand, the reappearance of structural scarcity in the realm of energy enabled the OPEC countries to multiply the price of oil by ten in the 1970s, i.e. to have it determined by the oilfields where production costs are the highest, thereby assuring the owners of the cheapest oil wells in Arabia, Iran, Libya, etc. of huge differential mineral rents.

Marx's theory of land and mineral rent can be easily extended into a general theory of rent, applicable to all fields of production where formidable difficulties of entry limit mobility of capital for extended periods of time. It thereby becomes the basis of a Marxist theory of monopoly and monopoly surplus profits, i.e. in the form of cartel rents (Hilferding 1910) or of technological rent (Mandel 1972). Lenin's and Bukharin's theories of surplus profit are based upon analogous but not identical reasoning (Bukharin 1914, 1926; Lenin 1917).

But in all these cases of general application of the Marxist theory of rent, the same caution should apply as Marx applied to his theory of land rent. By its very nature, capitalism, based upon private property, i.e. 'many capitals' – that is, competition – cannot tolerate any 'eternal' monopoly, a 'permanent' surplus profit deducted from the sum total of profits which is divided among the capitalist class as a whole. Technological innovations, substitution of new products for old ones including the field of raw materials and of food, will in the long run reduce or eliminate all monopoly situations, especially if the profit differential is large enough to justify huge research and investment outlays.

Marx's Theory of Money

In the same way as his theory of rent, Marx's theory of money is a straightforward application of the labour theory of value. As value is but the embodiment of socially necessary labour, commodities exchange with each other in proportion of the labour quanta they contain. This is true for the exchange of iron against wheat as it is true for the exchange of iron against gold or silver. Marx's theory of money is therefore in the first place a commodity theory of money. A given commodity can play the role of universal medium of exchange, as well as fulfil all the other functions of money, precisely because it is a commodity, i.e. because it is itself the product of socially necessary labour. This applies to the precious metals in the same way it applies to all the various commodities which, throughout history, have played the role of money.

It follows that strong upheavals in the 'intrinsic' value of the money-commodity will cause strong upheavals in the general price level. In Marx's theory of money, (market) prices are nothing but the expression of the value of commodities in the value of the money commodity chosen as a monetary standard. If £1 sterling $= \frac{1}{10}$ ounce of gold, the formula 'the price of 10 quarters of wheat is £1' means that 10 quarters of wheat have been produced in the same socially necessary labour time as $\frac{1}{10}$ ounce of gold. A strong decrease in the average productivity of labour in gold mining (as a result for example of a depletion of the richer gold veins) will lead to a general depression of the average price level, all other things remaining equal. Likewise, a sudden and radical increase in the average productivity of labour in gold mining, through the discovery of new rich gold fields (California after 1848; the Rand in South Africa in the 1890s) or through the application of new revolutionary technology, will lead to a general increase in the price level of all other commodities.

Leaving aside short-term oscillations, the general price level will move in medium and long-term periods according to the relation between the fluctuations of the productivity of labour in agriculture and industry on the one hand, and the fluctuations of the productivity of labour in gold mining (if gold is the money- commodity), on the other.

Basing himself on that commodity theory of money. Marx therefore criticized as inconsistent Ricardo's quantity theory (Marx, *h*, part 2). But for exactly the same reason of a consistent application of the labour theory of value, the quantity of money in circulation enters Marx's economic analysis when he deals with the phenomenon of paper money (Marx, *c*).

As gold has an intrinsic value, like all other commodities, there can be no 'gold inflation', as little as there can be a 'steel inflation'. Abstraction made of short-term price fluctuations caused by fluctuations between supply and demand, a persistent decline of the value of gold (exactly as for all other commodities) can only be the result of a persistent increase in the average productivity of labour in gold mining, and not of an 'excess' of circulation in gold. If the demand for gold falls consistently, this can only indirectly trigger off a decline in the value of gold through causing the closure of the least productive gold mines. But in the case of the money-commodity, such overproduction can hardly occur, given the special function of gold of serving as a universal reserve fund, nationally and internationally. It will always therefore find a buyer, be it not, of course, always at the same 'prices' (in Marx's economic theory, the concept of 'price of gold' is meaningless. As the price of a commodity is precisely its expression in the value of gold, the 'price of gold' would be the expression of the value of gold in the value of gold).

Paper money, bank notes, are a *money sign* representing a given quantity of the money-commodity. Starting from the above-mentioned example, a banknote of £1 represents $\frac{1}{10}$ ounce of gold. This is an objective 'fact of life', which no government or monetary authority can arbitrarily alter. It follows that any emission of paper money in excess of that given proportion will automatically lead to an increase in the general price level, always other things remaining equal. If £1 suddenly represents only $\frac{1}{20}$ ounce of gold, because

paper money circulation has doubled without a significant increase in the total labour time spent in the economy, then the price level will tend to double too. The value of $\frac{1}{10}$, ounce of gold remains equal to the value of 10 quarters of wheat. But as $\frac{1}{10}$, ounce of gold is now represented by £2 in paper banknotes instead of being represented by £1, the price of wheat will move from £1 to £2 for 10 quarters (from two shillings to four shillings a quarter before the introduction of the decimal system).

This does not mean that in the case of paper money, Marx himself has become an advocate of a quantity theory of money. While there are obvious analogies between his theory of paper money and the quantity theory, the main difference is the rejection by Marx of any mechanical automatism between the quantity of paper money emitted on the one hand, and the general dynamic of the economy (including on the price level) on the other.

In Marx's explanation of the movement of the capitalist economy in its totality, the formula *ceteris paribus* is meaningless. Excessive (or insufficient) emission of paper money never occurs in a vacuum. It always occurs at a given stage of the business cycle, and in a given phase of the longer-term historical evolution of capitalism. It is thereby always combined with given ups and downs of the rate of profit, of productivity of labour, of output, of market conditions (overproduction or insufficient production). Only in connection with these other fluctuations can the effect of paper money 'inflation' or 'deflation' be judged, including the effect on the general price level. The key variables are in the field of production. The key synthetic resultant is in the field of profit. Price movements are generally epiphenomena as much as they are signals. To untwine the tangle, more is necessary than a simple analysis of the fluctuations of the quantity of money. Only in the case of extreme runaway inflation of paper money would this be otherwise; and even in that border case, *relative* price movements (different degrees of price increases for different commodities) would still confirm that, in the last analysis, the law of value rules, and not the arbitrary decisions of the Central Bank, or any other authority controlling or emitting paper money.

Marx's Theory of Surplus-Value

Marx himself considered his theory of surplus-value his most important contribution to the progress of economic analysis (Marx, *I*; letter to Engels of 24 August 1867). It is through this theory that the wide scope of his sociological and historical thought enables him simultaneously to place the capitalist mode of production in its historical context, and to find the roots of its inner economic contradictions and its laws of motion in the specific relations of production on which it is based.

As said before, Marx's theory of classes is based on the recognition that in each class society, part of society (the ruling class) appropriates the social surplus product. But that surplus product can take three essentially different forms (or a combination of them). It can take the form of straightforward unpaid surplus labour, as in the slave mode of production, early feudalism or some sectors of the Asian mode of production (unpaid corvée labour for the Empire). It can take the form of goods appropriated by the ruling class in the form of use-values pure and simple (the products of surplus labour), as under feudalism when feudal rent is paid in a certain amount of produce (produce rent) or in its more modern remnants, such as sharecropping. And it can take a money form, like money-rent in the final phases of feudalism, and capitalist profits. Surplus-value is essentially just that: the money form of the social surplus produce or, what amounts to the same, the money product of surplus labour. It has therefore a common root with all other forms of surplus product: unpaid labour.

This means that Marx's theory of surplus-value is basically a deduction (or residual) theory of the ruling classes' income. The whole social product (the net national income) is produced in the course of the process of production, exactly as the whole crop is harvested by the peasants. What happens on the market (or through appropriation of the produce) is a distribution (or redistribution) of what already has been created. The surplus product, and therefore also its money form, surplus-value, is the residual of that new (net) social product (income) which remains after the producing classes have received their compensation

(under capitalism: their wages). This 'deduction' theory of the ruling classes' income is thus *ipso facto* an exploitation theory. Not in the ethical sense of the word – although Marx and Engels obviously manifested a lot of understandable moral indignation at the fate of all the exploited throughout history, and especially at the fate of the modern proletariat – but in the economical one. The income of the ruling classes can always be reduced in the final analysis to the product of unpaid labour: that is the heart of Marx's theory of exploitation.

That is also the reason why Marx attached so much importance to treating *surplus-value as a general category*, over and above profits (themselves subdivided into industrial profits, bank profits, commercial profits etc.), interest and rent, which are all part of the total surplus product produced by wage labour. It is this general category which explains both the existence (the common interest) of the ruling class (all those who live off surplus value), and the origins of the class struggle under capitalism.

Marx likewise laid bare the economic mechanism through which surplus-value originates. As the basis of that economic mechanism is a huge social upheaval which started in Western Europe in the 15th century and slowly spread over the rest of the continent and all other continents (in many so-called underdeveloped countries, it is still going on to this day).

Through many concomitant economic (including technical), social, political and cultural transformations, the mass of the direct producers, essentially peasants and handicraftsmen, are separated from their means of production and cut off from free access to the land. They are therefore unable to produce their livelihood on their own account. In order to keep themselves and their families alive, they have to hire out their arms, their muscles and their brains, to the owners of the means of production (including land). If and when these owners have enough money capital at their disposal to buy raw materials and pay wages, they can start to organize production on a capitalist basis, using wage labour to transform the raw materials which they buy, with the tools they own, into finished products which they then automatically own too.

The capitalist mode of production thus presupposes that the producers' *labour power has become a commodity.* Like all other commodities, the commodity labour power has an exchange value and a use value. The exchange value of labour power, like the exchange value of all other commodities, is the amount of socially necessary labour embodied in it, i.e. its reproduction costs. This means concretely the value of all the consumer goods and services necessary for a labourer to work day after day, week after week, month after month, at approximately the same level of intensity, and for the members of the labouring classes to remain approximately stable in number and skill (i.e. for a certain number of working-class children to be fed, kept and schooled, so as to replace their parents when they are unable to work any more, or die). But the use value of the commodity labour power is precisely its capacity to create new value, including its potential to create more value than its own reproduction costs. Surplus-value is but that difference between the total new value created by the commodity labour power, and its own value, its own reproduction costs.

The whole Marxian theory of surplus-value is therefore based upon that subtle distinction between 'labour power' and 'labour' (or value). But there is nothing 'metaphysical' about this distinction. It is simply an explanation (demystification) of a process which occurs daily in millions of cases.

The capitalist does not buy the worker's 'labour'. If he did that there would be obvious theft, for the worker's wage is obviously smaller than the total value he adds to that of the raw materials in the course of the process of production. No: the capitalist buys 'labour power', and often (not always of course) he buys it at its *justum pretium*, at its real value. So he feels unjustly accused when he is said to have caused a 'dishonest' operation. The worker is victim not of vulgar theft but of a social set-up which condemns him first to transform his productive capacity into a commodity, then to sell that labour power on a specific market (the labour market) characterized by institutional inequality, and finally to content himself with the market price he can get for that commodity, irrespective of whether the new value

he creates during the process of production exceeds that market price (his wage) by a small amount, a large amount, or an enormous amount.

The labour power the capitalist has bought 'adds value' to that of the used-up raw materials and tools (machinery, buildings etc.). If, and until that point of time, this added value is inferior or equal to the workers' wages, surplus-value cannot originate. But in that case, the capitalist has obviously no interest in hiring wage labour. He only hires it because that wage labour has the quality (the use value) to add to the raw materials' value more than its own value (i.e. its own wages). This 'additional added value' (the difference between total 'value added' and wages) is precisely surplus-value. Its emergence from the process of production is the precondition for the capitalists' hiring workers, for the existence of the capitalist mode of production.

The institutional inequality existing on the labour market (masked for liberal economists, sociologists and moral philosophers alike by juridical equality) arises from the very fact that the capitalist mode of production is based upon generalized commodity production, generalized market economy. This implies that a propertyless labourer, who owns no capital, who has no reserves of larger sums of money but who has to buy his food and clothes, pay his rent and even elementary public transportation for journeying between home and workplace, *in a continuous way* in exchange of money, is under the *economic compulsion* to sell the only commodity he possesses, to wit his labour power, also on a continuous basis. He cannot withdraw from the labour market until the wages go up. He cannot wait.

But the capitalist, who has money reserves, can temporarily withdraw from the labour market. He can lay his workers off, can even close or sell his enterprise and wait a couple of years before starting again in business. This institutional difference makes price determination of the labour market a game with loaded dice, heavily biased against the working class. One just has to imagine a social set-up in which each citizen would be guaranteed an annual minimum income by the community, irrespective or whether he is employed or not, to understand that 'wage determination' under these circumstances would be quite different from what it is under capitalism. In such a set-up the individual would really have the economic choice whether to sell his labour power to another person (or a firm) or not. Under capitalism, he has no choice. His is forced by economic compulsion to go through with that sale, practically at any price.

The economic function and importance of trade unions for the wage-earners also clearly arises from that elementary analysis. For it is precisely the workers' 'combination' and their assembling a collective resistance fund (what was called by the first French unions *caisses de résistance*, 'reserve deposits') which enables them, for example though a strike, to withdraw the supply of labour power temporarily from the market so as to stop a downward trend of wages or induce a wage increase. There is nothing 'unjust' in such a temporary withdrawal of the supply of labour power, as there are constant withdrawals of demand for labour power by the capitalists, sometimes on a huge scale never equalled by strikes. Through the functioning of strong labour unions, the working class tries to correct, albeit partially and modestly, the institutional inequality on the labour market of which it is a victim, without ever being able to neutralize it durably or completely.

It cannot neutralize it durably because in the very way in which capitalism functions there is a powerful built-in corrective in favour of capital: the inevitable emergence of an industrial reserve army of labour. There are three key sources for that reserve army: the mass of precapitalist producers and self-employed (independent peasants, handicraftsmen, trades-people, professional people, small and medium-sized capitalists); the mass of housewives (and to a lesser extent, children); the mass of the wage-earners themselves, who potentially can be thrown out of employment.

The first two sources have to be visualized not only in each capitalist country seen separately but on a world scale, through the operations of international migration. They are still unlimited to a great extent, although the number of wage-earners the world over (including agricultural wage labourers) has already passed the one billion mark. At the third source, while it is obviously

not unlimited (if wage labour would disappear altogether, if all wage labourers would be fired, surplus- value production would disappear too; that is why 'total robotism' is impossible under capitalism), its reserves are enormous, precisely in tandem with the enormous growth of the absolute number of wage earners.

The fluctuations of the industrial reserve army are determined both by the business cycle and by long-term trends of capital accumulation. Rapidly increasing capital accumulation attracts wage labour on a massive scale, including through international migration. Likewise, deceleration, stagnation or even decline of capital accumulation inflates the reserve army of labour. There is thus an upper limit to wage increases, when profits (realized profits and expected profits) are 'excessively' reduced in the eyes of the capitalists, which triggers off such decelerated, stagnating or declining capital accumulation, thereby decreasing employment and wages, till a 'reasonable' level of profits is restored.

This process does not correspond to any 'natural economic law' (or necessity), nor does it correspond to any 'immanent justice'. It just expresses the inner logic of the *capitalist* mode of production, which is geared to profit. Other forms of economic organization could function, have functioned and are functioning on the basis of other logics, which do not lead to periodic massive unemployment. On the contrary, a socialist would say — and Marx certainly thought so — that the capitalist system is an 'unjust', or better stated 'alienating', 'inhuman' social system, precisely because it cannot function without periodically reducing employment and the satisfaction of elementary needs for tens of millions of human beings.

Marx's theory of surplus-value is therefore closely intertwined with a *theory of wages* which is far away from Malthus's, Ricardo's or the early socialists' (like Ferdinand Lassalle's) 'iron law of wages', in which wages tend to fluctuate around the physiological minimum. That crude theory of 'absolute pauperization' of the working class under capitalism, attributed to Marx by many authors (Popper 1945, et al.), is not Marx's at all, as many contemporary authors have convincingly demonstrated (see among others Rosdolsky 1968). Such an 'iron law of wages' is essentially a demographic one, in which birth rates and the frequency of marriages determine the fluctuation of employment and unemployment and thereby the level of wages.

The logical and empirical inconsistencies of such a theory are obvious. Let it be sufficient to point out that while fluctuations in the supply of wage-labourers are considered essential, fluctuations in the demand for labour power are left out of the analysis. It is certainly a paradox that the staunch opponent of capitalism, Karl Marx, pointed out already in the middle of the 19th century the potential for wage increases under capitalism, even though not unlimited in time and space. Marx also stressed the fact that for each capitalist wage increases of other capitalists' workers are considered increases of potential purchasing power, not increases in costs (Marx, *d*).

Marx distinguishes two parts in the workers' wage, two elements of reproduction costs of the commodity labour power. One is purely physiological, and can be expressed in calories and energy quanta; this is the bottom below which the wage cannot fall without destroying slowly or rapidly the workers' labour capacity. The second one is historical-moral, as Marx calls it (Marx, *i*), and consists of those additional goods and services which a shift in the class relationship of forces, such as a victorious class struggle, enables the working class to incorporate into the average wage, the socially necessary (recognized) reproduction costs of the commodity labour power (e.g. paid holidays after the French general strike of June 1936). This part of the wage is essentially flexible. It will differ from country to country, continent to continent, and from epoch to epoch, according to many variables. But it has the upper limit indicated above: the ceiling from which profits threaten to disappear, or to become insufficient in the eyes of the capitalists, who then go on an 'investment strike'.

So Marx's theory of wages is essentially an *accumulation-of-capital theory of wages* which sends us back to what Marx considered the first 'law of motion' of the capitalist mode of production: the compulsion for the capitalists to step up constantly the rate of capital accumulation.

The Laws of Motion of the Capitalist Mode of Production

Marx's theory of surplus-value is his most revolutionary contribution to economic science, his discovery of the basic long-term 'laws of motion' (development trends) of the capitalist mode of production constitutes undoubtedly his most impressive scientific achievement. No other 19th-century author has been able to foresee in such a coherent way how capitalism would function, would develop and would transform the world, as did Karl Marx. Many of the most distinguished contemporary economists, starting with Wassily Leontief (1938), and Joseph Schumpeter, (1942) have recognized this.

While some of these 'laws of motion' have obviously created much controversy, we shall nevertheless list them in logical order, rather than according to the degree of consensus they command.

(a) *The capitalist's compulsion to accumulate.* Capital appears in the form of accumulated money, thrown into circulation in order to increase in value. No owner of money capital will engage in business in order to recoup exactly the sum initially invested, and nothing more than that. By definition, the search for profit is at the basis of all economic operations by owners of capital.

Profit (surplus-value, accretion of value) can originate outside the sphere of production in a precapitalist society. It represents then essentially a *transfer of value* (so-called primitive accumulation of capital); but under the capitalist mode of production, in which capital has penetrated the sphere of production and dominates it, surplus-value is currently produced by wage labour. It represents a constant increase in value.

Capital can only appear in the form of many capitals, given its very historical- social origin in private property (appropriation) of the means of production. 'Many capitals' imply unavoidable competition. Competition in a capitalist mode of production is competition for selling commodities in an anonymous market. While surplus-value is produced in the process of production, it is *realized* in the process of circulation, i.e. through the sale of the commodities. The capitalist wants to sell at maximum profit. In practice, he will be satisfied if he gets the average profit, which is a percentage really existing in his consciousness (e.g. Mr. Charles Wilson, the then head of the US automobile firm General Motors, stated before a Congressional enquiry: we used to fix the expected sales price of our cars by adding 15% to production costs). But he can never be sure of this. He cannot even be sure that all the commodities produced will find a buyer.

Given these uncertainties, he has to strive constantly to get the better of his competitors. This can only occur through operating with more capital. This means that at least part of the surplus-value produced will not be unproductively consumed by the capitalists and their hangers-on through luxury consumption, but will be accumulated, added to the previously existing capital.

The inner logic of capitalism is therefore not only to 'work for profit', but also to 'work for capital accumulation'. 'Accumulate, accumulate; that is Moses and the Prophets', states Marx in *Capital,* Vol. I (Marx, *e*, p. 742). Capitalists are *compelled* to act in that way as a result of competition. It is competition which basically fuels this terrifying snowball logic: initial value of capital → accretion of value (surplus- value) → accretion of capital → more accretion of surplus-value → more accretion of capital etc. 'Without competition, the fire of growth would burn out' (Marx, *g*, p. 368).

(b) *The tendency towards constant technological revolutions.* In the capitalist mode of production, accumulation of capital is in the first place accumulation of productive capital, or capital invested to produce more and more commodities. Competition is therefore above all competition between productive capitals, i.e. 'many capitals' engaged in mining, manufacturing, transportation, agriculture, telecommunications. The main weapon in competition between capitalist firms is cutting

production costs. More advanced production techniques and more 'rational' labour organization are the main means to achieve that purpose. The basic tend of capital accumulation in the capitalist mode of production is therefore a trend towards more and more sophisticated machinery. Capitalist growth takes the dual form of higher and higher value of capital and of constant revolutions in the techniques of production, of constant technological progress.

(c) *The capitalists' unquenchable thirst for surplus-value extraction.* The compulsion for capital to grow, the irresistible urge for capital accumulation, realizes itself above all through a constant drive for the increase of the production of surplus- value. Capital accumulation is nothing but surplus-value capitalization, the transformation of part of the new surplus-value into additional capital. There is no other source of additional capital than additional surplus-value produced in the process of production.

Marx distinguishes two different forms of additional surplus-value production. *Absolute surplus-value* accretion occurs essentially through the extension of the work day. If the worker reproduces the equivalent of his wages in 4 hours a day, an extension of the work day from 10 to 12 hours will increase surplus-value from 6 to 8 hours. *Relative surplus-value* accretion occurs through an increase of the productivity of labour in the wage-goods sector of the economy. Such an increase in productivity implies that the equivalent of the value of an identical basket of goods and services consumed by the worker could be produced in 2 hours instead of 4 hours of labour. If the work day remains stable at 10 hours and real wages remain stable too, surplus-value will then increase from 6 to 8 hours.

While both processes occur throughout the history of the capitalist mode of production (viz. the contemporary pressure of employers in favour of overtime!), the first one was prevalent first, the second one became prevalent since the second half of the 19th century, first in Britain, France and Belgium, then in the USA and Germany, later in the other industrialized capitalist countries, and later still in the semi-industrialized ones. Marx calls this process the *real subsumption* (subordination) of *labour under capital* (Marx, *k*), for it represents not only an economic but also a physical subordination of the wage-earner under the machine. This physical subordination can only be realized through social control. The history of the capitalist mode of production is therefore also the history of successive forms of – tighter and tighter – control of capital over the workers inside the factories (Braverman 1974); and of attempts at realizing that tightening of control in society as a whole.

The increase in the production of relative surplus-value is the goal for which capitalism tends to periodically substitute machinery for labour, i.e. to expand the industrial reserve army of labour. Likewise, it is the main tool for maintaining a modicum of social equilibrium, for when productivity of labour strongly increases, above all in the wage-good producing sectors of the economy, real wages and profits (surplus-value) can both expand simultaneously. What were previously luxury goods can even become mass-produced wage goods.

(d) *The tendency towards growing concentration and centralization of capital.* The growth of the value of capital means that each successful capitalist firm will be operating with more and more capital. Marx calls this the tendency towards growing concentration of capital. But in the competitive process, there are victors and vanquished. The victors grow. The vanquished go bankrupt or are absorbed by the victors. This process Marx calls the centralization of capital. It results in a declining number of firms which survive in each of the key fields of production. Many small and medium-sized capitalists disappear as independent business men and women. They become in turn salary earners, employed by successful capitalist firms. Capitalism itself is the big 'expropriating' force, suppressing

private property of the means of production for many, in favour of private property for few.

(e) *The tendency for the 'organic composition of capital' to increase.* Productive capital has a double form. It appears in the form of *constant* capital: buildings, machinery, raw materials, energy. It appears in the form of *variable* capital: capital spent on wages of productive workers. Marx calls the part of capital used in buying labour power variable, because only that part produces additional value. In the process of production, the value of constant capital is simply maintained (transferred *in toto* or in part into the value of the finished product). Variable capital on the contrary is the unique source of 'added value'.

Marx postulates that the basic historic trend of capital accumulation is to increase investment in constant capital at a quicker pace than investment in variable capital; the relation between the two he calls the 'organic composition of capital'. This is both a technical/physical relation (a given production technique implies the use of a given number of productive wage earners, even if not in an absolutely mechanical way) and a value relation. The trend towards an increase in the 'organic composition of capital' is therefore a historical trend towards *basically labour-saving technological progress.*

This tendency has often been challenged by critics of Marx. Living in the age of semi-automation and 'robotism', it is hard to understand that challenge. The conceptual confusion on which this challenge is mostly based is an operation with the 'national wage bill', i.e. a confusion between wages in general and variable capital, which is only the wage bill of productive labour. A more correct index would be the part of the labour costs in total production costs in the manufacturing (and mining) sector. It is hard to deny that this proportion shows a downward secular trend.

(f) *The tendency of the rate of profit to decline.* For the workers, the basic relation they are concerned with is the rate of surplus-value, i.e. the division of 'value added' by them between wages and surplus-value. When this goes up, their exploitation (the unpaid labour they produce) obviously goes up. For the capitalists however, this relationship is not meaningful. They are concerned with the relation between surplus-value and the *totality* of capital invested, never mind whether in the form of machinery and raw materials or in the form of wages. This relation is the *rate of profit*. It is a function of two variables, the organic composition of capital and the rate of surplus-value. If the value of constant capital is represented by c, the value of variable capital (wages of productive workers) by v and surplus-value by s, the rate of profit will be $s/(c + v)$. This can be rewritten as

$$\frac{s/v}{(c+v)/(v)} + 1$$

with the two variables emerging ($(c + v)/(v)$ obviously reflects c).

Marx postulates that the increase in the rate of surplus value has definite limits, while the increase in the organic composition of capital has practically none (automation, robotism). There will therefore be a basic tendency for the rate of profit to decline.

This is however absolutely true only on a very long-term, i.e. essentially 'secular', basis. In other time-frameworks, the rate of profit can fluctuate under the influence of countervailing forces. Constant capital can be devalorized, through 'capital saving' technical process, and through economic crises (see below). The rate of surplus-value can be strongly increased in the short or medium term, although each strongly increase makes a further increase more difficult (Marx, *d*, pp. 335–6); and capital can flow to countries (e.g. 'Third World' ones) or branches (e.g. service sectors) where the organic composition of capital is significantly lower than in the previously industrialized ones, thereby raising the average rate of profit.

Finally, the increase in the mass of *surplus-value* – especially through the extension of wage labour in general, i.e. the total number of workers – offsets to a large extent the depressing

effects of moderate declines of the average rate of profit. Capitalism will not go out of business if the mass of surplus-value produced increases 'only' from £10 to £17 billion, while the total mass of capital has moved from 100 to 200 billion; and capital accumulation will not stop under these circumstances, nor necessarily slow down significantly. It would be sufficient to have the unproductively consumed part of surplus-value pass e.g. from £3 to £2 billion, to obtain a rate of capital accumulation of 15/200, i.e. 7.5%, even higher than the previous one of 7/100, in spite of a decline of the rate of profit from 10 to 8.5%.

(g) *The inevitability of class struggle under capitalism.* One of the most impressive projections by Marx was that of the inevitability of elementary class struggle under capitalism. Irrespective of the social global framework or of their own historical background, wage-earners will fight everywhere for higher real wages and a shorter work day. They will form elementary organizations for the collective instead of the individual sale of the commodity labour power, i.e. trade unions.

While at the moment Marx made that projection there were less than half a million organized workers in at the most half a dozen countries in the world, today trade unions encompass hundreds of millions of wage-earners spread around the globe. There is no country, however remote it might be, where the introduction of wage labour has not led to the appearance of workers' coalitions.

While elementary class struggle and elementary unionization of the working class are inevitable under capitalism, higher, especially political forms of class struggle, depend on a multitude of variables as to the rapidity with which they extend beyond smaller minorities of each 'national' working class and internationally. But there too the basic secular trend is clear. There were in 1900 innumerably more conscious socialists than in 1850, fighting not only for better wages but, to use Marx's words, for the abolition of wage labour (Marx, *i*) and organizing working class parties for that purpose. There are today many more than in 1900.

(h) *The tendency towards growing social polarization.* From two previously enumerated trends, the trend towards growing centralization of capital and the trend towards the growth of the mass of surplus-value, flows the trend towards growing social polarization under capitalism. The proportion of the active population represented by wage-labour in general, i.e. by the modern proletariat (which extends far beyond productive workers in and by themselves) increases. The proportion represented by self-employed (small, medium-sized and big capitalists, as well as independent peasants, handicraftsmen, tradespeople and 'free professions' working without wage-labour) decreases. In fact, in several capitalist countries, the first category has already passed the 90 per cent mark, while in Marx's time it was below 50 per cent everywhere but in Britain. In most industrialized (imperialist) countries, it has reached 80 – 85 per cent.

This does not mean that the petty entrepreneurs have tended to disappear. Ten or 15 – 20 per cent out of 30 million people, not to say out of 120 million, still represent a significant social layer. While many small businesses disappear, especially in times of economic depression, as a result of severe competition, they also are constantly created, especially in the interstices between big firms, and in new sectors where they play an exploratory role. Also, the overall social results of growing proletarization are not simultaneous with the economic process in and by itself. From the point of view of class consciousness, culture, political attitude, there can exist significant time-lags between the transformation of an independent farmer, grocer or doctor into a wage-earner, and his acceptance of socialism as an overall social solution for his own and society's ills. But again, the secular trend is towards *growing homogeneity,* less and less heterogeneity, of the mass of the wage-earning class, and not the other way around. It is sufficient to compare the differences in consumer patterns, attitudes towards unionization or voting habits between manual workers, bank employees and government functionaries in say 1900 and

today, to note that they have decreased and not increased.

(i) *The tendency towards growing objective socialization of labour.* Capitalism starts in the form of private production on a medium-sized scale for a limited number of largely unknown customers, on an uncontrollably wide market, i.e. under conditions of near complete fragmentation of social labour and anarchy of the economic process. But as a result of growing technological progress, tremendously increased concentration of capital, the conquest of wider and wider markets throughout the world, and the very nature of the labour organization inside large and even medium-sized capitalist factories, a powerful process of objective socialization of labour is simultaneously set in motion. This process constantly extends the sphere of economy in which not blind market laws by conscious decisions and even large-scale cooperation prevail.

This is true especially inside mammoth firms (inside multinational corporations, such 'planning' prevails far beyond the boundaries of nation-states, even the most powerful ones!) and inside large-scale factories; but it is also increasingly true for buyer/seller relations, in the first place on an inter-firm basis, between public authorities and firms, and more often than one thinks between traders and consumers too. In all these instances, the rule of the law of value becomes more and more remote, indirect and discontinuous. Planning prevails on a short and even medium- term basis.

Certainly, the economy still remains capitalist. The rule of the law of value imposes itself brutally through the outburst of economic crises. Wars and social crises are increasingly added to these economic crises to remind society that, under capitalism, this growing objective socialization of labour and production is indissolubly linked to private appropriation, i.e. to the profit motive as motor of economic growth. That linkage makes the system more and more crisis-ridden; but at the same time the growing socialization of labour and production creates the objective basis for a general socialization of the economy, i.e. represents the basis of the coming socialist order created by capitalism itself, within the framework of its own system.

(j) *The inevitability of economic crises under capitalism.* This is another of Marx's projections which has been strikingly confirmed by history. Marx ascertained that periodic crises of overproduction were unavoidable under capitalism. In fact, since the crisis of 1825, the first one occurring on the world market for industrial goods to use Marx's own formula, there have been twenty-one business cycles ending (or beginning, according to the method of analysis and measurement used) with twenty-one crises of overproduction. A twenty-second is appearing on the horizon as we are writing.

Capitalist economic crises are always crises of *overproduction of commodities (exchange values)*, as opposed to pre- and post-capitalist economic crises, which are essentially crises of *underproduction of use-values.* Under capitalist crises, *expanded reproduction* – economic growth – is brutally interrupted, not because too few commodities have been produced but, on the contrary, because a mountain of produced commodities finds no buyers. This unleashes a spiral movement of collapse of firms, firing of workers, contraction of sales (or orders) for raw materials and machinery, new redundancies, new contraction of sales of consumer goods etc. Through this *contracted reproduction*, prices (gold prices) collapse, production and income is reduced, capital loses value. At the end of the declining spiral, output (and stocks) have been reduced more than purchasing power. Then production can pick up again; and as the crisis has both increased the rate of surplus-value (through a decline of wages and a more 'rational' labour organization) and decreased the value of capital, the average rate of profit increases. This stimulates investment. Employment increases, value production and national income expand, and we enter a new cycle of economic revival, prosperity, overheating and the next crisis.

No amount of capitalists' (essentially large combines' and monopolies') 'self- regulation', no amount of government intervention, has been able to suppress this cyclical movement of capitalist production. Nor can they succeed in achieving that result. This cyclical movement is inextricably linked to production for profit and private property (competition), which imply periodic over-shooting (too little or too much investment and output), precisely because each firm's attempt at maximizing profit unavoidably leads to a lower rate of profit for the system as a whole. It is likewise linked to the separation of value production and value realization.

The only way to avoid crises of overproduction is to eliminate all basic sources of disequilibrium in the economy, including the disequilibrium between productive capacity and purchasing power of the 'final consumers'. This calls for elimination of generalized commodity production, of private property and of class exploitation, i.e. for the elimination of capitalism.

Marx's Theory of Crises

Marx did not write a systematic treatise on capitalist crises. His major comments on the subject are spread around his major economic writings, as well as his articles for the *New York Daily Tribune.* The longest treatment of the subject is in his *Theorien über den Mehrwert,* subpart on Ricardo (Marx, *h*, Part 2). Starting from these profound but unsystematic remarks, many interpretation of the 'Marxist theory or crisis' have been offered by economists who consider themselves Marxists. 'Monocausal' ones generally centre around 'disproportionality' (Bukharin, Hilferding, Otto Bauer) – anarchy of production as the key cause of crises – or 'underconsumption' – lack of purchasing power of the 'final consumers' as the cause of crises (Rosa Luxemburg, Sweezy). 'Non-monocausal' ones try to elaborate Marx's own *dictum* according to which *all* basic contradictions of the capitalist mode of production come into play in the process leading to a capitalist crisis (Grossman, Mandel).

The question of determining whether according to Marx, a crisis of overproduction is first of all a crisis of overproduction of commodities or a crisis of overproduction of capital is really meaningless in the framework of Marx's economic analysis. The mass of commodities is but one specific form of capital, commodity capital. Under capitalism, which is generalized commodity production, no overproduction is possible which is not simultaneously overproduction of commodities and overproduction of capital (over-accumulation).

Likewise, the question to know whether the crisis 'centres' on the sphere of production or the sphere of circulation is largely meaningless. The crisis is a disturbance (interruption) of the process of enlarged reproduction; and according to Marx, the process of reproduction is precisely a (contradictory) unity of production and circulation. For capitalists, both individually (as separate firms) and as the sum total of firms, it is irrelevant whether more surplus-value has actually been produced in the process of production, if that surplus-value cannot be totally realized in the process of circulation. Contrary to many economists, academic and Marxist alike, Marx explicitly rejected any Say-like illusion that production more or less automatically finds its own market.

It is correct that in the last analysis, capitalist crises of overproduction result from a downslide of the average rate of profit. But this does not represent a variant of the 'monocausal' explanation of crisis. It means that, under capitalism, the fluctuations of the average rate of profit are in a sense the seismograph of what happens in the system as a whole. So that formula just refers back to the sum-total of partially independent variables, whose interplay causes the fluctuations of the average rate of profit.

Capitalist growth is always disproportionate growth, i.e. growth with increasing disequilibrium, both between different departments of output (Marx basically distinguishes department I, producing means of production, and department II, producing means of consumption; other authors add a department III producing non-reproductive goods – luxury goods and arms – to that list), between different branches and between

production and final consumption. In fact, 'equilibrium' under capitalism is but a conceptual hypothesis practically never attained in real life, except as a border case. The above mentioned tendency of 'overshooting' is only an illustration of that more general phenomenon. So 'average' capital accumulation leads to overaccumulation which leads to the crisis and to a prolonged phenomenon of 'underinvestment' during the depression. Output is then consistently inferior to current demand, which spurs on capital accumulation, first to a 'normal' level and then to renewed overaccumulation, all the more so as each successive phase of economic revival starts with new machinery of a higher technological level (leading to a higher average productivity of labour, and to a bigger and bigger mountain of produced commodities. Indeed, the very duration of the business cycle (in average 7.5 years for the last 160 years) seemed for Marx determined by the 'moral' life-time of fixed capital, i.e. the duration of the reproduction cycle (in value terms, not in possible physical survival) of machinery.

The ups and downs of the rate of the profit during the business cycle do not reflect only the gyrations of the output/disposable income relation; or of the 'organic composition of capital'. They also express the varying correlation of forces between the major contending classes of bourgeois society, in the first place the short-term fluctuations of the rate of surplus-value reflecting major victories or defeats of the working class in trying to uplift or defend its standard of living and its working conditions. Technological progress and labour organization 'rationalizations' are capital's weapons for neutralizing the effects of these fluctuations on the average rate of profit and on the rate of capital accumulation.

In general, Marx rejected any idea that the working class (or the unions) 'cause' the crisis by 'excessive wage demands'. He would recognize that under conditions of overheating and 'full employment', real wages generally increase, but the rate of surplus-value can simultaneously increase too. It can, however, not increase in the same proportion as the organic composition of capital. Hence the decline of the average rate of profit. Hence the crisis.

But if real wages do not increase in time of boom, and as they unavoidably decrease in times of depression, the average level of wages during the cycle in its totality would be such as to cause even larger overproduction of wage goods, which would induce an even stronger collapse of investment at the height of the cycle, and in no way help to avoid the crisis.

Marx energetically rejected any idea that capitalist production, while it appears as 'production for production's sake', can really emancipate itself from dependence on 'final consumption' (as alleged e.g. by Tugan-Baranowsky). While capitalist technology implies indeed a more and more 'roundabout-way-of-production', and a relative shift of resources from department II to department I (that is what the 'growing organic composition of capital' really means, after all), it can never develop the productive capacity of department I without developing in the medium and long-term the productivity capacity of department II too, admittedly at a slower pace and in a lesser proportion. So any medium or long-term contraction of final consumption, or final consumers' purchasing power, increases instead of eliminates the causes of the crisis.

Marx visualized the business cycle as intimately intertwined with a *credit cycle,* which can acquire a *relative* autonomy in relation to what occurs in production properly speaking (Marx, *g*, pp. 570 – 73). An (over)expansion of credit can enable the capitalist system to sell temporarily more goods that the sum of real incomes created in current production plus past savings could buy. Likewise, credit (over) expansion can enable them to invest temporarily more capital than really accumulated surplus-value (plus depreciation allowances and recovered value of raw materials) would have enabled them to invest (the first part of the formula refers to net investments; the second to gross investment).

But all this is only true temporarily. In the longer run, debts must be paid; and they are not automatically paid through the results of expanded output

and income made possible by credit expansion. Hence the risk of a *krach,* of a credit or banking crisis, adding fuel to the mass of explosives which cause the crisis of overproduction.

Does Marx's theory of crisis imply a theory of an inevitable final collapse of capitalism through purely economic mechanisms? A controversy has raged around this issue, called the 'collapse' or 'breakdown' controversy. Marx's own remarks on the matter are supposed to be enigmatic. They are essentially contained in the famous chapter 32 of volume I of *Capital* entitled 'The historical tendency of capitalist accumulation', a section culminating in the battle cry: 'The expropriators are expropriated' (Marx, *e*, p. 929). But the relevant paragraphs of that chapter describe in a clearly non-enigmatic way, an interplay of 'objective' and 'subjective' transformations to bring about a downfall of capitalism, and not a purely economic process. They list among the causes of the overthrow of capitalism not only economic crisis and growing centralization of capital, but also the growth of exploitation of the workers and of their indignation and revolt in the face of that exploitation, as well as the growing level of skill, organization and unity of the working class. Beyond these general remarks, Marx, however, does not go.

Marx and Engels on the Economy of Post-Capitalist Societies

Marx was disinclined to comment at length about how a socialist or communist economy would operate. He thought such comments to be essentially speculative. Nevertheless, in his major works, especially the *Grundrisse* and *Das Kapital,* there are some sparse comments on the subject. Marx returns to them at greater length in two works he was to write in the final part of his life, his comments on the *Gotha Programme* of united German social-democracy (Marx, *j*), and the chapters on economics and socialism he wrote or collaborated with for Engels' *Anti-Dühring* (1878). Generally his comments, limited and sketchy as they are, can be summarized in the following points.

Socialism is an economic system based upon conscious planning of production by associated producers (nowhere does Marx say: by the state), made possible by the abolition of private property of the means of production. As soon as that private property is completely abolished, goods produced cease to be commodities. Value and exchange value disappear. Production becomes production for use, for the satisfaction of needs, determined by conscious choice (*ex ante* decisions) of the mass of the associated producers themselves. But overall economic organization in a postcapitalist society will pass through two stages.

In the first stage, generally called 'socialism', there will be relative scarcity of a number of consumer goods (and services), making it necessary to measure exactly distribution based on the actual labour inputs of each individual (Marx nowhere refers to different quantities and *qualities* of labour; Engels explicitly *rejects* the idea that an architect, because he has more skill, should consume more than a manual labourer). Likewise, there will still be the need to use incentives for getting people to work in general. This will be based upon strict equality of access for all trades and professions to consumption. But as human needs are unequal, that formal equality masks the survival of real inequality.

In a second phase, generally called 'communism', there will be plenty, i.e. output will reach a saturation point of needs covered by material goods. Under these circumstances, any form of precise measurement of consumption (distribution) will wither away. The principle of full needs satisfaction covering all different needs of *different* individuals will prevail. No incentive will be needed any more to induce people to work. 'Labour' will have transformed itself into meaningful many-fold activity, making possible all-round development of each individual's human personality. The division of labour between manual and intellectual labour, the separation of town and countryside, will wither away. Humankind will be organized into a free federation of producers' and consumers' communes.

Selected Works

There is still no complete edition of all of Marx's and Engels's writings. The standard German and Russian editions by the Moscow and East Berlin Institutes for Marxism-Leninism, generally referred to as *Marx-Engels-Werke* (MEW), do not include hundreds of pages printed elsewhere (e.g. Marx's *Enthüllungen zur Geschichte der Diplomatie im 18. Jahrhundert* [Revelations on the History of 18th- century Diplomacy]), and several thousand pages of manuscripts not yet printed at the time these editions were published. At present, a monumental edition called *Marx-Engels-Gesamtausgabe* (MEGA) has been started, again both in German and in Russian, by the same Institutes. It already encompasses many of the unpublished manuscripts referred to above, in the first place a previously unknown economic work which makes a bridge between the *Grundrisse* and vol. 1 of *Capital*, and which was written in the years 1861–3 (published under the title *Zur Kritik der Politischen Oekonomie – Contribution to a Critique of Political Economy 1861–1863* in MEGA II/3/1–6, Berlin Dietz Verlag, 1976–1982). Whether it will include all of Marx's and Engels's writings remains to be seen.

In English, key works by Marx and Engels have been systematically published by Progress Publishers, Moscow, and Lawrence & Wishart, London; but this undertaking is by no means an approximation of the *Marx-Engels-Werke* mentioned above. The quality of the translation is often poor. The translations of Marx's and Engels's writings published by Penguin Books in the *Marx Pelican Library* are quite superior to it. We therefore systematically refer to the latter edition whenever there is a choice. Marx's and Engels's books and pamphlets referred to in the present text are mostly in chronological order:

(Marx *a*) *Die Deutsche Ideologie* (1846), together with Friedrich Engels.

(Marx *b*) *Manifest der Kommunistischen Partei* (1848), written in collaboration with Friedrich Engels. In English: *Manifesto of the Communist Party,* in *Marx: The Revolutions of 1848,* Harmondsworth: Penguin Books, 1973.

(Marx c) Zur Kritik der Politischen Oekonomie (1858). In English: Contribution to the Critique of Political Economy, London: Lawrence & Wishart, 1970.

(Marx *d*) *Grundrisse der Kritik der Politischen Oekonomie* (written in 1858-1859, first published in 1939). English edition: *Foundations of a Critique of Political Economy,* Harmondsworth: Penguin Books, 1972.

(Marx *e*): *Das Kapital, Band I* (1867). In English: *Capital,* Vol. I, Harmondsworth: Penguin Books, 1976.

(Marx *f*) *Das Kapital, Band II,* published by Engels in 1885. In English: *Capital,* Vol. II, Harmondsworth: Penguin Books, 1978.

(Marx *g*) *Das Kapital, Band III,* published by Engels in 1894. In English: *Capital,* Vol. III, Harmondsworth: Penguin Books, 1981.

(Marx *h*) *Theorien über den Mehrwert*, published by Karl Kautsky 1905–10. In English: *Theories of Surplus Value,* Moscow: Progress Publishers, 1963.

(Marx *i*) *Lohn, Preis und Profit,* written in 1865. In English: *Wages, Price and Profits,* in *Marx-Engels Selected Works,* Vol. II, Moscow: Progress Publishers, 1969.

(Marx j) Kritik des Gothaer Programms, written in 1878 in collaboration with Engels. In English: Critique of the Gotha Programme, in Marx-Engels: The First International and After, Harmondsworth: Penguin Books, 1974.

(Marx *k*) *Resultate des unmittelbaren Produktionsprozesses* (unpublished section VII of Vol. I of *Capital*), first published in 1933. In English: *Results of the Immediate Process of Production, Appendix to Capital*, Vol. I, Harmondsworth: Penguin Books, 1976.

(Marx *l*) *Marx-Engels: Briefwechsel (Letters)*. There is no complete English edition of the letters. Some are included in the *Selected Works* in 3 vols, published by Progress Publishers, Moscow.

(Engels): *Anti-Dühring* (1878). The chapter on economy was written by Marx, who also read all the other parts and collaborated in their final draft. In English: *Anti-Dühring*, London: Lawrence & Wishart, 1955.

Bibliography

There are innumerable books and articles devoted to comments or elaborations on Marx's economic thought, or which criticize them. We list here those works we refer to in the above text, as well as those we consider the most important ones (based, needless to say, upon subjective judgement).

Baran, P.A. 1957. *The political economy of growth*. London: John Calder.

Baran, P.A., and P.M. Sweezy. 1966. *Monopoly capital*. New York/London: Monthly Review Press.

Böhm-Bawerk, E. von. 1896. *Zum Abschluss des Marxschen Systems*. English edn, *Karl Marx and the Close of this System*, including a reply by Rudolf Hilferding, *Böhm-Bawerk's Criticism of Karl Marx*, ed. P.M. Sweezy. New York: Augustus M. Kelley, 1949.

Bortkiewicz, L. von. 1907. *Zur Berichtigung der grundlegenden theoretischen Konstruktion von Marx im Dritten Band des 'Kapital'.* Trans. P.M. Sweezy as 'On the Correction of Marx's Fundamental Theoretical Construction in the Third Volume of *Capital'.* In Böhm-Bawerk (1949), 197–221.

Marx's Analysis of Capitalist Production

Duncan Foley and Gérard Duménil

Abstract

This article discusses Marx's analysis of capitalism, including the concepts of historical materialism, class society, exploitation, commodity, value, money, capital, labour-power, value of labour-power, surplus-value, constant and variable capital, commodity law of exchange, capitalist law of exchange, equalization of the profit rate, prices of production, absolute and relative surplus value, the circuit of capital, simple and expanded reproduction, capital accumulation, centralization and concentration of capital, technical change, reserve armies of labour, rent, interest, commercial and bank profit, the falling rate of profit, viable technical change, and cyclical crises.

Keywords

Absolute rent; Abstract labour time; Biased technical change; Business cycles; Capital accumulation; Capitalism; Capitalist law of exchange; Circulating and fixed capital; Circulation of capital; Class; Commercial, industrial and money-dealing capital; Commodity; Commodity law of exchange; Commodity money; Competition; Composition of capital; Concentration and centralization of capital; Constant and variable capital; Crises of overproduction; Differential rent; Division of labour; Exchange value and use value; Exploitation; Fictitious capital; Fixed capital; Historical materialism; Increasing returns; Industrial capital; Innovation; Iron law of wages; Labour power; Labour theory of value; Law of value; Marx's analysis of capitalist production; Marxian transformation problem; Money; Money-dealing capital; Monopoly; Organic composition of capital; Over-accumulation of capital; Population

Karl Marx's analysis of capitalist production is best understood in the context of his broad theory of human societies and their history, namely, *historical materialism.* This theory argues that, after passing through various stages in which societies are divided into classes and the exploitation of a majority of producers by a privileged minority prevails, humanity will finally eliminate classes and class domination by a revolutionary process conducted by the organized *proletariat* in capitalism. This revolutionary stand was based on a 'scientific' investigation of history in general and capitalism in particular, with a special emphasis on economics, always with a political perspective. Whether historical materialism has a scientific or ideological character obviously remains controversial between Marxists and non-Marxists: Marxist theory is considered a discredited doctrine of the past by non-Marxists, while Marxists consider mainstream social and economic thinking as a continuing apologetics of capitalism.

After an introductory section devoted to locating the capitalist mode of production as a particular epoch in human history, the main focus below is on Marx's analysis of capitalist production. There are two facets to the theory of capital in the strict sense: *surplus value* (exploitation), and *the circuit of capital* (its 'circulation'). These are introduced separately, and then gradually combined in the analysis of more complex phenomena. Finally, we consider three broad sets of basic mechanisms directly related to the hold of capital on the functioning of the economy: (1) competition, (2) accumulation, technological and distributional changes, and (3) crises and the business cycle. We do not consider other important aspects of Marx's thinking such as his analysis of class struggle, and his theory of the state. The interpretation of even very fundamental aspects of Marx's thought remains contested among Marxist scholars. The bibliography contains a selective list of works that represent some of these different perspectives.

The Capitalist Mode of Production

The historical materialist point of view starts from the observation that all human societies must produce in order to reproduce both individuals and society itself. Production in this general sense always involves the combination of human labour with previously produced means of production and the natural resources of the earth. With the emergence of settled agriculture a *surplus product* over and above what is necessary for reproduction becomes possible. In societies with a surplus product, class exploitation, an institutionalized form of inequality, arises. Societies divide into a small *exploiting class* which appropriates, controls, and distributes the surplus product created by the labour of a much larger *exploited class* of producers who receive on average only what is necessary for their reproduction. Marx and Engels distinguish two aspects of these *class societies.* The *forces of production* comprise the population, natural resources, and technology which make a surplus product possible; the *social* relations *of production* comprise the institutional framework (such as property relations) through which the exploiting class appropriates the surplus product. The forces and social relations of production together constitute a *mode of production.* For example, in the slave mode of production characteristic of ancient Greek and Roman civilizations, the institution of slavery sustained by military force and political power was the means through which slave-owners appropriated a surplus product created by the labour of slaves, who received a minimum

subsistence. In the feudal mode of production, the institutions of serfdom sustained by military force and religious and political power were the means through which the lords of the manor appropriated a fraction of the labour time of serfs, who also laboured in their own fields to feed and reproduce themselves (or the serf had to pay a rent in kind or, later, in money, in addition to various taxes). This is what *exploitation* means in Marx's thought: to live on the product of the labour of other people.

From the historical materialist point of view, capitalism is a class society in which the institutions of private property in the means of production and free wage labour are the means through which capitalists appropriate the *surplus value* created by workers producing commodities (or services), who receive wages. In feudalism, the exploitation of the serfs was transparent: the serfs worked a certain part of the week on their own plots for their own subsistence, and a certain part of the week on the lord's land to supply his consumption and armies. Marx's theory of capitalism demonstrates that, though the mechanism of capitalist exploitation through the social relation of wage labour based on the formal legal equality of workers and employers is less transparent, capitalists also appropriate the surplus labour time of the workers. Capitalism, therefore, defines a specific stage of the history of class societies. Capitalism's decentralized, highly competitive organization creates powerful incentives for the rapid development of the forces of production through population growth, technical innovation, and a widening division of labour, but it is unable to control the forces it has itself stimulated.

Marx and Engels expected that the capitalist working class (the *proletariat*), once it had a clear understanding of capitalist exploitation and reached a high degree of organization, would overthrow the social relations of capitalism in a revolution to establish a classless society based on social control of the large surplus product made possible by the forces of production developed by capitalism. A violent transition was required, the *dictatorship of the proletariat,* to attain socialism and finally communism, marking the end of the 'prehistory' of humanity. Marx developed this analysis in collaboration with Friedrich Engels in *The Communist Manifesto* (1848).

Marx's main work, *Capital,* is devoted to the analysis of capitalist production. The first volume was published, in 1867, while Marx (1818–83) was still alive. Volumes II and III were published later by Friedrich Engels, from extensive notebooks still in draft form at the time of Marx's death. In what follows, we refer to *Capital* by volumes and chapters; for example, 'III, 25' means Chapter 25 of Volume III. References and quotations can be found on Internet, for example in the *Marx/ Engels Library,* http://www.marxists.org/archive/marx/works, or in Marx (1976, 1978, 1981). We have put square brackets around our own interpolations in quotes; everything else comes from the source.

The Definition of Capital (I, 4)

Marx defines capital as *value* (to be defined below) participating in a dynamic process of self-expansion. A capitalist spends money to hire workers and buy means of production, and then sells the resulting output for enough money to cover his initial outlay and secure a profit (the form taken by 'surplus value'). In this process value appears in various forms: first under the form of money; then as the value of productive inputs (labour power, raw materials, machinery, and buildings); then as the value of the commodities produced; and finally as money value again after the produced commodities have been sold. This process of capital is pointless unless, as is normally the case when capitalists make a profit, the money realized in the sale of commodities is greater than the money initially spent to start the process. Capital is not value as such, but value in movement:

> If we pin down the specific forms of appearance assumed in turn by self-valorising value, in the course of its life, we reach the following elucidation: capital is money, capital is commodities. In truth, however, value is here the subject of a process in which, while constantly assuming the form in turn of money and commodities, it changes its own magnitude, throwing off surplus- value from itself considered as original value. (I, 4)

Two aspects of capital are present in this definition: (1) capital is expanding value; and (2) capital value changes its form. These two aspects of capital are also called the *process of self-expansion* (sometimes called *valorization*), and the *process of circulation of capital* (or circuit of capital). Marx means here that: (1) the capitalist invests a certain capital with the intent of making profits (expansion); (2) capital is invested in commodities and money, and constantly passes from one form to the other (for example, when an output is sold, value changes form from commodity to money).

The first two volumes of *Capital* treat the processes of *self-expansion* and *circulation* of capital separately (with a few exceptions); the third volume considers the combination of these two elements. Before entering into the analysis of capital, it is necessary, however, to introduce two other preliminary concepts, *commodity* and *money,* and the related concepts of *value* (at the centre of the definition of capital) and *price*, to which Marx devotes the first three chapters of Volume I, prior to the analysis of capital. In Volumes I and II, the three concepts are considered successively: commodity (including value), money (including price), and capital (valorization and circulation). (This outline is logical, not historical: historically commodities and money reach their full development only with the capitalist mode of production.) We will follow this outline in our exposition here.

Commodities, Value, Money, and Prices

Commodities and Value (I, 1)

A *product* is the result of human labour, working with produced means of production and the natural resources of the earth. Useful products become *commodities* when they are regularly exchanged rather than being consumed directly by their producers. 'Useful' must be taken in a very broad sense as something desired by someone, for whatever reason. A producer who exchanges his product receives social recognition for his own labour in the form of the other commodities he acquires. Marx denotes the labour time required for the production of a commodity under average conditions, as *socially necessary labour time.* As the outcome of a parcel of social labour time, the commodity has an *exchange value,* or more briefly a *value.* Thus, according to Marx (who here follows Adam Smith), a commodity has a dual character as: (1) *object of utility,* or equivalently a *use value,* and (2) an *exchange value,* or *value.* The value of the commodity is the sum of labour embodied in previously produced inputs, *dead labour*, and newly incorporated labour, *living labour.* Marx sometimes calls this definition the *law of value,* although he rarely uses the expression. Later economists often refer to this framework as the *labour theory of value.*

The dual character of the commodity is reflected on labour itself. The concrete quality of labour (weaving, computer-programming) corresponds to the use-value aspect of the commodity it produces. But all categories of social labour materialized in the production of commodities have in common the ability to produce exchange values and, as such, are defined as *abstract labour.* There is no a priori rule accounting for this process of abstraction. Exchange dissolves the specific character of concrete labours, and the repetition of exchange establishes their quantitative equivalence. If one category of concrete labour is not adequately compensated, its supply will decline, and its wage will rise. In a similar manner, it is exchange which establishes the normal degree of intensity, skill, and technical efficiency in production.

Abstracting from the capitalist character of production, commodities would 'normally' exchange in proportion to their values. For example, if the value of commodity A is twice that of commodity B, one unit of A will exchange for two of B. If the exchange ratio were only one B for one A, producers of A would switch to producing B; a shortage of A would ensue and the exchange value of A would rise. This is the *commodity law of exchange,* sometimes confused with the law of value. The distinction is important because the law of value is a fundamental characteristic of commodity production, whether commodities exchange in proportion to their values or not. (In competitive capitalist economies they typically do not, as we will see.)

Money and Prices (I, 3)

We begin with the definition of money, and its first function as *measure of value,* and introduce the other functions of money, and the concept of the *price form* of value.

The value of commodities cannot be expressed on the market directly in abstract labour time (which nobody can observe or measure). In the exchange of two commodities, such as linen for a coat, the value of one commodity is expressed in the body of the other (measured in units such as a length or weight) as its direct *equivalent.* With the repetition of exchange, some specific commodity, such as gold, will emerge as a *socially accepted general equivalent,* that is, as *money.* Thus for Marx the original function of money is as *measure of value.* In addition to its function as measure of value, money comes to serve as *medium of circulation* if purchases and sales are paid for directly, and as *means of payment* if payment is deferred. Value can be accumulated temporarily in money hoards. Another function of money is, therefore, as a *store of value* (though any durable, valuable commodity can serve as a store of value).

Prices are values as expressed in monetary units. They are *forms of value.*

When commodities exchange at prices proportional to their values, the price of a commodity expresses the socially necessary (abstract) labour time required for its production of this commodity, qualitatively and quantitatively in a straightforward manner. This is the framework of Volumes I and II. But the prices of commodities may deviate from their values, and we will later return to this issue. The State can establish a *standard of price* by defining a local currency unit such as the franc or dollar as a certain amount of gold or other money commodity. Valueless tokens, 'symbols or tokens of value' in Marx's words, such as paper currency, may also be circulated in place of commodity money:

> In the same way as the exchange-value of commodities is crystallised into gold money as a result of exchange, so gold money in circulation is sublimated into its own symbol, first in the shape of worn gold coin, then in the shape of subsidiary metal coin, and finally in the shape of worthless counters, scraps of paper, mere *tokens of value.* (Marx 1859, 2.B.2.c)

Money also takes the form of a stock of purchasing power in an account in a financial institution. In contemporary capitalism, there is no commodity money.

The Monetary Expression of Value and the Quantity of Money

Inherent in Marx's theory is the relation between abstract labour time and its price form in money terms. There is a quantitative aspect to this relation. The ratio – for example, dollars per hour of abstract socially necessary labour time – can be called the monetary expression of labour time, or the monetary expression of value.

The determination of this ratio, which is a way of looking at the general price level in an economy, is discussed by Marx in his critique of Ricardo's quantity of money theory of prices, under the assumption of the existence of a commodity money. Marx explains that the quantity of money required to circulate the mass of commodities produced in any period depends on the quantity of the commodities exchanged, their money prices, determined by their costs of production, and the velocity of money, the average number of transactions in which each unit of money participates in the period (an institutional characteristic). Money flows in and out of hoards (reserves) to accommodate the requirements of circulation. He interprets this principle as governing the quantity of money required for purchases and sales, in contrast to Ricardo's quantity of money theory of prices, which sees the prices of commodities adjusting to a given quantity of money. In Marx's theory the general level of prices is determined by the relative costs of production of the money commodity and other commodities when a commodity like gold is used as money. (The critique of Ricardo's theory is developed in Marx 1859, 2.C.)

The Theory of Surplus Value

The labour theory of value is the foundation of Marx's theory of exploitation, or surplus value.

When a produced commodity is purchased or sold no new value is created. If a commodity sells at a price proportional to its value, given the monetary expression of value, the buyer and seller exchange money and commodity representing equal values. If the commodity sells above or below its value, the value gained by one party is just offset by the value lost by the other.

Productive Labour-Power and Surplus-Value (I, 7–9)

Marx explains surplus value in relation to the purchase of the labour power of waged workers. The capability to work, denoted as *labour power*, is a commodity, with a use-value and a value. The *use value* of labour power is labour itself, because a capitalist buys labour power to obtain the right to use the labour of the worker. The *value* of labour power is the value equivalent of the purchasing power of the wage on the commodities the worker can buy. (We will discuss later Marx's view of the actual purchasing power of workers.)

Only 'productive workers', that is, workers involved directly in production within capitalist enterprises, produce new value in Marx's analysis, in contrast to 'unproductive workers', whose labour power is employed by capitalists to maximize their profit rate. If the value of the labour power of productive workers is less than the value they produce, capitalist production on average adds more value in the production of commodities than it expends in hiring workers. (One can, equivalently, say that the money wage must be smaller than the monetary expression of the labour time expended by the average worker.) Because capitalist production can produce a surplus over the subsistence of productive workers, typically the value of labour power is smaller than the value labour produces, and surplus value results.

Thus, labour power has a property not shared by other commodities. While the purchase and sale of a produced commodity can only redistribute a given value between buyer and seller, the capitalist's purchase and use of labour-power, in contrast, results in the creation of surplus-value. The capitalist buys labour-power at a wage reflecting the necessary labour time required by the production of the consumption basket of the worker, say, four hours a day, but on average the worker can work longer, say, eight hours. Thus, the capitalist can appropriate *surplus labour,* here four hours, in the form of surplus value. (If the monetary expression of labour time is ten dollars per hour, the surplus value created by an average worker in a day under these assumptions would be 40 dollars.) Under the wage system, once a capitalist has paid a worker the agreed wage, the product of the worker's labour and its value belong to the capitalist. The production of surplus value is thus compatible with transactions at prices proportional to values, including the purchase of labour power at a wage proportional to the value of productive labour power. Marx argues that capitalist exploitation does not violate the commodity law of exchange, that is, it would take place even if all commodities exchanged at prices proportional to their values.

The actual appearance of labour power available for hire historically depends on two preconditions. First, workers must be legally free to sell their labour power. This explains the historic hostility of capitalism to bound forms of labour such as serfdom and slavery. Second, workers cannot have access to their own means of production, such as the feudal commons, so that they have no choice but to sell their labour power to the owner of means of production to live. This explains the historic support of capitalism for the enclosure of common lands and their conversion into private property. Marx devotes the last part of Volume I to *primitive accumulation,* the actual historical process through which the capitalist mode of production came into being. There he shows how, in the first steps of accumulation in England, the availability of labour power was achieved by way of straightforward social violence. The *enclosure* of common lands deprived the rural population of its old conditions of reproduction, and subjected it to the dependency on capital. It is important to keep such mechanisms in mind in the investigation of the historical dynamics of capitalism. Marx emphasizes the crucial historical importance of the transformation of produced means of production and labour,

which are universal aspects of human production, into the specific commodity forms of capital, including labour power.

The value of the produced inputs the capitalist purchases to undertake production is recovered in the sales price unchanged, so that Marx calls it *constant capital*, denoted by the symbol *c*. The value of the labour power the capitalist buys as an input to production, on the other hand, is recovered in the sales price expanded by the addition of the surplus value, so that Marx calls it *variable capital*, denoted by the symbol *v*. The sum of constant capital, *c*, variable capital, *v*, and surplus value, *s*, is the total value of the product. The sum $c + v$ is the total cost of the commodity. The sum $v + s$ is the *living labour,* as opposed to *dead labour, c,* and measures the *value added* by the production process. The *rate of surplus value, s*/*v*, is the ratio of *unpaid* to *paid* labour time, so that Marx also calls it the *rate of exploitation.* The ratio *c*/*v*, which measures the ratio of dead to living labour in the cost of the commodity, is the *value composition* of capital.

This decomposition of the value of a commodity is parallel to the income statement of a capitalist firm, which exhibits *profit* (Marx's surplus-value, *s*) as the difference between sales price (Marx's value of the commodity, $c + v + s$), and the cost of the means of production and wages required to produce the commodity (Marx's $c + v$).

Absolute and Relative Surplus Value, Manufacture and Industry (I, 12–16)

Identifying surplus value as surplus labour time does not tell what determines its magnitude and variation. Many natural, social and political conditions are involved, and vary historically. Labour performed by members of the family at home, women in particular, crucially affects the level of exploitation compatible with the reproduction of the workers and their families. In his analysis of surplus value in Volume I, Marx introduces important developments concerning the historical transformation of technology and organization.

Surplus value can be increased in two analytically distinct ways (which can be combined in real production): first, by lengthening the duration of labour time without increasing the value of labour power, *absolute surplus value*; second, by diminishing the value of labour power by cheapening worker's consumption through productivity gains holding the duration of labour time constant, *relative surplus value.* In Marx's view relative surplus value is the origin of the most important developments in the historical transformation of the organization of labour and technology by capitalism.

Marx sees distinct periods in which this transformation of production took different forms. In 'manufacture', a large number of individual workers, each processing his or her own means of production, are brought together in one location primarily for the purpose of increasing the capitalist's surveillance and control of production (which Marx describes as the 'formal subsumption' of labour to capital). In 'large-scale industry', the capitalist takes the further step of imposing a detailed division of labour on the production process, transforming the workers' relation to the production process (which Marx describes as the 'real subsumption of labour to capital'). Both technology and organization enter into these transformations. In manufacture, workers originally worked with the same tools they previously used in production at home; in large-scale industry, by contrast, capital has completely transformed technology and the organization of labour.

We will return to Marx's theory of technical change in capitalism in the discussion of the falling rate of profit.

The Circulation of Capital

As defined earlier, capital is self-expanding value moving through various forms (money, commodity…). We now turn to the analysis of the circulation of capital. The emphasis is on the motion from one form to the other, and the coexistence of the various fractions of capital under the three forms at a given point in time.

The Circuit of Capital (II, 1–4)

A capitalist spends money to buy inputs (means of production and labour power); organizes

production; stockpiles and sells the resulting product; and realizes a certain amount of money in sales revenue, normally larger than the original capital outlay. Each atom of capital goes through the various *forms:* money-capital, M, commodity capital in the form of inputs to production, C, *productive capital, P,* the value of partially finished commodities and plant and equipment in the workshop, and again commodity capital in the form of inventories of commodities awaiting sale, C', and finally returning to money through the sale of the produced commodities, M'. Marx represents this sequence in a diagram of the *circuit of capital*:

$$M — C \ldots P \ldots C' — M'$$

Here M is the money the capitalist uses to buy inputs to production C, P represents the actual production process, and C' are the produced commodities which are sold for money M'. The dashes represent purchase and sale of commodities on the market. The circuit is a chain, which can be viewed as beginning in M, C, or P, the *circuits of money, commodity,* and *productive capital,* three distinct formula of the same circuit.

The speeds at which the values of the various components of capital go through the productive form of capital, P, can be quite different. The value of some components, like raw materials, returns quickly to the money form in the sale of the commodity, while others like the value of buildings and machinery (whose value is only transferred to the product along their service life) returns only after a long period of time. From these differences in turnover time follows the distinction between *circulating* and *fixed capital*.

Capital is also a stock of value at any point in time. All the circuits overlap simultaneously: at the same moment new means of production and labour-power are being purchased while production is going on and finished output is being sold. The capital of a capitalist is the total value, tied up at any moment in these circuits. The total capital, K, is divided into three component stocks: *money capital, M, commodity capital, C,* and *productive capital, P.* The sum $K = M + C + P$ parallels the total of the assets on the capitalist's balance sheet.

Industrial, Commercial and Money-Dealing Capital (III, 16; III, 19)

Industrial capital undergoes the complete circuit of capital as above, taking on the forms M, C, and P in turn. Some capitals, however, are specialized to limited segments of the circuit. The first is *commercial capital*, which buys finished commodities from industrial capitalists to sell them to final purchasers, in the reduced circuit M—C—M': commercial capitalists buy in order to sell the same commodity. The second category, *money-dealing capital*, refers to the technical activity of banks in handling money payments into and out of accounts (and the exchange of currencies). Since no productive labour is expanded in these circuits, no surplus value is created. How industries engaged in such activities can make profits is part of the theory of competition considered below.

Marx's Schemes of Reproduction (II, 18–21)

Although Volume II of *Capital* is devoted to the circulation of capital, the analysis of the *schemes of reproduction,* combines valorization (c, v, s) and circulation (M, C and P).

Three departments are distinguished which produce the physical commodities to satisfy the demand emanating from c, v, and s: Department I produces means of production, Department II commodities consumed by workers, and Department III commodities consumed by capitalists. If all of the surplus value is consumed, no accumulation takes place, and the size of the capitalist economy remains unchanged, the case of *simple reproduction.* If a fraction of the surplus value is accumulated, the corresponding purchasing power is spent on additional means of production, and the capitalist economy expands, the case of *expanded reproduction.*

Marx assumes that all capital in the three industries accomplishes exactly one circuit: at the beginning and at the end of the period, all capital is assumed to be under the form C (the stocks of means of production and worker and capitalist consumption goods waiting to be sold). In this

setting reproduction requires certain proportionalities to hold: for example, in simple reproduction the value added of Department I must equal the constant capital of Departments II and III.

In this framework, Marx considers two types of issues. The first issue is the definition of output and its relation to income. The *net product* is the value of the final product, C', minus the value of what is now denoted as intermediate inputs, either produced in the previous period, in C, or during the present period but purchased as inputs by firms. Marx shows that the value of this net product is equal to total income or *value added*, as in contemporary national accounting, the sum of wages and surplus value (including rent, interest and profit as we will see): $v + s$. Second, Marx investigates the circulation of money. He attempts to demonstrate how the money thrown into circulation by capitalists returns as sales revenue, taking into account the activities of a sector producing the money commodity if such a money commodity exists.

The Functions of the Capitalist and Their Delegation to Employees (II, 6)

Being a capitalist is not a sinecure: both the appropriation of surplus value and the circuit of capital require active attention. In contemporary language: enterprises must be managed. Marx refers to these tasks as 'capitalist functions', in particular commercial transactions:

> The transformations of the forms of capital from commodities into money and from money into commodities are at the same time transactions of the capitalist, acts of purchase and sale. The time in which these transformations of forms take place constitutes subjectively, from the standpoint of the capitalist, the time of purchase and sale; . . . the time in which the capitalist buys and sells and scours the market is a necessary part of the time in which he functions as a capitalist, i.e., as personified capital. It is a part of his business hours. (II, 6)

The tasks considered are variegated, from the overseeing of labour in the workshop to the acceleration of the circuit of capital (as in the market activities mentioned above). All these tasks are unproductive, though they are useful. Their purpose is the *maximizing of the profit rate* of the capitalist. (The profit rate is defined below in the treatment of competition.)

The capitalist delegates some of these unproductive tasks to employees. They require means of production as well as labour power, like industrial capitalist production, though they produce no value. The wage and capital costs of these unproductive activities are a deduction from the surplus value. Marx denotes them as 'costs', in particular *costs of circulation* (the control and acceleration of the circuit of capital). As a consequence Marx categorizes some wage labour employed in capitalist production as unproductive, as in, for example, the case of overseers and employees in trade.

The Distribution of Surplus Value as Income

In Volume III, surplus value in its relation to both self-expansion and circulation is renamed *profit*. Profit is a form of surplus value. Once extracted, surplus value is at the origin of various categories of incomes, which appear as deductions from profit. The payment of such incomes to agents who employ no labour is thus consistent with the labour theories of value and surplus value. These channels of distribution of surplus value correspond to specific fractions of ruling classes in capitalism, such as active capitalists (entrepreneurs), money capitalists and landowners.

Interest and Profit of Enterprise. Interest-Bearing Capital (III, 21–3)

Some capitalists do not engage directly in capitalist production, but put their capital at the disposal of another functioning industrial capitalist, the *active capitalist* (or *entrepreneur*). This transaction may take the form of a loan in exchange for a share of the surplus value as *interest*, or the purchase of shares of stock in the firm which pays *dividends*. Marx treats both cases as *interest-bearing capital*, and this category of capitalists as *money capitalists* (sometimes referred to as 'financial capitalists'). Marx explains interest as a portion of the surplus-value realized by active capitalists. The profit remaining after the active capitalist has paid dividends and interest is *profit*

of enterprise. The existence of a developed loan market with a uniform rate of interest (for each maturity and risk of the loan) leads active capitalists to regard their own capital as loan capital, and to impute interest on it as an opportunity cost. Thus profit of enterprise appears as a kind of wage to the entrepreneurial activities of the active capitalist.

Rent (III, 38, 45)

Owners of scarce natural resources ('land' in the terminology of the classical political economists) also receive incomes in deduction from profits, in the form of rents. Due to their monopoly ownership of specific pieces of land, landowners can bargain with individual capitalists for a share of the surplus-value as rent (or royalties in other instances). How rents are quantitatively determined can only be examined in relation of the theory of competition.

Finance

Banking Capital and Money Capitalists (II, 19; III, 29)

The tasks of money-dealing capital are performed by banks. This represents their first source of income.

Banks also concentrate and use available masses of capital. One source of funds for banks is the idle balances of money in the economy, which are deposited in bank accounts. Thus, the money capital of enterprises is pooled within banks together with the balances of money held by other agents, such as households. While individual balances fluctuate, the aggregate pools are much more stable. A second source of funds is the capital of money capitalists (interest-bearing capital, including stock shares), who, instead of dealing directly with entrepreneurs, use banks as intermediaries. (Marx is aware of the capability of banks to 'create' money, but his view of banking mechanisms remains dominated by intermediation.) The theory of banking capital unites these two facets of the theory of capital: money-dealing capital and the handling of the capital of money capitalists.

Besides the management of accounts, the main function of banks is to make these funds available to agents seeking financing. Banks actually become the 'administrators' of the capital of money capitalists, and 'confront' capital as used by enterprises:

> Borrowing and lending money becomes their [banks'] particular business. They act as middlemen between the actual lender and the borrower of money capital. Generally speaking, this aspect of the banking business consists of concentrating large amounts of the loanable money capital in the bankers' hands, so that, in place of the individual money-lender, the bankers confront the industrial capitalists and commercial capitalists as representatives of all money-lenders. They become the general managers of money capital. On the other hand by borrowing for the entire world of commerce, they concentrate all the borrowers vis-à-vis all the lenders. A bank represents a centralisation of money capital of the lenders, on the one hand, and, on the other, a centralisation of the borrowers. (III, 25)

It is in these pages of Volume III of *Capital* that Marx analyses the issuance of paper currency by private banks and the Bank of England.

Fictitious Capital and Financial Instability (III, 25)

Marx's original definition of capital, as value in a movement of self-expansion, does not apply to securities like Treasury bills, or even to the stock shares of corporations. To refer to these securities, Marx uses the phrase *fictitious capital.* A public bond is in no way 'fictitious' for its holder, but it has no counterpart in the *M*, *C* and *P* of the circuit of capital. Once bonds or equities have been sold by a capitalist firm and are being traded on a secondary market, their values are also fictitious. The emergence of a market interest rate leads to the phenomenon of the *capitalization* of income flows such as the interest on government debt and dividends on equity: the market, where expectations concerning the future of these flows are taken into account, assigns a principal value to any flow of income. Thus, the accumulation of capital is paralleled in capitalism by that of such fictitious capital. Marx sees this capitalization of revenue flows as a source of instability.

The Institutional Framework of Modern Capitalism (III, 21–3)

As noted earlier, with the development of capitalism, the functions of the active capitalist are gradually delegated to managers and employees. This configuration, in which funding is provided by money capitalists with banks acting as intermediary, and the bulk of capitalist functions is delegated to a salaried personnel is that of modern capitalism:

> But since, on the one hand, the mere owner of capital, the money capitalist, has to face the functioning capitalist, while money capital itself assumes a social character with the advance of credit, being concentrated in banks and loaned out by them instead of its original owners, and since, on the other hand, the mere manager who has no title whatever to the capital, whether through borrowing it or otherwise, performs all the real functions pertaining to the functioning capitalist as such, only the functionary remains and the capitalist disappears as superfluous from the production process. (III, 23)

The Trinity Formula of Capital and Classes in Capitalism (III, 48; III, 52)

A major objective of *Capital* is to establish surplus value as the source of all incomes in capitalist society except wages. But capitalist practice hides this origin of capitalist incomes in what Marx calls the 'trinity formula':

> Capital—profit (profit of enterprise plus interest), land—ground-rent, labour—wages, this is the trinity formula which comprises all the secrets of the social production process. (III, 48)

Actually, this configuration is again altered in what we called above the institutions of modern capitalism:

> Furthermore, since as previously demonstrated interest appears as the specific characteristic product of capital and profit of enterprise on the contrary appears as wages independent of capital, the above trinity formula reduces itself more specifically to the following: Capital—*interest, land—ground-rent, labour—wages*, where profit, the specific characteristic form of surplus-value belonging to the capitalist mode of production, is fortunately eliminated. (III, 48)

To Marx, this trinity formula is 'irrational', because it confuses the source of incomes in the distribution of surplus-value with the role of necessary inputs in the production of use-values.

Volume III of *Capital* stops on a single-page chapter (obviously incomplete), entitled 'Classes'. There Marx establishes a straightforward relationship between his analysis of incomes and the fundamental class pattern of capitalism:

> The owners merely of labour-power, owners of capital, and land-owners, whose respective sources of income are wages, profit and ground-rent, in other words, wage-labourers, capitalists and land-owners, constitute the three big classes of modern society based upon the capitalist mode of production. (III, 52)

To this one could add fractions of capitalist classes corresponding to the various circuits of capital and the division of surplus value as above: (1) industrial capitalists, commercial capitalists, bankers, and (2) entrepreneurs (active capitalists) and money capitalists.

The Distribution of Surplus Value Through Competition

The analysis of capitalist production we have summarized so far, based on the idea that surplus value (and hence capitalist profit) arises from the exploitation of productive labour, runs counter to the apparent linkage of profit to the value of capital invested, regardless of the amount of labour it employs, or indeed whether or not that labour produces commodities at all. Marx offers a systematic account of the way in which competition among capitals gives rise to this linkage of profit with total capital invested by redistributing the surplus value created by productive labour.

Prices and the Collective Character of Exploitation (III, 9)

Because prices are not necessarily proportional to values, surplus value is not necessarily realized by the capitalists who hired the labour-power that created it. Exploitation is thus a 'collective'

mechanism for the capitalist class. It is as if surplus labour was collected in a single pool, and then distributed among capitalists in proportion to their invested capital (though the division of the surplus value among the individual capitals is actually the result of a fierce competitive struggle):

> Thus, although in selling their commodities the capitalists of the various spheres of production recover the value of the capital consumed in their production, they do not secure the surplus-value, and consequently the profit, created in their own sphere by the production of these commodities. What they secure is only as much surplus-value, and hence profit, as falls, when uniformly distributed, to the share of every aliquot part of the total social capital from the total social surplus-value, or profit, produced in a given time by the social capital in all spheres of production. . . . So far as profits are concerned, the various capitalists are just so many [100] stockholders in a stock company in which the shares of profit are uniformly divided per 100, so that profits differ in the case of the individual capitalists only in accordance with the amount of capital invested by each in the aggregate enterprise, i.e., according to his investment in social production as a whole, according to the number of his shares. (III, 9)

It is, consequently, necessary to distinguish between the mechanisms which govern the overall *appropriation* of surplus-value and its *realization* by particular capitalists:

1. The total surplus value depends on the value of labour power and the total number of workers capitalists employ.
2. Any system of commodity prices 'distributes' this total surplus value to individual producers (and landowners).

Marx describes this process of redistribution of surplus value as a 'metabolism' of value. Note that prices remain 'forms of value', as stated in the analysis of money and prices, but the hours of social abstract labour are reshuffled. At issue is no longer the labour actually expended to produce each commodity individually, but value as socially 'distributed' by prices (purchasing power as a fraction of social value 'conveyed' by the price of each commodity).

The Transformation Problem (III, 9)

At the beginning of Volume III, Marx pursues two objectives simultaneously. On the one hand, he analyses the basic mechanisms of competition in capitalism, in which the determination of a particular set of prices is implied, with equalized profit rates among industries, and, on the other hand, he uses this particular case to discuss the metabolism of value introduced above. This exposition obscures the fact that the underlying mechanism of exploitation operates whatever the prevailing system of prices; the theory of exploitation does not depend on the particular properties of commodity prices and, in particular, not on the attainment of a market equilibrium at which profit rates are equalized. The failure to separate the two projects, and to appreciate the restricted context of the discussion of the metabolism of value in this particular case, has created much confusion in the history of Marxist economic theory.

In the later literature the two problems, those of the metabolism of value and the prevalence of a particular set of prices in capitalist competition, are usually treated jointly as the *transformation problem.* Because of its importance in the history of Marxism, a specific entry is devoted to this controversial issue (see Marxian transformation problem).

The Classical Marxian Long-Period Equilibrium Prices of Production (III, 10)

The analysis of this process of redistribution of surplus value through competition marks an important break in the present account of Marx's analysis in *Capital.* Beginning with the definition of capital (and the corresponding requirement of the analysis of commodity and money, actually a preliminary to the exposition of capital), we first followed Marx in his investigation of the two components of the theory of capital: the extraction of surplus value and the circuit of capital. These two aspects were then combined in analyses such as the reproduction schemes or capitalist functions. Finally, attention turned to the division of surplus value: (1) its distribution as interest and dividends to money capitalists, and as rents to

landowners; (2) its realization by various categories of capitals, such as commercial capital and banking capital, in which no surplus value is produced; and (3), in the present section, its reallocation to capitalists of various industries independently of the extraction by individual capitalists, as in competition. We now enter a new category of developments, in which dynamic processes are involved: the mechanisms of competition, accumulation and employment, technical and distributional changes, and crises and the business cycle.

The basic idea in the analysis of capitalist competition is straightforward. If capital is free to move from one line of production to another in search of profit, the competitive movement of capitals will tend to move prices of specific commodities up or down until the rate of profit is equalized in all sectors. The *equalization of the rate of profit,* clearly stated by Adam Smith and David Ricardo, represents competition at the most fundamental level of analysis. The appropriation and realization of surplus value, as stated above, is thus specified quantitatively: one industry where little labour is used proportionally to total capital, in comparison to another industry, realizes more surplus value as profit than its workers actually contribute to the total surplus value (and conversely).

The *profit rate* is central in this analysis of competition. The profit rate is defined as the ratio of profit, s, to total capital, $K = M + C + P$, that is $r = s/K$. The ratio of the value of the average total capital invested during one unit of time (for example, a year) to the flow of value corresponding to the cost of production engaged during this unit of time, $T = K/(c + v)$, is the *turnover time* of capital measured in units of time such as months or years. In the Marxist literature, the turnover time is often implicitly or explicitly assumed to be unity, in which case the profit rate $r = s/K$ is equal to the *profit margin*, the ratio of profit to costs of production, $s/(c + v)$.

The movement of capital in the pursuit of profit results in a tendency toward the equalization of profit rates among industries. Marx calls commodity prices which are consistent with an equalized profit rate *prices of production:*

> But capital withdraws from a sphere with a low rate of profit and invades others, which yield a higher profit. Through this incessant outflow and influx, or, briefly, through its distribution among the various spheres, which depends on how the rate of profit falls here and rises there, it creates such a ratio of supply to demand that the average profit in the various spheres of production becomes the same, and values are, therefore, converted into prices of production. (III, 10)

Actual *market prices* tend to gravitate around prices of production, and this property defines the *capitalist law of exchange* (which supersedes the commodity law of exchange when production is organized by capital). As stated earlier, Marx calls the substitution of one law of exchange for the other a 'transformation', the *transformation of values* (actually prices proportional to individual values) *into prices of production.*

The Profit of Commercial and Money-Dealing Capital (III, 16; III, 19)

Although commercial and money-dealing capitals do not contribute to the extraction of surplus value, they do participate in its realization, along the lines indicated above, like any other capital. Commercial capital, for example, must secure a profit by buying commodities from industrial capitalists at prices below the prices at which those commodities will be sold to final purchasers. In this way commercial capital appropriates part of the surplus value actually created in the circuit of industrial capital. Similarly, the fees charged by money-dealing capital transfer surplus value created in the circuit of other capitals (abstracting from interest paid by other agents such as households or the state). Thus, the profit of commercial and money-dealing capital is part of the surplus value produced by labour employed by industrial capital.

Differential and Absolute Rent (III, 38; III, 45)

The level at which rents can be established is directly related to the level of the average and tendentially uniform profit rate in the overall economy. The condition for the cultivation of a land of lesser fertility or for a more intensive investment is that the marginal investment must yield the average profit rate. All capitalists

(including capitalist farmers) expect to realize the average profit rate prevailing throughout the economy. This condition is assured if landowners bargain for rents just high enough to assure capitalists the average rate of profit on their land. This defines *differential rent.* Marx also assumes that landowners as a class may withhold their lands until a minimum rent is paid, which defines *absolute rent.*

The Centralization and Concentration of Capital, Monopoly (I, 25)

The Classical–Marxian analysis, which assumes equalized profit rates among industries (not firms, because of differences in their productive efficiency), does not seem to match the features of competition in modern capitalism. Followers of Marx, from Hilferding and Lenin in the early 20th century to contemporary Marxist economics, point to the historical transformation of competition through the emergence of monopolies and oligopolies. The notion of the interplay of large firms is already part of Marx's analysis. In the process of accumulation the size of individual capitalist firms is altered by the *concentration* and *centralization* of capital. In Marx's account, concentration refers to the rise of the size of firms which parallels accumulation, while centralization denotes the outcome of merger or acquisition (and the process of competitive elimination of smaller and less efficient firms in an industry). Monopoly capital is not, however, part of Marx's analysis of capitalism, and Marx does not question the classical analysis of competition on such grounds. Rather than the view that the size of firms could hamper the process of equalization of profit rates among industries, Marx repeatedly asserts that credit mechanisms, including banks, are a crucial factor in the ability of capital to migrate among industries and, therefore, in the formation of prices of production.

Accumulation, and Technological and Distributional Change

The *accumulation of capital* refers to the situation where a fraction of surplus value is saved and devoted to increasing the value of capital. While the analysis of expanded reproduction considers a steady growth path of the economy (on which the key ratios, the rate of surplus value, the organic composition of capital, the value of labour power, and the composition of demand, are assumed to remain constant), Marx's theory of accumulation incorporates the qualitative change in capitalist production that actually accompanies its expansion.

Capital Accumulation and Employment (I, 25)

For accumulation to succeed, a number of conditions must be met. In particular, an expanded supply of labour power must be made available to permit the expansion of production, an issue which Marx addresses at the end of Volume I. Marx rejects the conclusions of classical economists such as Thomas Malthus, who proposed universal laws governing population growth and a 'natural' path of accumulation of capital, and blamed low wages on the fecundity of workers and the limits of natural resources. Marx argues that each mode of production evolves its own characteristic laws of population, and that capitalism in particular gives rise to a number of mechanisms that ensure a rough proportionality between population growth and the accumulation of capital.

How much labour is necessary to meet the demands of capital accumulation? How is the supply of labour roughly adapted to accumulation? Marx explains, in his *law of capitalist accumulation,* that the amount of labour required depends on (1) the pace of accumulation and (2) technical change as manifested in the variation of the composition of capital – that is, the ratio of capital outlays on means of production (*constant capital*) to capital outlays on wages (*variable capital*). If accumulation is rapid, and the composition of capital unaltered, the demand for labour power grows in proportion to accumulation and real wages tend to increase. This is the most favourable situation for workers. Technical change may moderate this tendency through an increase in the composition of capital, as the same accumulation requires less additional labour, and the demand for labour power grows

more slowly than capital as a whole. A priori, any relation between the pace of accumulation and the change in the composition of capital may occur. Marx points, however, to the fact that the composition of capital tends historically to rise and, thus, the pressure on employment is regularly relaxed.

Two mechanisms contribute to remedy any potential lack of available labour power. First, technical change leading to increases in the composition of capital makes some employed labour redundant. Second, recurrent crises periodically restore what Marx calls the *floating reserve army of labour,* with the decline of output.

Thus, the process of accumulation is uneven. Accumulation first proceeds during phases of more or less balanced growth; gradually the reserve army of unemployed workers is reabsorbed and wages rises. This is an inducement towards technical change increasing the composition of capital. If, however, the demand for labour grows too rapidly, a crisis occurs, the demand for labour is relaxed. Finally, a new wave of accumulation resumes after the crisis, during which a fraction of capital is devalued or destroyed. We will return below to these episodes in which a rise of wages provokes crises, which Marx calls situations of 'over-accumulation'.

In addition to this recurring fluctuation of unemployment, capitalism historically has drawn workers from the *latent reserve army*, through the destruction of traditional agricultural modes of production, and the consequent migration of displaced workers to the capitalist labour market. The potential competition of the latent reserve army puts a long-term downward pressure on wages as well.

The overall interaction of these factors is complex, because technical change and the income distribution cannot be treated as independent mechanisms. Marx considers that rising wages, and a correspondingly diminished rate of surplus value, increase the incentives for capitalists to seek labour-saving technical changes. This leads to a rise in the composition of capital, as more machinery is employed, precisely in order to avoid increased wage costs. This analysis must be supplemented by the consideration of fundamental political conditions, in particular, the strength of workers' class struggle, since Marx believed that, over and above the mechanisms involved in the law of capitalist accumulation, organized labour struggles could influence both wages and the length of the working day.

One of Marx's main goals in presenting his theory of accumulation, at the end of Volume I of *Capital,* is to show that the scarcity of labour power is not an absolute barrier to capital accumulation. The main thesis there is that, in the race between capital accumulation and the supply of labour power that governs the evolution of real wages, employment, and the rate of surplus value, capital has the edge over labour as a result of the capability of capital to substitute fixed capital (machinery) for labour:

> The same causes which develop the expansive power of capital, develop also the labour-power at its disposal. The relative mass of the industrial reserve army increases therefore with the potential energy of wealth. But the greater this reserve army in proportion to the active labour-army, the greater is the mass of a consolidated surplus-population, whose misery is in inverse ratio to its torment of labour. The more extensive, finally, the Lazarus-layers of the working-class, and the industrial reserve army, the greater is official pauperism. *This is the absolute general law of capitalist accumulation.* Like all other laws it is modified in its working by many circumstances, the analysis of which does not concern us here. (I, 25–4)

Besides the resistance of organized workers, this capability of capitalism to perpetuate an available reserve army by technical change is limited by the cost of the addition of capital which is required to displace labour, as Marx will contend in his analysis of technical change and the tendency for the profit rate to fall.

Technical Change (III, 13–15)

The social and technical conditions of production and their historical transformation are central to Marx's analysis of capitalist production. The term 'technology' is convenient but somewhat misleading. Marx always describes conditions of production in a perspective which combines technology in the strict sense and organization, that is, the institutional framework in which production is performed; the notion of social relations cannot be

neglected in this context. This is the case, for example, in the analysis of relative surplus value, as discussed earlier in reference to manufacture and large-scale industry.

Although Marx often discussed specific historical determinants of technical innovations, his main theory of technical change in capitalism sees it as an endogenous response to pressures from competitors and workers. Each capitalist has a strong motivation to find cost-reducing technical innovations (or profit-increasing product innovations) because the firm which first successfully exploits such innovations is in a position to capture higher-than-average profit rates ('super-profits') as a result of its temporary monopoly on the innovation. Innovating capitalists may also use their cost advantage aggressively to increase their market share. (In this respect Marx develops the theory of technical change Ricardo 1817, presents in his chapter on machinery.) Over time, competitors will find equivalent innovations and the advantage of the innovating capitalist will erode.

Capitalist technical innovation in Marx's framework begins with the discovery of a range of potential new productive techniques and forms of labour organization. The accumulated store of technical knowledge available to capitalist society at any moment is the result of this historical process of innovation: there is no set of predetermined techniques as is assumed in the neoclassical production function. Marx's theory of induced technical change is basically evolutionary. The capitalist evaluates the cost of these alternatives at prevailing prices and wages, and forms expectations concerning profit rates. Only those technologies that promise to reduce costs or increase profits at prevailing prices and wages are *viable* candidates for adoption. The criterion is an increased profit rate.

Marx emphasizes that, because capitalism places both strong incentives for technical change and the power to implement in the hands of competing capitalist firms, it is a *technically progressive* mode of production, in contrast to slavery and feudalism. In this respect Marx resembles Smith, who emphasizes increasing returns inherent in the division of labour, rather than Ricardo, who emphasizes diminishing returns due to limited natural resources (land).

The Tendency for the Profit Rate to Fall (III, 13–15)

In Volume III of *Capital,* Marx describes trajectories of technical and distributional changes that he denotes as *historical tendencies*. They are unbalanced (nonhomothetic) growth trajectories, which Marx considered typical of the dynamics of capitalism, which we will describe as *trajectories à la Marx.* Along such very long-term paths, the growth rates of capital, output, and employment gradually fall, labour productivity and the composition of capital rise, the share of wages in total income is constant or diminishing, and the profit rate declines. In the speaking of historical tendencies, 'historical' refers to a very long-term time frame; 'tendency' means that though accumulation in capitalism tends to follow such trajectories, the trajectory does not necessarily prevail due to the action of what Marx labels *counteracting factors.* It is in this framework that Marx defines the *tendential fall in the rate of profit.* This 'law' expresses sophisticated insights into the historical dynamics of capitalist economic growth. It is one of the major disputed issues in contemporary Marxist economics (along with the transformation problem).

In Volume III, the profit rate is written as a ratio of two flows or, equivalently, the turnover time of capital is assumed to be unity: $r = s/K = s/(c + v)$. Dividing by v, Marx obtains: $r = (s/v)/(c/v + 1)$. The numerator is the rate of surplus value, and the denominator is the *value composition of capital, the ratio of constant to variable capital,* plus 1. Marx calls this value composition the *organic composition* of capital. In this simple presentation, the conflicting impacts of the rate of exploitation and the organic composition of capital are clearly evident.

Although *labour productivity* does not appear in this formal setting, it is explicitly a key variable in Marx's analysis. Without altering the basic framework, it is possible to write: $r = (s/(v + s))/((c + v)/(v + s))$. Here, $s/(v + s)$ is the share of profit in total income, and $(c + v)/(v + s)$ is total capital per hour worked, which is another measure of the organic

M

composition of capital. (This ratio can also be read as the ratio of capital to output, since output is equal to total income, or equivalently the inverse of what is frequently loosely called 'capital productivity'.) The numerator, the share of profit, can be written $1 - (v/(v + s))$, that is, 1 minus the share of wages. The share of wages is equal to real wages divided by labour productivity. Thus, the profit rate can be expressed as the ratio of the profit share to the total capital per hour worked, which we call simply the *composition of capital*:

$$\text{profit rate} = \frac{1 - \dfrac{\text{real wage}}{\text{labor productivity}}}{\text{composition of capital}}$$

Marx's fundamental insight can be sketched as follows. To maintain or increase profits (which appear in the numerator of the profit rate), when there is no fall in the real wage, capitalists must increase the productivity of labour, which is the mechanism of relative surplus value. Marx contends, however, that this increase has a considerable cost for capitalists because increases in labour productivity typically require the investment of more capital per hour worked: productivity gains are realized by way of an increased mechanization of production. Thus, the composition of capital rises, and the rate of profit may fall. The actual evolution of the rate of profit also depends on what happens to the real wage and, consequently, to the rate of surplus value as labour productivity increases, which depends on labour market factors and class struggle, which are beyond the control of any individual capitalist.

Marx considers the case where the rate of surplus value remains constant to refute the argument that the falling profit rate is the result of an excessive growth in the cost of labour to the capitalists. When the productivity of labour rises, a constant rate of surplus value implies a rising real wage. Thus in making this argument, Marx does not assume a constant real wage. His thesis is rather that it is difficult for capitalists to counteract rising wages by technical change, since a more efficient technique in terms of labour productivity typically requires a rising composition of capital. The linchpin of Marx's thesis is, therefore, a hypothesis on the features of available techniques, that is, the profile of innovation: it is comparatively easy to find labour-saving devices if the cost of mechanization is not considered, but opportunities to reduce labour costs without inflating capital costs are rare.

Thus, on trajectories à la Marx the productivity of labour rises, while the productivity of capital (the inverse of the composition of capital) falls, a pattern of technical change sometimes called *Marx-biased*:

> The law of the falling rate of profit, which expresses the same, or even a higher, rate of surplus-value, states, in other words, that any quantity of the average social capital, say, a capital of 100, comprises an ever larger portion of means of production, and an ever smaller portion of living labour. Therefore, since the aggregate mass of living labour operating the means of production decreases in relation to the value of these means of production, it follows that the unpaid labour and the portion of value in which it is expressed must decline as compared to the value of the advanced total capital. ... The relative decrease of the variable and increase of the constant capital, however much both parts may grow in absolute magnitude, is, as we have said, but another expression for greater productivity of labour. (III, 13)

Though Marx never articulated the entire framework, this analysis of the biased pattern of technical change supplements the mechanisms at work in the law of capitalist accumulation. Accumulation recurrently pushes employment to the limits of the supply of labour power available and drives real wages upward. Technical change and recurrent crises allow for the partial relaxation of this pressure (as we have seen), but, in typical periods, the new techniques available are such that technical change can only partially offset the rise in real wages, and the profit rate falls. Accumulation is pursued in spite of the diminished profit rate, which will only be apparent after the fact, when a major crisis occurs.

The analysis Engels published from Marx's notes in Volume III of *Capital* is incomplete, and was not intended for publication in the form in which we read it. Consequently, it is not too surprising that Marx's analysis of the tendency for the profit rate to fall remains controversial among Marxists. A central issue is the assumption made concerning real wages, and its relationship to the

profitability criterion in the adoption of new techniques. Marx is clear that the innovating capitalist initially makes a surplus profit, while his competitors gradually adopt the new technique and prices fall through competition towards the prices of production corresponding to the new technology. Marx contends that the new uniform average profit rate tends to be lower than the original one. Nobuo Okishio (1972) has demonstrated that if the real wage remains unchanged during this process the new average profit rate can never fall. But along a trajectory à la Marx real wages do increase, as we have explained, although the possibility of a tendency for the rate of profit to fall is consistent with Marx's assumption that the rate of surplus value is constant or even rising.

The problem of the evolution of real wages, the value of labour power, and the rate of surplus value over time as labour productivity rises is controversial among Marxists, due to a change of Marx's view on this subject during his lifetime. Engels explained that Marx originally accepted the so-called *iron law of wages,* which assumes that real wages are constantly driven downward to a minimum compatible with the reproduction of the labour force, but later abandoned it. Marx sometimes refers to a 'socially and historically determined' cost of reproduction of labour power, as an external constraint on the evolution of the real wage. But this 'exogenous' variable is explicitly subject to a number of economic and social determinations: (i) class struggle impacts on wages and the duration of labour; and (ii) the outcome of struggles crucially depends on the conditions of accumulation and the population available to work (as in the law of accumulation). Marx's understanding of the determination of wages is similar to his view of technical change: the path of real wages is the result of the interaction of extra-economic factors with economic mechanisms such as accumulation and crises.

Crises and the Business Cycle (III, 15)

There is no systematic treatment of crises and of the business cycle in Marx's work, although the issue plays a prominent role in his analysis of capitalism. In early works, like the *Communist Manifesto,* even prior to Marx's serious study of political economy, the idea that crises will prove more violent with the evolution of capitalism is central. Recurrent crises became a feature of capitalism during the first half of the 19th century. This link between economic mechanisms and class struggle had a considerable impact on Marx's view of the historical dynamics of capitalism. Then, Marx became gradually better aware of the complexity of the phenomenon of crises, in particular the relationship between real and financial mechanisms and crises.

Partial Crises and Crises of General Overproduction

Before capitalism, poor crops and the devastation of war and disease were the major causes of disruptions of production. David Ricardo (1817) observed the existence of recurring crises more directly related to the nature of capitalism, which he called *states of distress.* These crises struck specific industries, like textiles. Consequently, Ricardo interpreted these situations as the effect of *disproportions*, that is, the outcome of the excessive accumulation of capital in one industry. Ricardo did not believe in the possibility of a general glut of the market. Marx devoted much energy to the refutation of Ricardo's interpretation. He contended that the existence of a delay between the sale of a commodity and the spending of its money price on another commodity invalidates 'Say's Law', the principle that the sale of a commodity constitutes a direct demand for another commodity. Monetary exchange thus implies the *possibility* of crises, because, by functioning as intermediary in exchanges, money allows for the interruption of the chain of exchanges. Only the 'possibility' of crises is, however, implied, not their actual mechanisms in capitalism.

Marx identified a new category of crises, *crises of general overproduction,* where all industries were simultaneously affected. Marx did not deny the existence of crises specific to particular industries, that he called *partial crises*, but contrasted the two types of situations, partial and general, and was specifically concerned with the latter.

The Ultimate Ground of Crisis. Profitability and Social Needs

Marx described general crises of overproduction as typical of capitalism. In capitalism, the purpose of production is not the satisfaction of the needs of the population, but the appropriation of profits. The 'ultimate ground' of crisis in capitalism is this disconnection between production and social needs:

> The ultimate reason [*ground*] for all real crises always remains the poverty and restricted consumption of the masses as opposed to the drive of capitalist production to develop the productive forces as though only the absolute consuming power of society constituted their limit. (III, 30)

This quotation is often misunderstood. Marx did not believe that higher wages would solve the problem of crises in capitalism. The cause of crises, proper to capitalism, is the recurrent inability to pursue production *at a certain rate of profit*. Therefore, profitability is always the crucial variable in Marx's explanation of crises:

> Over-production of capital is never anything more than overproduction of means of production – of means of labour and necessities of life – which may serve as capital, *i.e.,* may serve to exploit labour at a given degree of exploitation; . . . too many means of labour and necessities of life are produced at times to permit of their serving as means for the exploitation of labourers at a certain rate of profit. (III, 15–3)

The Business Cycle and Its Determinants

Marx described the fluctuating pattern of production in capitalism as 'the cycles in which modern industry moves – state of inactivity, mounting revival, prosperity, over-production, crisis, stagnation, state of inactivity, etc.' (III, 22).

Production is recurrently destabilized by mechanisms which affect the profitability of capital in the short run (a sudden decline rather than a steady downward trend). The first mechanism is *over-accumulation*. Periodically, employment gets closer to the limits of the population available to work (the reserve army is reabsorbed, as in the law of capitalist accumulation). Wages tend to rise, and profitability is diminished. A second mechanism is the rise of interest rates. During the phase of rapid accumulation, the mass of credits increases and, at a certain point, interest rates rise. Again, profitability is affected and the economy destabilized. Marx is well aware of the relationship between real and financial mechanism, and he interprets the direction of causation as reciprocal.

As stated above, Marx did not explain crises by the deficient level of wages (except in his very early work), and refuted this explanation in the manuscripts of Volume II:

> It is sheer tautology to say that crises are caused by the scarcity of effective consumption, or of effective consumers. The capitalist system does not know any other modes of consumption than effective ones, except that of *sub forma pauperis* or of the swindler. That commodities are unsalable means only that no effective purchasers have been found for them, i.e., consumers (since commodities are bought in the final analysis for productive or individual consumption). But if one were to attempt to give this tautology the semblance of a profounder justification by saying that the working-class receives too small a portion of its own product and the evil would be remedied as soon as it receives a larger share of it and its wages increase in consequence, one could only remark that crises are always prepared by precisely a period in which wages rise generally [over-accumulation] and the working-class actually gets a larger share of that part of the annual product which is intended for consumption. From the point of view of these advocates of sound and 'simple' (!) common sense, such a period should rather remove the crisis. (II, 20)

Structural Crises and the Falling Profit Rate

Since the profitability of capital is central in Marx analysis of crises, there is a link between the tendency for the profit rate to fall and crises. Marx's view is that actual phases of decline of the profit rate make crises more likely, more frequent and deeper. He points to the existence of periods of sustained instability, which, although Marx does not use the term, can be called *structural crises.* A declining and depressed profit rate (both the tendency and levels are at issue) disturbs capitalist accumulation:

> . . . in view of the fact that the rate at which the total capital is valorised, i.e. the rate of profit, is the spur to capitalist production . . ., a fall in this rate slows down the formation of new, independent capitals and thus appears as a threat to the development of the capitalist production process; it promotes overproduction, speculation and crises, and leads to the existence of excess capital alongside a surplus population. (III, 15)

This insight concerning the link between the profit rate and the occurrence of periods of

historical perturbation in the course of accumulation provides a powerful framework for understanding the real history of capitalist economies.

Abstract

The transformation problem relates the labour theory of value and the competitive equalization of the rate of profit. Marx distinguishes the production of surplus-value from its redistribution through prices. Critics claim that the labour theory of value is an unnecessary detour to the determination of prices because total value and surplus-value are not conserved. The Single-System Labour Theory of Value (SS-LTV) argues that at any prices (1) the price of the net product expresses the labour expended, and (2) total profits are the price form of surplus-value, because the value of labour-power is the labour time equivalent of the wage.

Marx's Framework: Value, Surplus-Value, Prices and Competition

Marx consistently distinguishes the notions of *value* and *price*, in contrast to contemporary economic language, which uses the term 'value' to refer to prices in a situation of general equilibrium, though the use of the term is rather flexible; for example 'value added' is actually the value of net product measured in price terms. For Marx, value is a 'social substance' manifested in economic relations in the 'form' of prices, though prices are not necessarily proportional to values, as we will see.

Value and Surplus-Value

We first recall Marx's basic concepts (see also Marx's analysis of capitalist production). Central to Marx's framework of analysis in *Capital* is the *labour theory of value* (LTV), which defines the value of a commodity as the 'socially necessary' labour time required by its production, that is, the labour time required by average available techniques of production for workers of average skill.

The LTV is central to Marx's theory of exploitation, a term he uses to describe a situation in which one individual or group lives on the product of the labour of others. According to the LTV, when commodities are exchanged through sale and purchase, no value is created. But this principle does not apply to capitalists' purchase of the *labour power* of workers. Workers sell their labour power, that is, their capability to work, to a firm, owned by a capitalist. The buyer uses this labour power in production to add value to the commodity produced. The *value of labour power* is the labour time required by the production of the commodities the worker buys. But the worker can typically work more hours than are on average required to produce this bundle of commodities. For example, the goods the worker can buy may require eight hours of labour per day, when the labour-day lasts 12 hours. The difference, four hours, is unpaid labour time. If an hour of social labour on average produces a value whose price form is \$10, four hours of unpaid labour time results in a surplus-value whose price form is \$40, which is appropriated by the capitalist. The *rate of surplus-value* is the ratio of unpaid to paid labour time, in this case 4/8, that is, 50 per cent.

Two Laws of Exchange

Marx situates his discussion in the context of the distinction made by Adam Smith and David Ricardo between 'market prices' and 'natural prices'. Market prices are the prices at which commodities actually exchange from day to day in the market. Smith and Ricardo, however, regarded market prices as fluctuating (or 'gravitating') around centres of attraction they called 'natural prices'. ('Gravitation' means that the economy is in a permanent situation of disequilibrium, though in a vicinity of equilibrium where natural prices would prevail.)

In the above analysis, Marx assumes that commodities tend to exchange at their values (at *prices proportional to values*), that is, in proportion to the labour time embodied in them. 'Tend' means here that deviations are obviously possible, but that such prices will 'regulate' the market, in the sense that if the prevailing set of prices systematically under-compensates the labour used in the production of a commodity, labour will move to the production of better-paid commodities. As a result, the supply of the under-compensated commodity will decline, and its price will rise. In reality prices would gravitate around values, which would play the role of natural prices in such an economy. This is the *commodity law of exchange*.

In a capitalist economy, however, capitalists buy not only the labour power of workers (which Marx denotes as *variable capital*), but also non-labour inputs, such as raw materials, and fixed capital, such as machinery (which Marx denotes as *constant capital*). If natural prices were proportional to labour inputs, as the commodity law of exchange posits, capitalists using more constant capital per worker than the average would realize smaller profit in comparison to their total capital advanced, that is, lower profit rates. Marx accepts the idea that competition tends to equalize profit rates in various industries, despite differences in capital advanced per worker, which is the *capitalist law of exchange*. Marx uses the term 'prices of production' to describe a system of prices which guarantee to the capitalists of various industries a uniform profit rate. Capitalists will invest more where profit rates are larger, and conversely in the symmetrical case. They move their capital from one industry to another seeking maximum profit rates, and this movement results in a gravitation of market prices around prices of production. Marx regards prices of production as the centres of gravitation of market prices, and thus the natural prices relevant to a competitive capitalist economy.

Is the Theory of Surplus-Value Compatible with the Theory of Competition?

The problem is posed of the compatibility of the capitalist law of exchange at prices of production with the theory of exploitation as extraction of surplus-value. Marx's line of argument is that surplus-value is *created* in production through the exploitation of labour, that is, in proportion to labour expended, but *realized* proportionally to total capital invested. According to Marx, this separation between the locus of extraction and the locus of realization does not contradict the theory of exploitation so that capitalist competition is compatible with his theory of exploitation through the appropriation of surplus-value from unpaid labour time.

To support this argument, Marx presents a pair of tables (1981, ch. 9) showing the redistribution of surplus-value through deviations of price from values proportional to embodied labour times. All variables are measured in hours of labour time, and as a result prices of production are expressed in the same unit. Because Marx's own calculations involve some extraneous complexity (differential turnover rates among sectors), it is more useful to consider the simplified case shown in Table 1. Two industries exist, each of which advances the same capital of 100, but divided in different proportions between the purchase of non-labour inputs (C) and labour inputs (V). All capital is used up during the period, so that the rate of profit is the ratio of surplus-value to total capital advanced, $r = s/(c + v)$. The rate of surplus-value is uniform and equal to 100 per cent. Consequently, surplus-values are equal to variable capitals. Surplus-values and values are computed in each industry. When prices are proportional to values, profit rates differ between the two sectors. Prices of production are determined in Marx's procedure by summing up all surplus-value, a total of 40, and redistributing it in proportion to total capital, that is 20 in each industry, to equalize profit rates on the capitals advanced.

The procedure illustrates a straightforward 'redistribution' of surplus-value. Clearly, the sum of prices, 240, is equal to the sum of values, and total surplus-value is, by construction, conserved in the form of profit. These observations are expressed in two *Marxian equations* concerning the entire economy:

$$\textit{Sum of values} = \textit{sum of prices of production}$$
$$\textit{Sum of surplus value} = \textit{sum of profits}$$

Note that these compact formulations are not rigorous, since values and surplus-value are measured in labour time and prices and profits in money. Thus, 'Sum of values' should read 'Sum of prices proportional to values'. A simple way out of the problem of units is to use one of these equations to define the general level of prices. For example, the sum of prices of production could be set equal to the number of hours corresponding to the sum of values. Then, Marx's line of argument implies that the surpluses in both sets of prices are equal, as in the second equation. This simple

Marxian Transformation Problem, Table 1 Marx's calculation of prices of production from values

Industry	Constant capitals, C	Variable capitals, V	Total capitals, $K = C + V$	Surplus-values, $S = V$	Values of commodities produced, $\Lambda = K + S$	Profits, Π	‹Prices of production› of commodities produced, $P = K + \Pi$
1	70	30	100	30	130	20	120
2	90	10	100	10	110	20	120
Total economy	160	40	200	40	240	40	240

calculation illustrates the idea that profits are 'forms' of surplus-value, that is, unpaid labour.

Approximations

Marx is, however, aware that the type of computation illustrated in Table 1 is not satisfactory, since the evaluations of constant and variable capital have not been modified despite the fact that prices have changed.

First, when natural prices are prices of production, non-labour inputs are purchased on the market at prices of production, not at prices proportional to values. It is, therefore, not correct to conserve the evaluation of constant capital:

> We had originally assumed that the cost-price of a commodity equalled the value of the commodities consumed in its production. But for the buyer the price of production of a specific commodity is its cost-price, and may thus pass as cost-price into the prices of other commodities. Since the price of production may differ from the value of a commodity, it follows that the cost-price of a commodity containing this price of production of another commodity may also stand above or below that portion of its total value derived from the value of the means of production consumed by it. It is necessary to remember this modified significance of the cost-price, and to bear in mind that there is always the possibility of an error if the cost-price of a commodity in any particular sphere is identified with the value of the means of production consumed by it. Our present analysis does not necessitate a closer examination of this point. (Marx 1981, ch. 9)

Second, there is a similar problem concerning variable capital. When commodities exchange at prices of production, workers will not be able to buy the same bundle of commodities with a wage corresponding to a purchasing power expressed, as in Marx's calculation, as a certain number of hours of labour time, as when prices are proportional to values. Marx is also aware of this problem:

> [. . .] the average daily wage is indeed always equal to the value produced in the number of hours the labourer must work to produce the necessities of life. But this number of hours is in its turn obscured by the deviation of the prices of production of the necessities of life from their values. However, this always resolves itself to one commodity receiving too little of the surplus-value while another receives too much, so that the deviations from the values which are embodied in the prices of production compensate one another. Under capitalist production, the general law acts as the prevailing tendency only in a very complicated and approximate manner, as a never ascertainable average of ceaseless fluctuations. (Marx 1981, ch. 9)

It is not easy to understand Marx's position from these notes (which he never revised for publication). It does seem that the analysis requires a 'closer analysis', since the revaluation of constant capital at prices of production will in general make the sum of prices of production deviate from the sum of values, or make the sum of profits deviate from the sum of surplus-values. While it is true that a redistribution of surplus-value through a system of prices of production does not alter the living labour expended in production, so that over the whole economy the deviations from value 'compensate one another', the value of labour power will remain constant only if workers consume commodities in the same proportion as they are produced in the whole economy, which is implausible. The phrase 'average of ceaseless fluctuations' suggests the averaging out of market prices to prices of production rather than the averaging of surplus-value across sectors.

If Marx's use of the term 'approximately' is taken literally, it would appear that the LTV

and the theory of exploitation he introduced in volume 1 of *Capital* are only 'approximately' true! Although Marx is conscious of the problem, it is impossible to consider his solution as rigorous. In the formulation of the two equations above, it appears that, when the calculation is done rigorously as in the formal setting below, the second equation *does not hold*! Later critics have judged this a devastating refutation of Marx's theories of value and exploitation, which in turn has led to ongoing controversy.

Earlier Approaches

The foundations of the transformation problem can be found in the first analyses of competition and prices in capitalism, beginning with Adam Smith and David Ricardo, on which Marx elaborated. The distinction between values and prices remains somewhat fuzzy in these authors. Smith fails to establish a clear relationship between value and profit rate equalization as the principle determining 'natural prices'. Thus, one characteristic feature of these approaches, from which Marx was unable to depart completely, is that two sets of prices (the two laws of exchange above) are considered, one proportional to values (embodied labour times), and the other equalizing profit rates (a *dual system*), when only one price system prevails in real-world capitalism (a *single system*):

1. A system of prices proportional to values (embodied labour times) plays a role in the analyses of Smith, Ricardo and Marx. Only Marx, however, clearly distinguishes the two systems from the start.
2. The determination of the 'surplus', when such a concept exists (as in Ricardo and Marx), is posed in the first system and imported into the second, instead of being analysed directly within the second system.

This dual system approach lies at the basis of the phrase 'transformation problem', which refers to the transformation from one system into the other.

Adam Smith

Smith's point of departure is an 'early, rude' state of society, before the establishment of private property in land and means of production. There, Smith contends, products of human labour will exchange in proportion to the labour time required to produce them. Smith offers as an example that, if it requires two days on average to kill a beaver, but one day to kill a deer, a beaver will tend to exchange for two deer. Smith's argument supporting this conclusion rests on the assumption that any hunter can choose to allocate time to hunting deer or beaver, so that, if the exchange ratio were higher or lower than the labour time ratio, hunters would shift from the underto the over-remunerated productive activity, and force the exchange ratio back toward the labour time ratio. The viewpoint is clearly that of the commodity law of exchange.

Smith applies the same type of reasoning to argue that, once means of production have become private property (which he calls 'stock', and later economists called 'capital'), the ability of owners to shift their capital from one line of production to another will tend to equalize the profit rate across different sectors of production. The viewpoint is now that of the capitalist law of exchange.

David Ricardo

Ricardo critiques and corrects Smith's analysis. Ricardo originally based his theories of prices and distribution on Smith's first principle that the labour expended in producing a commodity determines its price in exchange. But Ricardo, elaborating on the dual system approach, examines the necessary quantitative difference between the two principles that might determine natural prices more carefully than Smith. Ricardo understood that the proportion between capitals invested in non-labour inputs and labour is not uniform across industries, and that this fact implies a discrepancy between the two sets of prices, but he regarded these deviations as quantitatively limited. Prefiguring Marx's investigation, Ricardo was concerned to work out the properties of the first system (values) to derive conclusions concerning

distribution, which he supposed were also valid in the second system (prices of production).

First, when natural prices are proportional to values (embodied labour times), it is obvious that there is a trade-off between the shares of output which respectively go to workers and capitalists: workers create all the value added to inputs, and buy a share of output whose production requires less labour time than they expend. In contrast to Smith, Ricardo had a clear view of this mechanism. This division of total output between workers and capitalists was crucial to his analysis, because of its implications in terms of economic policy. (For example, Ricardo was in favour of a low price of corn, which, in his opinion, would increase the profits of capitalists by lowering wages – and encourage capital accumulation.)

Second, Ricardo would have liked to conserve the straightforward distributional properties he derived from the assumption of prices proportional to values, even while acknowledging the quantitative difference between such natural prices proportional to values and natural prices that would equalize profit rates across industries. But Ricardo understood that, in the profit rate-equalizing system, the natural prices of commodities may change with a change in the real wage (due to the distinct compositions of capital) even if the labour required in production remains unaltered, contrary to what happens in the first system, where values remain unchanged with a change in the wage. Thus, with Ricardo's analysis, we are getting closer to Marx's framework and problems.

The Rebellious Classical Legacy in Marx

Marx adopted key elements from Smith and Ricardo's works: (*a*) a dual system approach to natural prices in capitalism (beginning, with Smith, as if labour was the unique input); (*b*) Ricardo's analysis of distribution as a 'trade-off' between wages and profit; and (*c*) Smith's analysis of competition that Ricardo had also adopted.

The two classical economists were the mainstream when Marx started his study of economics. Marx seized this opportunity to establish his theory of exploitation, in which surplus-value arises from unpaid labour time, on 'mainstream' grounds. Then he devoted hundreds of pages (in the manuscripts known as *The Theories of Surplus-value*) to the inability of these 'bourgeois' economists to establish a theory of exploitation, although Ricardo came close. This very smart political move on Marx's part eventually forced mainstream economic theory to abandon these 'dangerous' implications of the LTV.

The Transformation Controversy

A large literature is devoted to the transformation problem, starting with the critical contributions of Eugen von Böhm-Bawerk (1890) and Ladislaus von Bortkiewicz (1952) in the late 19th and early 20th centuries. This literature has led to considerable formal advance, though it has failed to resolve the basic controversy over which of Marx's conclusions, if any, are logically valid.

There are fundamentally two points raised by these critiques. First, the critics claim that the value system is useless as a preliminary to the calculation of prices of production. Paul Samuelson puts this point in the following manner: 'Contemplate two alternative and discordant systems. Write down one. Now transform by taking an eraser and rubbing it out. Then fill in the other one. *Voilá!* You have completed your transformation algorithm' (Samuelson 1971, p. 400). This point is, however, not really relevant, since Marx's objective was not to show that it is impossible to compute prices of production if values have not been previously determined, but rather to show that the theory of exploitation is consistent with the principle of capitalist competition.

Second, the main focus of this critique is the incompatibility of the two Marxian equations. This literature calculates surplus-value by deducting the value of a given bundle of worker's consumption from the worker's labour time. Profits, on the other hand, are calculated by deducting the price of this same bundle at prices of production from the value added (in prices). When prices of production are not proportional to values, these two quantities are not equal, violating the second Marxian equation. This treatment of the wage of workers, which allocates their

purchasing power to particular commodities, departs from Marx's apparent stipulation in his discussion of the transformation problem of the rate of surplus-value.

In face of this quantitative inequality between surplus-value and profit, the Fundamental Marxian Theorem (see Morishima 1973) argues that the LTV does provide a qualitative foundation for Marx's theory of exploitation, since the rate of profit will be positive if and only if the rate of surplus-value is positive. This interesting observation, however, falls short of fulfilling Marx's ambition to found his theory of exploitation on the LTV through the two Marxian equations.

A crucial moment in the criticism of Marx's transformation was the publication of Piero Sraffa (1960). This book is simultaneously a critique of Marx and of neoclassical economics, but it is, above all, a bold attempt to elaborate Ricardo's analysis. It is the origin of the neo-Ricardian school, represented by, in particular, Ian Steedman (1977) and Pierangelo Garegnani (1984). The central point, in the neo-Ricardian School, is that the LTV is useless, with respect to both the determination of prices of production and exploitation. The dual-system approach of Ricardo is abandoned in favour of the price of production system, as the reference to value is deemed irrelevant. Sraffa calculates prices of production directly from a description of technology and distribution. In this framework, he shows that Ricardo's trade-off between wages and the profit rate can be derived formally as a downward sloping relation (see the mathematical section below).

The Price of Net Product-Unallocated Purchasing Power Labour Theory of Value (PNP-UPP LTV) Approach to Exploitation

In the late 1970s, Gérard Duménil (1980, 1983, 1984) and Duncan Foley (1982) (independently) proposed new lines of interpretation of Marx's theory of value. In doing so, they followed distinct routes, but the basic principles underlying these reformulations converge to the same basic framework. This interpretation is inappropriately referred to, in the literature, as the 'New Interpretation'. It is more precise to describe it as the 'price of net product-unallocated purchasing power labour theory of value' (PNP-UPP LTV). It was rapidly adopted by Alain Lipietz (1982).

Value and Exploitation in the PNP-UPP LTV Approach

Beginning with Marx's two equations, as is traditional, there are two basic principles to this interpretation. First, Marx's equation concerning the 'sum of values' and 'sum of prices' holds for the net product of the period. 'Net product' means here, as in Marx's reproduction schemes and national accounting frameworks, output minus non-labour inputs inherited from the previous period. The important idea here is that it is the expenditure of living labour that creates value. Marx regards the value of a commodity as equal to the value transferred by the inputs consumed and the new value created by labour during the period. But the two perspectives are equivalent:

$$\begin{aligned} &\textit{Value transferred from inputs} \\ &+ \textit{value created by new labour} \\ &= \textit{value of output Value created by new labour} \\ &= \textit{value of output} \\ &- \textit{value transferred from inputs} \end{aligned}$$

The price form of the value created by the total productive labour expended during a period of time is the price of the net product of the period. (As is well known, the price of this net product is equal to total income, wages plus profits.) The PNP-UPP LTV interpretation argues that, when Marx (in the first quotation above) points to the fact that the cost-prices of commodities used as inputs to production must be adjusted to reflect the change to prices of production, the correct formulation would have been to exclude them from the first Marxian equation, which would then read 'Sum of values of net product = sum of price of net product'. Since values are expressed in labour time, while prices of production are expressed in terms of money, this equation implicitly defines an equivalence between value-creating labour time

and money, the *monetary expression of value or labour time* (MELT), which is the ratio of the price of net product (value added measured in money) to the productive labour time expended. If, for example, 250 billion hours of productive labour were expended in an economy to produce a net product worth $10 trillion, the monetary expression of labour time would be $40 per hour. The MELT expresses quantitatively (as a ratio of the price of the net product to the living labour expended) what Marx calls the 'price form' of the total value created during the period.

Second, the PNP-UPP LTV views the term 'surplus-value' in the second Marxian equation as referring to the monetary equivalent of unpaid labour time. The wage, as in Marx's calculation, is regarded as unallocated purchasing power giving workers the potential to buy a fraction of the net product. (This is the way capitalists look at wage payments, since the individual capitalist has no interest in how workers actually spend their wages.) Individual workers can allocate this purchasing power among the commodities they jointly produced (or even save some of it), in whatever proportions they choose. This can be described as the unallocated purchasing power (UPP) approach to exploitation. With this definition of surplus-value, the Marxian second equation immediately holds as an identity. The PNP-UPP LTV holds the rate of surplus-value rather than the consumption bundle of workers constant.

There is a sharp contrast between the PNP-UPP LTV and the traditional interpretation in the way they conceptualize distribution. Following Marx's procedure in his calculation, represented in the simplified example introduced earlier, it is impossible to assume that workers can buy the same bundle of commodities before and after the redistribution of surplus-value, since the purchasing power they receive will be spent at different prices. Consequently, the wage must be changed to keep the bundle of workers' consumption unchanged (and the rate of surplus-value must be altered – hence the controversy). The UPP approach to exploitation conserves the rate of exploitation, or, more rigorously, measures the value of labour power as the value whose price form is the price of the commodities workers can buy: an unallocated purchasing power on any commodities. The rate of surplus-value, as in Marx's calculation, is unchanged.

A Single-System Approach and Exploitation in any Set of Prices

A key aspect of the PNP-UPP LTV interpretation is that value is present in the theory of exploitation, as a social substance extracted in one place in the economy (firm, industry), and realized in another. But there is no logical anteriority in the value system, compared to the price system. This interpretation is a single-system approach to the LTV.

This property has important analytical consequences. There is only one economy, one system, not two. There is no 'underlying', hidden economy, which operates in 'values' where the distributional realities that structure the functioning of capitalism could be determined. The theory of exploitation is not dependent on the prevalence of any particular set of prices. The consideration of prices of production is not central to Marx's argument concerning exploitation, only an example that illustrates a much more general conclusion. Prices of production are just *one case* in which such a demonstration must be made, which Marx focused on because of the importance of this particular set of prices in competitive capitalism, as centres of gravitation of market prices.

The specific property expressed in the equality of the profit rate among industries cannot play any role in the theory of exploitation. Prices may deviate from prices of production because of gravitation; the amounts of surplus-value realized in each industry may also differ from what is implied by the prevalence of uniform profit rates because of the existence of non-reproducible resources and their rents; counteracting factors, such as monopoly, may also prevent equalization of profit rates. These deviations, inherent to capitalism, and also mentioned in Marx's analysis, do not invalidate his theory of value and exploitation.

An Ongoing Debate

The shift of perspective to single-system interpretations of Marx's labour theory of value has

led to further debate in this vein. Fred Moseley (2000) proposes to apply the reasoning of the SS-LTV approach not just to variable capital, but to constant capital as well. Moseley argues for retaining the original form of the Marxian equations by defining the total value of a commodity as the labour-time equivalent of the price of constant capital plus the living labour expended in adding value. Moseley argues that Marx's comments in the quotations above are unnecessary because Marx's tables themselves express his underlying understanding of the labour theory of value.

Alan Freeman, Giugelmo Carchedi, Andrew Kliman, and their co-authors (Freeman and Carchedi 1996) have put forward a 'temporal single-system' (TSS) interpretation of the labour theory of value. This interpretation sets the transformation problem in a temporal context, defining the value of commodities as the sum of the labour time equivalent of constant capital (calculated using a monetary expression of labour time) and the living labour expended in the current period in production. By construction, this interpretation makes the first Marxian equation hold for the total product, while the second Marxian equation holds when the monetary expression of labour time is appropriately defined (as in the SS-LTV). It is, however, clear in Marx's analysis that the value of a commodity is not determined by the actual amount of labour its production required in the past, but by the labour time it requires under present prevailing conditions:

> . . .the value of commodities is not determined by the labour-time originally expended in their production, but by the labour-time expended in their reproduction, and this decreases continually owing to the development of the social productivity of labour. On a higher level of social productivity, all available capital appears, for this reason, to be the result of a relatively short period of reproduction, instead of a long process of accumulation of capital. (Marx 1981, ch. 24)

This evaluation at 'replacement costs', however, does not imply that the economy is necessarily in a stationary state as the TSS critique has claimed.

A Mathematical Setting

The use of numerical examples to work out the quantitative implications of theoretical ideas is now outdated. The most common framework in the contemporary literature on the transformation problem is a pure circulating-capital model with a single technique in each sector, in which basic properties of solutions and interpretations can be elegantly and compactly expressed. A single homogeneous labour input works with stocks of an arbitrary but finite number of produced commodities available at the beginning of a production period. One unit of each commodity is produced by a single technique of production. This framework is consistent with the example in the first table above but not with Marx's tables since the circulating capital model does not include fixed capital, while Marx's examples do.

1. *Techniques of production*. The number of goods is n, also the number of techniques. A technique of production, indexed by j, is characterized by a column vector, $\boldsymbol{a}_j = (a_{j1}, \ldots, a_{ji}, \ldots, a_{jn})$, and a scalar l_j, where a_{ji} is interpreted as the quantity of the commodity i required as inputs, and l_j as the quantity of labour required for the production of one unit of commodity j. A technology consisting of the set of all available techniques is described by collecting corresponding inputs into a matrix $\mathbf{A}$, and the labour input scalars into a row vector $\boldsymbol{l}'$. A pattern of economic production is described by a vector of levels of operation of the techniques, $\boldsymbol{x} = (x_1, 1\ldots, x_j, \ldots, x_n)$. The inputs required with this pattern of production can compactly be written in matrix notation as $\mathbf{A}\boldsymbol{x}$, while the total labour required is $\boldsymbol{l}'\boldsymbol{x}$.
2. *The determination of values*. The value, λ_j, of commodity j is the sum of the direct labour, l_j, expended in its production, and the indirect labour contained in produced inputs required for its production, $\lambda_1 a_{j1} + \cdots + \lambda_n a_{jn} = \boldsymbol{\lambda}'\boldsymbol{a}_j$, that is $\lambda_j = \boldsymbol{\lambda}'\boldsymbol{a}_j + l_j$. The vector of values of commodities, $\boldsymbol{\lambda}'$, satisfies the equation: $\boldsymbol{\lambda}' = \boldsymbol{\lambda}'\mathbf{A} + \boldsymbol{l}'$. It can be written as:

$$\lambda' = \boldsymbol{l}'(\mathrm{I} - \mathrm{A})$$

The value of the net product $\boldsymbol{y} = (\mathrm{I} - \mathrm{A})\boldsymbol{x}$, is equal to the total labour time expended: $\lambda' \mathrm{y} = \boldsymbol{l}'\boldsymbol{x}$. It is the sum of variable capital (wages paid), and total surplus-value. We denote τ as the rate of surplus-value, and v, the value of one unit of labour power, or the share of wages in the net product. These two variables are linked by the relationship $v = 1/(1 + \tau)$.

3. *The example of the table*. Each element in the table (upper-case notation) refers to industries, that is the product of unit variables (lower-case notation) by levels of operation (industries are marked by the subscript j, while vectors have no subscript). Below we will use the notation, P_j, for the price of the output of industry j, p_j for the price of one unit of commodity j, and $\boldsymbol{p}'$ for the vector of unit prices.

$$\begin{aligned}
\text{Constant capitals}: &\quad C_j = \boldsymbol{\lambda}'\boldsymbol{a_j}x_j \text{ and } C = \boldsymbol{\lambda}'\mathbf{A}\mathbf{x}.\\
\text{Variable capitals}: &\quad V_j = v\, l_j x_j \text{ and } V = v\mathrm{l}'\mathrm{x}, \text{with } v = 1/(1+\tau) \text{ or } \tau = (1-v)/v.\\
\text{Total capitals}: &\quad K_j = C_j + V_j \text{ and } K = C + V.\\
\text{Surplus} - \text{values}: &\quad S_j = \tau V_j = (1-v)l_j x_j \text{ and } S = \tau V = (1-v)\boldsymbol{l}'\boldsymbol{x}.\\
\text{Values of commodities}: &\quad \Lambda_j = K_j + S_j = \left(\boldsymbol{\lambda}'\boldsymbol{a_j} + l_j\right)x_j = \lambda_j x_j \text{ and } \Lambda = K + S = (\boldsymbol{\lambda}'\mathbf{A} + \mathbf{l}')\mathrm{x} = \lambda'\mathrm{x}.
\end{aligned}$$

Marx determines the total surplus-value, S, and allocates it proportionally to total capital in each industry, so that the profit rates, r_j, in each industry is uniform: $r = S/K$ (or, equivalently, $1 + r = \Lambda/K$). Profits in each industry are: $\Pi_j = r\, K_j$. By construction, total profits are equal to total surplus-value. The price of production of the total output of industry j is: $P_j = K_j + \Pi_j = (1 + r)K_j$. For the price of one unit of commodity j, one has:

$$\begin{aligned}
p_j &= (1+r)\left(\boldsymbol{\lambda}'\boldsymbol{a_j} + v l_j\right) \text{ and } \boldsymbol{p}'\\
&= (1+r)(\boldsymbol{\lambda}'\mathbf{A} + v\boldsymbol{l}').
\end{aligned}$$

As is obvious, the two equations Sum of values ($\Lambda = \boldsymbol{\lambda}'\mathbf{x}$)= Sum of 'prices of production' ($\mathrm{P} = \boldsymbol{p}'\boldsymbol{x}$) and Sum of surplus-value (S) = Sum of profits ($\Pi = r\, K$) are satisfied.

4. *The determination of prices of production*. In the above calculation, Marx simply transfers the values of inputs to the price of production system instead of estimating them at their prices of production. Prices of production are a stationary price system (in which inputs have the same prices as outputs, as would be the case in a long-period equilibrium) at which profit rates in all sectors are equal to a given r, when the wage is paid at the beginning of the production period:

$$\begin{aligned}
&\boldsymbol{p}' = (1+r)(\boldsymbol{p}'\boldsymbol{A} + w\boldsymbol{l}'), \text{ which implies } \mathrm{p}'[r,w]\\
&= w(1+r)\boldsymbol{l}'(\mathbf{I} - (1+r)\mathbf{A})^{-1}.
\end{aligned}$$

The profit rate equalization conditions are n equations (one for each produced commodity) in $n + 2$ variables, the n prices $\boldsymbol{p}'$, r, and w. Since the accounting units in which prices and the wage are expressed are arbitrary, it is possible without loss of generality to add one further equation normalizing prices, such as $\boldsymbol{p}'\boldsymbol{N} = 1$, where $\boldsymbol{N}$ is a nonnegative bundle of commodities chosen as numéraire for the price system, or, alternatively $w = 1$, which specifies the unit wage as the numéraire.

In the treatment of the transformation problem the most intuitive normalization is to express prices in labour time units. These prices are often called 'direct prices', and the general price level in this metric is determined by: $\boldsymbol{p}'\boldsymbol{y} = \boldsymbol{l}'\boldsymbol{x}$. The price of the net product $\boldsymbol{p}'\boldsymbol{y}$, evaluated at direct prices, is equal to the total labour time expended: $\boldsymbol{l}'\boldsymbol{x}$. This is equivalent to saying that the numéraire is the net

product divided by the total number of hours expended: $\boldsymbol{N} = \boldsymbol{y}/\boldsymbol{l}'\boldsymbol{x}$. Using this numéraire one has:

$$\boldsymbol{p}'[r] = \frac{\boldsymbol{l}'x}{\boldsymbol{l}'(\mathbf{I} - (1+r)\mathbf{A})^{-1}y}\boldsymbol{l}'(\mathbf{I} - (1+r)\mathbf{A})^{-1}$$

Using this relationship and the expression of $\boldsymbol{p}'[r,w]$ above, one can determine the negative relation between wages and the profit rate, à la Ricardo and Sraffa:

$$w = \frac{1}{1+r}\,\frac{\boldsymbol{l}'x}{\boldsymbol{l}'(\mathbf{I} - (1+r)\mathbf{A})^{-1}y}$$

When the profit rate is 0, we have $w = 1$, and $\boldsymbol{p}' = \boldsymbol{l}'(\mathbf{I} - \mathbf{A})^{-1} = \boldsymbol{\lambda}'$: direct prices are equal to values.

5. *The historical transformation controversy.* The dual-system critique is based on comparing the aggregates (sum of values to sum of prices, and sum of surplus-values with sum of prices) under the assumption of a given real wage as a bundle, $\boldsymbol{d}$, of commodities. Thus, the value of labour power and surplus-value are respectively: $v = \boldsymbol{\lambda}'\,\mathbf{d}$, and $S = (1 - v)\boldsymbol{l}'\,\boldsymbol{x}$. Workers are assumed to buy the same commodities when prices of production prevail, so that $w = \boldsymbol{p}'\,\boldsymbol{d}$. Substituting $\boldsymbol{p}'[r,\ w]$, as above, for $\boldsymbol{p}'$ in this expression, the profit rate is the solution of the following implicit equation:

$$(1+r)\boldsymbol{l}(\mathbf{I} - (1+r)\mathbf{A})^{-1}\boldsymbol{d} = 1.$$

One can then calculate Π, which has no reason to be equal to S: in the general case, the second Marxian equation does not hold.

6. *The PNP-UPP LTV.* In the PNP-UPP LTV interpretation, in contrast, the same situation of distribution means the same rate of surplus-value. In general this means that workers will not be able to buy the same bundle of commodities at prices of production. The rate of surplus-values is: $\tau^{\mathrm{p}} = \Pi/W$. If, in the two systems, the price of production of the net product is set equal to its value, of which it is the price form (or, equivalently, if the monetary expression of value is set to 1), that is $\boldsymbol{p}'\boldsymbol{y} = \boldsymbol{\lambda}'\,\mathbf{y} = \boldsymbol{l}'\,\boldsymbol{x}$, then the total price of profits is equal to the sum of surplus-value, of which it is the price form. Thus the two Marxian equations (the first interpreted in terms of the net product) hold.

Marxian Value Analysis

John E. Roemer

JEL Classifications
B1

For Marx, the labour theory of value was not a theory of price, but a method for measuring the exploitation of labour. The exploitation of labour, in turn, was important for explaining the production of a surplus in a capitalist economy. In a feudal economy, the emergence of a net product, surplus to the consumption of producers and to the inputs consumed in production, was palpable. For the serf reproduced himself on his family plot of land during part of the week, and then worked for the lord, doing demesne or corvée labour during the other part. There was a temporal and physical division between production for subsistence or reproduction, and production which generated an economic surplus and was appropriated by the lord. Under capitalism, with the division of labour, such a demarcation no longer existed. If capitalism is characterized by competitive markets, where each factor is paid its true 'value', and no one makes a windfall profit by cheating his partner in exchange, how could a surplus emerge? In what manner could a sequence of equal exchanges transform an initial set of inputs into a larger quantity of outputs, with the surplus being appropriated systematically by one class, the capitalists? Marx's project was to explain the origin of profits in a perfectly competitive model, where each factor, including labour, received its competitive price in exchange.

Marx thought he had discovered the answer to this apparent economic sleight of hand by tracing what happened to labour as it passed from the workers who expended it, to the products in which it became embodied, and eventually to the profits of capitalists who sold these commodities. In some of his writings, notably in *Capital*, Volume I, he simplified the argument by assuming that the prices of goods were equal to the amounts of labour they embodied. The embodied labour in a good is the amount of labour necessary to produce that good, and to reproduce all inputs used up in its production. (Assume the only non-produced input is labour.) In particular, this is true also for the good 'labour power'; the embodied labour in a week's labour supplied by a worker is the amount of labour necessary to produce the goods which that worker consumes to reproduce himself for work the following week. If all goods exchange at their embodied labour values (the simplifying assumption) then, in particular, the worker receives a wage in consumption commodities (say, corn) which is just necessary to reproduce himself (which includes the reproduction of the working-class family). The secret of accumulation, for Marx, lay in the discovery that the embodied labour value of one week's labour was, let us say, four days of labour. In four days of socially expended labour, given the existing technology and stock of capital, the consumption commodities necessary to reproduce the worker could be produced. Thus the worker was paid an amount of corn which required four days to produce, his wage for seven days' labour. The surplus labour of three days became embodied in

commodities which were the rightful property of the capitalist who hired the worker. Why would the worker agree to such a deal? Because he had no access to the means of production necessary for producing his consumption goods on any better terms. Those means of production were owned by the capitalist class. (Although the simplifying assumption, that equilibrium prices are equal to or proportional to embodied labour values, is rarely true, Marx conjectured that the deviation of prices from labour values was not crucial to understanding the origin of profits. On this point he was correct. Much ink has been spent on the 'transformation problem', which tries to relate embodied labour values to equilibrium prices in general. As will be shown below, prices need not be proportional to embodied labour values for the theory of class and exploitation to be sensible. Hence the study of the transformation problem is a pointless detour.)

Imagine a corn economy, where there are two technologies for producing corn, a Farm and a Factory: – Farm: 3 days' labour produces 1 corn output – Factory: 1 days' labour + 1 corn (seed) produces 2 corn output. On the Farm, corn is produced from labour alone, perhaps by cultivating wild corn on marginal land. In the capital-intensive Factory technology, seed corn is used as capital. One unit of seed capital reproduces itself and produces one additional corn output with one day of labour. Suppose both techniques require one week for the corn to grow to maturity. Let there be 1000 agents, ten of whom each own 50 units of seed corn. The other 990 peasants own only their labour power. Suppose a person requires one corn per week to survive; his preferences are to consume that amount, and then to take leisure. Assume that if he owns a stock of seed corn, he is not willing to run it down: he must replenish the inputs which he uses up before consuming. What is an equilibrium for this economy, which is guaranteed to reproduce the stocks with which it begins?

Since there are only 500 bushels of seed corn, the required consumption of 1000 corn cannot be reproduced using only the Factory technology, since the seed capital of 500 must be replaced. Capital is scarce relative to the labour which is available for it to employ. The wage which the 'capitalists', who own the seed corn, will offer at equilibrium to those whom they employ will therefore be bid down to the wage which peasants can earn in the marginal Farm technology: 1/3 corn per day labour. At any higher wage, all peasants will wish to sell their labour to the capitalists, and there is insufficient capital to employ them all. (It is assumed peasants have no preference for life on the Farm over life in the Factory. All they care about is rate at which they can exchange labour for corn.) At the wage of 1/3 corn per day, 500/3 peasants become workers in the Factory, each working for three days, planting three units of seed corn, and earning a wage of one corn. This exhausts the capital stock. The remaining peasants stay on the Farm, and also earn one corn with three days' labour. The ten capitalists each work zero days; altogether, they make a profit of (500–500/3) = 333.3 corn, after paying wages and replenishing their seed stock.

In the Factory technology, the embodied labour value of one corn is one day's labour; that amount of labour produces one corn output and reproduces the seed capital used. But the worker, at equilibrium, must work three days to earn one corn. This is so because he does not own the capital stock required for operating the efficient Factory method. His alternative is to eke out a subsistence of one corn by doing three days' labour on the Farm. The worker is said to be *exploited* if the labour embodied in the wage goods he is paid is less than the labour he expends in production. This is the case here, and it is evidently what makes possible the production of a surplus, in an economy where all agents wish only to work long enough to reproduce themselves (and their capital stock). Note this last statement characterizes, as well, the capitalists: in this story, they get 333 corn profits and expend no labour, a result consistent with their having subsistence preferences, where each desires to work only so long as he must to consume his one corn per week.

Contrast this capitalist economy, where three classes have emerged – capitalists, workers, and peasants – to the following subsistence, peasant economy. Everything is the same as above, except the initial distribution of corn: let each of the 1000 persons own initially 0.5 corn. At equilibrium, each agent will work two days and consume one corn. First, he uses the Factory to turn his 0.5 seed corn into 0.5 corn net output, which costs him 0.5 days of labour; then he must produce another 0.5 corn for consumption, for which he turns to the Farm, where he works for 1.5 days. Each agent consumes one corn with two days' labour, an egalitarian society, which is classless. (There are other ways of arranging the equilibrium in this economy, in which one group of agents hires another group to work up its capital stock, while they, in turn, work on the Farm. But the final allocation of corn and labour is the same as in the equilibrium just described.) There is a fine point here: perhaps one should say, in both economies, that the amount of labour socially embodied in one corn is two days (not one, as written above), for that is what is required to produce society's necessary corn consumption given the capital stock and available techniques. This will not change the verdict that the workers in the capitalist economy are exploited, while no one is exploited in the egalitarian society.

Contrast these two economies, which differ only in the initial distribution of the capital stock. Inequality in the distribution of the means of production gives rise to: (1) the production of a surplus above subsistence needs, or accumulation; (2) exploitation, in the sense that some agents expend more labour than is embodied in the goods they consume and others expend less labour than is embodied in what the consume; and (3) classes of agents, some of whom hire labour, some of whom sell labour, and some of whom work for themselves. The exploitation of labour emerges with the unequal ownership of capital, or the 'separation' of workers from the means of production. The existence of an industrial reserve army (here, the peasantry) who have access to an inferior technology to reproduce themselves explains the equilibration of the wage at a level below that which exhausts the product of labour in the capitalist sector. Moreover, exploitation may be an indicator of an injustice of capitalism. If it does not seem fair that a serf must work three days a week for the lord perhaps it is not fair either that a wage labourer must expend more labour than is embodied in the wage goods he receives. That verdict, however, is not obvious and requires further analysis. Although the story can be made complicated, these simple models demonstrate the main features of the Marxian theory of labour exploitation.

Class, Exploitation and Wealth

Consider an economy of N agents, with n produced commodities and labour. The input–output matrix which specifies the linear technology is A, and the row vector of direct labour inputs needed to operate the technology is L. Agent i has an initial endowment vector of goods w^i and one unit of labour power. For simplicity, assume as above subsistence preferences: each agent wishes to earn enough income to purchase some fixed consumption vector b, and not run down the value of his initial endowment, valued at equilibrium prices. After working enough to earn that amount, he takes leisure. It is clear that each agent will only operate activities, at a given price vector, which generate the maximum rate of profit. Normalize prices by setting the wage at unity. For all activities to operate at equilibrium, the commodity price vector p must satisfy:

$$p = (1 + \pi)(pA + L) \tag{1}$$

Prices p obeying (1) generate a uniform and hence maximal rate of profit π for all activities. (The only activities we observe are the ones reported in A and hence without loss of generality, we may assume the profit rate must be equalized for all sectors of production, since agents only operate maximal profit rate activities.)

The vector of embodied labour values in commodities is Λ:

$$\Lambda = \Lambda(1 - A)^{-1} \tag{2}$$

A worker, whose initial endowments are none except his labour power, must earn wages sufficient to purchase the subsistence vector b, which requires:

$$pb = 1 \tag{3}$$

From these three equations, it can be demonstrated (see Morishima 1973; Roemer 1981) that:

$$\pi > 0 \text{ if and only if } \Lambda b < 1 \tag{4}$$

Equivalence (4) was coined by Morishima the 'fundamental Marxian theorem', as it shows that profits are positive precisely when labour is exploited (for the second inequality says that the labour embodied in the wage bundle is less than one unit of labour).

An agent in this model minimizes the labour he expends subject to earning revenues sufficient to buying his consumption b, and to replace the finance capital he uses. Suppose, for simplicity, there is no borrowing and all production must be financed from initial wealth. In general, an agent will optimize by hiring some labour, selling some of his own labour, and/or working on his own capital stock. Let x^i be the vector of activity levels which agent i operates himself, financed with his wealth; let y^i be the vector of activity levels he hires others to operate, which he finances; let z^i be the amount of labour he sells to other operators. His problem is to choose vectors x^i, y^i, and z^i to:

$$\min Lx^i + z^i$$

subject to

(i) $pAx^i + pAy^i \leq pw^i$

(ii) $p(q - A)x^i + p(q - A)y^i - Ly^i + z^i \geq pb$

The first constraint requires him to finance the activities operated out of his endowment, and the second requires that his revenues, net of wages paid and replacement costs, suffice to purchase the consumption bundle b. As well as the price vector satisfying (1), equilibrium requires that the markets for production inputs, consumption goods, and labour must clear. It can be proved that at such a 'reproducible solution', society is divided into five classes of agents, characterized by their relation to the hiring or selling of labour, as follows. There is a class of *pure capitalists,* who only hire labour (y^i is non-zero, but x^i and z^i are zero vectors); there is a class of *mixed capitalists*, who hire labour and work for themselves as well ($y^i \neq 0 \neq x^i$, $z^i = 0$); there is a class of *petty bourgeoisie,* who only work for themselves, and neither hire nor sell labour ($x^i \neq 0$; $y^i = 0 = z^i$); there is a class of *mixed proletarians,* who work for themselves part-time, and also sell their labour power on the market ($x^i \neq 0 \neq z^i$, $y^i = 0$); and there are *proletarians,* who only sell their labour power ($z^i \neq 0$, $x^i = 0 = y^i$). It is clear, from consulting the agent's programme, that this last class comprises those agents who own nothing but their labour power. More generally, the *Class-Wealth Correspondence Theorem* states that the five classes named, in that order, list agents in descending order of wealth. This verifies an intuition of classical Marxism.

There is, as well, a relation of class to exploitation. The *Class–Exploitation Correspondence Principle* states that the agents who hire labour are exploiters and the agents who sell labour are exploited. The exploitation status of agents in the petty bourgeoisie is ambiguous. Exploitation is defined as before: an agent is exploited if he expends more labour than is embodied in the vector b, and he is an exploiter if he expends less labour than that. It is important to note that this relationship of class to exploitation is a theorem of the model, not a postulate. Both the class and exploitation status of an agent emerge in the model as a consequence of optimizing behaviour, determined by the initial distribution of endowments, technology and preferences. These aspects

of agents which in classical Marxism were taken as given (their class and exploitation status) are here proved to emerge as part of the description of agents in equilibrium, from initial given data of a more fundamental sort (endowments, etc.). For this reason, the model described provides microfoundations for classical Marxian descriptions. Generalizations and discussion of the model are pursued in Roemer (1982, 1985a). See Wright (1985) and Bardhan (1984, ch. 13) for empirical applications. For a general evaluation of the Marxian theory of exploitation and class, see Elster (1985, ch. 2, 4 and 5).

From the viewpoint of modern capitalism, many criticisms can be levelled against these stories. Foremost among them, perhaps, is the assumption of subsistence preferences. What happens if agents have more general preferences for income and leisure? The Class–Exploitation Correspondence Principle continues to hold, but the correspondence between class and wealth may fail. It fails, however, only for preference orderings which are unusual: the Class–Wealth Correspondence is true if the elasticity of labour supplied by the population viewed cross-sectionally with respect to its wealth is less than or equal to unity. There can, therefore, be no general claim that exploitation corresponds to wealth, in the classical way – that the poor are exploited by the rich. Whether the exploitation–wealth correspondence holds depends on the labour supply behaviour of agents as their wealth changes.

Exploitation as a Statistic

Note that the fundamental conclusions of classical Marxian value analysis – the association of exploitation with class, in a certain way, and the association of exploitation with profits and accumulation – hold even when equilibrium prices are not proportional to labour values. For the prices of equation (1) are not, except in a singular case, proportional to the labour values of equation (2). Therefore, the usefulness of exploitation theory need not rest upon the false labour theory of value. It is for this reason that the transformation problem, for so long a central concern in Marxian economics, is unimportant.

That usefulness, instead, depends on how good a statistic exploitation is for the phenomena it purports to represent. Does the exploitation of labour explain accumulation? The 'fundamental Marxian theorem' would seem to say so. But, in fact, it can be shown that in an economy capable of producing a surplus, every commodity can be viewed as exploited, not just labour power. If corn is chosen as the value numeraire, then the amount of corn value embodied in a unit of corn is less than one unit of corn, so long as profits are positive. Thus labour power is not unique, as Marx thought, in regard to its potential for being exploited, and it is a false inference that the exploitation of labour 'explains' profits any more than the exploitation of corn or steel or land does. (For versions of this 'generalized commodity exploitation theorem', see Vegara (1979), Bowles and Gintis (1981), Samuelson (1982), and Roemer (1982).)

Is exploitation a good statistic for the injustice of capitalist appropriation of the surplus? Only if the initial distribution of endowments, which gives rise to such appropriation, is unjust. Marx claimed this was so, by arguing that initial capitalist property was established by plunder and enclosure (*Capital,* volume 1, Part 8). But suppose there were a clean capitalism, in which initial inequalities in the ownership of capital were generated by differential hard work, skills, risk-taking postures, and perhaps luck of the agents. Would the ensuing class structure, exploitation and differential wealth indicate an injustice, or would it reflect the consequences of persons exercising traits which are rightfully theirs, and from which they deserve differentially to benefit? These topics are pursued in Cohen (1979) and Roemer (1985b).

In sum, the Marxian theory of exploitation is liberated from the labour theory of value. The link between class and exploitation is robust; but Marx's claim that the exploitation of labour is the unique explanans of accumulation is false. If one's class, defined above as one's relation to

hiring or selling of labour, is important sociologically in determining behaviour (such as collective action against another class) and preferences, then the positive theory of class determination described is of use. Exploitation remains a statistic, of some value, for the inequality in the distribution of productive assets. But in this role, exploitation may not correspond to wealth as in the classical story: if the labour supplied by agents responds with excessive enthusiasm to increases in their wealth, then the rich can be 'exploited' by the poor. The ethical conclusion from an observation of exploitation is in this case unclear.

Even aside from this peculiar case, exploitation is a circuitous proxy for differential wealth in productive assets, and one's normative evaluation of exploitation depends on one's view of the process that generates that inequality. If agents are the rightful owners of their alienable means of production, because they accumulated them based on the exercise of their rightfully owned talents and preferences then exploitation does not represent unjust expropriation. If agents are not entitled to own alienable productive assets, either because they have no right to their talents and preferences (whose distribution is morally arbitrary), or because they came to possess those assets in some other unjustifiable way, then exploitation represents an expropriation. Inheritance, for example, might be an unjust way of acquiring assets which were originally acquired in an untainted manner. The essential question which lies behind the theory of exploitation concerns the fairness of a system of property allowing private ownership of alienable productive assets. The concept of exploitation based on the calculation of surplus labour accounts is, in this writer's view, a circuitous route towards the discussion of that central issue.

Ethical views concerning what kinds of asset may justifiably be privately appropriated change through history. Property in other persons, as in slavery, or more limited rights over the powers of other persons, as in feudalism, are no longer viewed as legitimate. The Marxian theory of exploitation is associated with a call for the abolition of private property in the productive assets external to persons. (Marx himself did not explicitly base his call for the abolition of such property on grounds of fairness, but on grounds of efficiency, despite the clear ethical tone of his attacks on capitalism. For an evaluation of the debate surrounding this question, see Geras (1985).) The cogency of that call must be established independently of the theory of exploitation.

Marxism

Andrew Arato

The term 'Marxism' is much overused today: the category is deemed applicable by all sides of political divides unable to agree on anything else. No taxonomic sense, however, can be given to the conceptual chaos behind the wide variety of identifications. Only the historical reasons can be explored in the present context. Here *Marxism* will signify a *tradition* combining two related, originally nineteenth-century, intellectual complexes: (1) a particular, philosophically materialist, comprehensive world view seeking to give a unified, this-worldly explanation to all dimensions of human existence and (2) a 'theory of movement' (R. Koselleck) oriented to the struggles of the industrial working class designed to accelerate historical time, to help bring a (logically, normatively or historically) necessary future closer to the present by 'linking theory and practice'. Both of these complexes are derived from the philosophy of history (or one of the philosophies of history) of Karl Marx, but the founder had little interest in working out a general *Weltanschauung*. In this respect Friedrich Engels was, in works such as *Herr Eugen Dühring's Revolution in Science* and the posthumous *Dialectics of Nature*, the founder of Marxism. Those who look back to the original work of Marx as against the tradition founded by Engels should be identified by the adjective '*Marxian*', as in Marxian philosophy, economics, social theory or anthropology, etc. Nevertheless Marx's relation to Marxism is too complex to allow a neat division between the two. As Lukacs first demonstrated in 1923, Engels's interpretation of Marx's oeuvre in the sense of a generalized worldview and a unified science missed the actual philosophical depth of the latter's theory of history, social theory and critique of political economy. The cost was the elimination, misunderstanding or de-emphasis of fundamental concepts like alienation, reification, fetishism, praxis, subject, etc. Nevertheless, the great power and influence of Engels's synthesis came from Marx's own marriage of science and philosophy of history, bringing together the intellectual prestige of enlightenment with the motivating power of the concepts of romanticism. In another respect as well, Marx, despite having supposedly declared that he was not a 'Marxist', contributed to the foundations of Marxism. He *did* interpret his own thought in all of its phases as providing a theory of movement based on a philosophy of history whose major concepts included (typically) historical stage, transition, revolution and progress. The specific content of this theory was meant to be both an interpretation of *the meaning* of the movement of the industrial working class, and contribution to its enlightenment. No doubt, Marx understood scientific commun*ism* or social*ism* not only as the diagnosis of the crisis of this time, but also as its resolution in anticipation and acceleration of a desired future. This future was conceived in different ways in his various works, but always involved the abolition of differentiated economic and political institutions and the creation of conscious, planned, collective control over economic life as well as direct, democratic participation in all 'political' processes. It is important to note on the one hand that Marx's views of the transition to such a condition were heterogeneous and at different times involved authoritarian étatistic forms (*Communist Manifesto*), the direct democratic (*Civil Wars in France*) and even parliamentary democratic forms (various addresses, and possibly *Class Struggles in France* as well as *The 18th Brumaire of Louis Bonaparte*). Common to all these forms on the other hand was the postulate of the abolition of the division of state and civil society, i.e. an independent civil society with its mediating institutions. The plurality of forms of transition worked out by Marx points to the different politics of later Marxisms, the underlying hostility between civil society and the state strengthening the logic of all the politically significant varieties.

The historical influence of Marxism had been nothing short of spectacular. Until World War II and in some countries until the 1970s, it was the dominant ideology of the various European continental labour movements in Social Democratic,

Communist, Socialist and Euro-Communist forms. The theoretical works oriented to these movements were often of the highest quality; it is enough to mention only the best works of Kautsky, Bernstein, Hilferding, Luxemburg, the Austro-Marxists, Lukacs, Gramsci and countless others. Secondly, from 1905 or so to as late as the 1970s, another version of Marxism eclipsed even nationalism as the dominant revolutionary ideology of 'underdeveloped' or 'peripheric' agrarian societies. Again significant intellectual output accompanied this process, from Lenin, Parvus, Trotsky and Bukharin to Mao, Guevera and Cabral. Finally, from 1917 but more globally from 1945, an increasing number of regimes have used a version of Marxism (Marxism-Leninism, Soviet Marxism) as their 'science of legitimation', their official state cult. While the early phases of this process even here involved serious intellectual work – for example, the 1920s soviet debates about economic development (Preobrazhensky, Bukharin and others) and the problems of law and politics (Pashukanis, Stukha, et al.) – from the 1930s Marxism in power always meant tremendous simplification and even falsification of the doctrines of classical Marxism (not to speak of Marxian theory). However, this intellectual reduction was for a time amply compensated by the prestige of successful revolutions. Thus Communist movements outside the powers of Communist regimes continued to attract an astonishing number of philosophers, scientists, economist, historians, social theorists, legal scholars, writers, poets and plastic artists, even as their counterparts were suppressed in the Soviet Union, and later Eastern Europe and China.

Today one senses an ever deepening exhaustion of Marxism in all of the areas of its greatest historical influence. Among the mass parties and unions of European labour only an ever smaller minority remains or even calls itself Marxist. The official Marxisms of the established regimes are increasingly ritualized, the operative beliefs of the leaders and ideologists themselves have been shifting toward other doctrines: nationalism, authoritarian technocracy, pragmatism, great power politics, small nation *raison d'état*. Even among third world movements, the remaining area of dynamic influence, Marxism today has more powerful competitors than ever before.

The idea of the 'crisis of Marxism' is almost as old as Marxism itself. There are, nevertheless, deep-seated reasons today why the epoch of Marxism as defined here (and not the rich and varied influence of the thinker Karl Marx) is over. As a world-view Marxism has certainly been shaken by the general secularization, decentralization, differentiation and pluralization of world-views that is for better or worse the hallmark of modernity. More importantly, as a theory of movement it is paradoxically the very successes of Marxism that have undermined it. It is this second aspect that is decisive, because inhibiting the often attempted transformation of Marxism in a direction no longer bound to a comprehensive, metaphysical worldview, i.e. toward a 'critical theory' or a 'philosophy of praxis' in the sense of the early theorists of Western Marxism: Lukacs, Korsch, Gramsci, Horkheimer and Marcuse.

In most general terms then, politically failed attempts can be described as breaks with the tradition of Engels in order to build a new *Marxism* around the *Marxian* legacy itself. This implied in each case not only a return to the Hegelian foundations of Marx's thought, a revival of the key concepts of alienation, reification, consciousness of subjectivity, but also a primary emphasis on the theory of movement dimension and in particular the mediation of theory and praxis. The latter emphasis however depended on an intellectually adequate and politically favourable response on the part of those to be addressed by theory, an impossibility in the case of the actually successful regimes and movements. In the case of the Soviet regime it hardly mattered that the very first Western Marxists sought to give it a new philosophical justification. The abandonment of the metaphysical world-view of Marxism could not be contemplated first of all because Lenin in his *Materialism and Empiriocriticism* helped to canonize it. More fundamentally, such a world view, along with the deterministic and closed structure it lent to Marxian philosophy of history, allowed the ritualization of the doctrine as a new state cult. The anti-authoritarian biases of Western Marxism, formulated in a much repeated critique of bureaucracy,

expressed well the incompatibility of Western and Soviet Marxism, whatever the particular political choices of individual Western Marxists. In the case of Social Democracy the problem was not so much the abandonment of the general world-view of Engels et al., for the Austro-Marxists and other Kantian socialists did this *within* the existing organizational frameworks. The renewed stress on a theory of movement emphasizing revolutionary rupture and future orientation was understood by Social Democrats (except the Austro-Marxists) as expressing the spirit of the rival Bolshevism, with which some founders of Western Marxism were associated. Again more fundamentally the clash was between present and future orientation, bureaucratic organization and movement, (welfare) statism and anti-statism.

In world-historical terms Marxism represented a set of ideological and political responses to the epoch of classical capitalism, to the first stage of K. Polanyi's 'Great Transformation': the self-regulating market. Both of the two major types of outcomes with which 'successful' Marxist movements had an 'elective affinity' were powerfully state strengthening: the emergence of étatist forms of modernization-industrialization where private capital could not or could no longer promote economic development (A. Gerschenkron) and the construction of democratic, interventionist, welfare states in already developed capitalist countries where the 'normal' operation of the self-regulating market produced disastrous consequences not only for the substratum of human life but also for the market economy itself (K. Polanyi). In both cases versions of Marxism were dynamic and influential as ideologies of the process ('revolution' and 'reform') and were made gradually irrelevent by the results. The issue was not only that soviet-type societies and democratic welfare states are not the Marxist 'utopia' or even the 'transitional society'. More damaging was the fact that the Marxian philosophy of history in any of its original versions had no place for a new, industrial form of domination; neither capitalism or socialism, or even a hybrid of the two, while the Marxian critique of political economy had no concepts to deal with the 'primacy of the political' and tended to exclude the possibility of a reconstructed, capitalist society involving a good deal of state interventionism and redistributive activity built upon the institutionalization and integration of the working class and class-based conflict.

Neither the formidable attempts of Trotsky (*Revolution Betrayed*, etc.) and of historians to depict the Soviet Union as a deformed workers' state, nor bureaucratic collectivism or state capitalism, nor the various theories of state-organized monopoly or state monopoly capitalism could successfully address the new contexts. The reason was of course that all these attempts involved a desperate desire to stay within the historico-philosophical framework of Marxism that was deeply enmeshed within the ideological counter-attack of the modern state, or more properly of state-strengthening elites, against the apparently more powerful (under classical capitalism) institutional complex of the modern economy. For this reason above all Marxism has found it hard to remain or to become a critical theory where a version of the modern bureaucratic state became the centre of societal steering and control (Soviet-type societies) or even where modern state and capitalist economy shared steering and control functions in historically unprecedented combinations (welfare states).

The failure of Marxism in face of the modern state has been manifested most openly in the context of the emergence of new types of social movements. The problem was not simply that movements have now been forced to oppose the state (something hardly unprecedented) but, rather the very goals were now reconceived as 'society strengthening'. As a result of important historical learning experiences victory was no longer seen in terms of inclusion in state power ('Reform') or even as smashing the state ('Revolution') but, in the case of the most advanced segments of movements, as rebuilding civil society and controlling (rather than abolishing) market economy and bureaucratic state. Unlike the Social Democracy the state was found not to be a neutral force that could be simply occupied and used by different classes. But as against Bolshevism and even the older Western Marxism (both more orthodox here than Social Democracy) the

programme of smashing the state and the utopia of the withering away of the state were now implicitly recognized as powerfully étatistic. If the modern state does not simply express the power of a class in society but of an independent structure, then contrary to the claim of Engels in *Anti-Dühring* the project of the withering away of the state by way of the abolition of classes and the nationalization of the means of production cannot be successful. On the contrary the very attempt presupposes enormous concentration of state power feeding on the continued social division which it itself constitutes. The actual experience of Marxist revolutionary states (as all previous revolutions according to the judgement of Marx in *The 18th Brumaire*) was a dramatic confirmation of this process, the results representing the most serious challenge to all who seek to defend Marxism in the face of the projects of the new movements.

Of course we cannot yet speak of the actual death of Marxism. In Soviet-type societies as well as in various third world adaptations of this model, Marxism-Leninism still exist as the official state doctrine and cult. However, in a period of the crisis of this model and the failure (after 1968) of bloc-wid reform strategies, the rational elements of any Marxism (e.g. the project and the expectation of dysfunction and crisis free incremental economic development) had to be eliminated. The result is a ritualized, de-intellectualized doctrine increasingly cynically held. This affects Third World contexts, where under Western hegemony and/or right-wing authoritarian domination something like earlier revolutionary versions of Leninism are still upheld. Here the future orientation of Marxian theory is increasingly determined by the actual outcome of the Soviet model which is known and which is decreasingly attractive as against a utopia drawn from Western sources, presupposing Western tradition, one that was nowhere realized. Third World Marxism increasingly reduces to a merely present orientation that involves primarily the assumption of a specific position in world conflicts, or (less attractively) to a conscious preparation for future power positions of the Soviet type. Since the mid-1970s neither of these orientations seem to be able to match more dynamic and radical ideologies where these are available in particular national self determination and religious fundamentalism. Paradoxically, Marxism in the Third World is at its most influential where it is allied with the cultural and political forces of its old enemies: nationalism and radical Catholicism.

The intellectually most significant attempts to renew Marxism in our time (mid-1950s and after) occurred in its historical homeland: Western and Central Europe. The goals of all the relevant trends were to work out critical theories of Soviet type and/or advanced capitalist socialist societies, for the orientation of new types of opposition. What is common among all of them was the attempt, once again, to break with Marxism as a general, metaphysical world-view, while the dimension of a theory of movement was held on to and built upon. Three (and a possible fourth) stages or types can be distinguished in this whole development – each with a relatively different relationship to actual movements.

(1) *Revisionism* was the first of those, primarily of East Central European origins, but radiating to the communist parties of the West as well as to the Soviet Union. Revisionism involved the recovery of the democratic socialist stress of turn of the century revisionism (E. Bernstein et al.), and the corresponding abandonment of Marxian doctrines deemed especially antidemocratic, e.g. the dictatorship of the proletariat. The political high point of revisionism was the preparation of 1956 in Poland and Hungary. The intellectual foundations of revisionism were, however, rather shallow and eclectic; on the one hand non-objectionable features and even the style of Marxism-Leninism were adhered to (at times for pragmatic reasons) and on the other there were attempts to make the very same set of doctrines vehicles for 'socialist legality', industrial democracy, market socialism and at times party pluralism. Thus the failure of revisionism was not only political but also theoretical, and all subsequent attempts to renew Marxism involved far greater efforts at genuine theory building.

(2) The *Renaissance* of Marxism (Lukacs) otherwise called the philosophy of praxis (partially overlapping with Revisionism) was of simultaneously West European, East European and Yugoslav origins. Its return was not only to Marx's own philosophy and social theory, but also to its real predecessor the Western Marxism of the 1920s and 1930s. However, unlike Western Marxism, the Renaissance of Marxism involved at least some attempts to apply Marxian theory to the critique of Soviet type societies. The Renaissance of Marxism, in spite of its common intellectual style was oriented to different political projects in East and West. In East Europe it became the ideology of the internal democratization of communist parties and of reform from above, culminating in the Czech events in 1968. In the West the relevant political streams were the New Left and in some countries movements of working class youth, culminating in the French 1968 as well as the Italian 'hot autumn' 1 year later. Almost all major trends in the Renaissance of Marxism, like their Western Marxist forerunners, were open to at least some elements of non-Marxist thought: Husserl and Heidegger, Freud and Weber, structural linguistics and anthropology, Keynes and the neo-Keynesians were of major influence. The classical intellectual products included the works of Polish, Yugoslav, Czech and Hungarian praxis philosophers, Modzelewski and Kuron's *Open Letter*, Sartre's *Critique*, the early *Socialisme ou Barbarie*, Baran and Sweezy's *Monopoly Capital*, Marcuse's *Soviet Marxism* and *One-Dimensional Man*, the revivals of the older critical theory in West Germany and the United States, of Gramsci in Italy, and finally a good deal of Marx scholarship in France and West Germany. The purely intellectual achievements of the Renaissance of Marxism were significant; to it we owe the present availability of all dimensions of the ouevre of Marx. Politically, however, the Renaissance of Marxism was doomed when established regimes turned away from internal reform in the East, and when the New Left dissipated or proceeded to imitate authoritarian Marxisms imported from the Third World.

The last two stages of the attempted renewal of Marxism, its *Reconstruction* (3) and *Transcendence* (4) are to be located first of all in the changed contexts of movements: the new social movements of the West and the democratic opposition of the East. Each of the two types of attempts is to be found in both world contexts, but the *Reconstruction* of Marxism has its centre in the West while the *Transcendence* of Marxism is primarily Eastern even if there has been very strong French participation. Interestingly enough the movements addressed by both trends are those that reflectively incorporate and criticize the experience of the étatist response to the capitalist economy – thus in a sense they are all 'post Marxist'. Nevertheless, both the Reconstruction and Transcendence of Marxism seek to address post-Marxist movements in ways residually continuous with the tradition. In the case of the first, associated primarily with younger members of the Frankfurt School (Habermas, Offe, Wellmer et al.) the aim was (at least until the mid-1970s) to serve the normative project of human emancipation inherited from Marx and Western Marxism with entirely new theoretical instruments: linguistic philosophy, hermeneutics, systems theory, symbolic interactionism, structural functionalism, social scientific conflict theory, developmental psychology, etc. The Marxian critique of political economy preserved a certain model character for this trend, but only for a non-economistic crisis theory. In the early 1980s it has become clear that the new movements of ecology, feminism, youth and peace (rather than some intellectual new class as some have charged) were the projected addresses of this theoretical strategy.

The transcendence of Marxism, anticipated by Merleau-Ponty's *Adventures of the Dialectic* is represented by thinkers such as Castoriadis, Lefort, Touraine and Gorz in France, and above all a whole series of East European writers, publicists and philosophers like Kolakowski, Juron, Michnik, Kis, Bence and Vajda. In the United States this position is represented by *Telos*, a

journal of radical social thought. The figures of this intellectual topos are not simply non-Marxists or anti-Marxists: they declare their rejection of both dimensions of Marxism as defined here (and especially their foundation: Marx's philosophy of history) while continuing to rely on some key categories of the tradition (theory and practice, state and civil society). This preservation, however, involves some characteristic twists: in particular the normative project of the radical democratic unification of state and society is rejected in the name of an independent civil society and its mediating institutions.

The specific achievement of the Transcendence of Marxism and of the East European opposition addressed by it is the thematization of a self-limiting radical democracy seeking to rebuild or democratize independent societal institutions, seeking to control rather than to absorb modern state and economy. Such a model also seems to correspond to the project of the non-fundamentalist wings of new social movements in the West (the French CFDT and second left, the *Realpolitiker* fraction of the German Greens, etc.) even if the great rhetorical presence of fundamentalists tends to occlude this fact. Furthermore, the project corresponds also to the programmes of present day democratizing movements under Latin American dictatorships: in particular in Argentina, Brazil and Chile. The increasing universality of self-limiting radical democracy or the democratization of civil society has had, since the mid-1970s an apparently decisive effect even on the theorists of the Reconstruction of Marxism, in particular the work of Habermas in the 1980s.

On the other side the achievement of the Reconstruction of Marxism has been above all the creation of a social theory that has surpassed the best in the Marxsian tradition in complexity, scope and self-reflection. Unfortunately we cannot yet speak of the post-Marxist generation either equalling or fully appropriating this social theory. Thus a synthesis of the normative concerns of the transcendence of Marxism with the analytical power of the works of the Reconstruction of Marxism has occurred more in the West than the East, more in Germany than in France. At the same time the politically most advanced expression of such a synthesis took place in the East, in the Polish democratic movement, and was better understood in France than in Germany. Thus it is the paradox of the present situation of even the illegitimate offsprings of Marxism (reminiscent of one described by Marx in 1843) that there is a geopolitical disjuncture between the most advanced version of theory and the most self-reflective form of political action. It is too early to tell if theory and praxis can be brought closer together and if any version of Marxism can serve as a bridge between them. The archaeological link between all versions of Marxism and the strengthening of the state speaks against such possibility in the epoch of the offensive of different models of civil society against the state. The popular understandings of Marxism cannot be easily liberated from previous experience. It may also be the case that the incorporation of the critique of the state in any reconstructed Marxism is destined to burst all conceivable forms that would guarantee even a tenuous continuity with the tradition.

Marxist Economics

Andrew Glyn

By Marxist economics we mean the work of those later economists who based their methodology and approach on the work of Karl Marx. Excluded from discussion here is the enormous body of exegetical literature seeking to amplify the genesis of and development of Marx's own thinking (Rosdolsky 1968). Before discussing three areas where the contribution of Marxists has been most striking and important, it is helpful to bear in mind certain general features of their approach which could be said to separate them off from other traditions in economic theory.

Marxist economists view the capitalist system as essentially *contradictory*, in the sense that its malfunctions derive in an essential way from its structure, rather than representing 'imperfections' in an otherwise harmonious mechanism. At the heart of this structure is the relationship between capital and labour, which is necessarily an exploitative one. The conflict which results has a crucial influence on the way the capitalist system develops in every respect, from the form of technologies developed to the pattern of state policies adopted. Capital accumulation, the motor of the system, cannot therefore be analysed simply in quantitative terms: the structural changes in the economy which it brings are influenced by, and in turn help to shape, relations between the classes. So while the underlying logic of capitalism has remained unchanged, its history can be divided into different periods characterized by particular sets of class relations, technologies, state policies and international structures.

If some of these ideas would seem practically self-evident to economists with any interest in economic history, this underlines the powerful confirmation which the past century has provided for many of Marx's central ideas. It cannot, unfortunately, be said that mainstream economic theory has caught up with this, hiding, under ever more powerful formal techniques, an unchanging conceptual superficiality in its approach.

The body of Marxist economics which underpins the approach of Marxist economists to the analysis of particular phases and aspects of capitalist development may be divided into three main parts: (1) the labour process; (2) value, profits and exploitation; (3) capital accumulation and crises. What follows represents a brief survey of debates around and developments of these aspects of Marx's work; it is necessarily narrowly 'economic' (excluding work on the theory of the state and of classes) and concentrates on theoretical debate rather than on historical application.

The Labour Process

Marx's most fundamental criticism of his Classical predecessors, and especially of Ricardo, was that they failed to analyse how the capitalist system emerged as a specific mode of production resulting from a particular historical process. The dispossession of previously independent producers led to a division of society into workers, with only their labour power to sell, and employers who owned and controlled the means of production. This ownership was the basis of the profit appropriated by the capitalists, for it gave them control over the process of production itself. It allowed the capitalist class as a whole to force the working class to work longer than was required to produce their means of subsistence. Marx paid special attention to this control over the labour process, analysing in great detail how the development of machinery qualitatively increased the depth of this control by literally taking the pace of work out of the hands of the workers. This stress on the process of production as a *labour* process is arguably the most important distinguishing feature of Marxist economics as compared to other schools, which analyse production solely in technical terms (Rowthorn 1980, ch. 1).

It was not, however, until more than 100 years after the publication of volume I of *Capital* that his analysis of capitalist control over the labour process was applied to subsequent developments. Harry Braverman's *Labour and Monopoly Capital* (1972) had as its central theme the striving of employers to separate the conception of tasks from their execution, in order to preserve and enhance their control over the process of work. Frederick Taylor's system of Scientific Management, for example, analysed the operations required of skilled machine tool operatives so that 'scientific' timings could readily be allocated for new types of work. Ford's introduction of the assembly line was similarly intended to force a certain pace of work. Subsequent writers have extended this analysis to describe systems of 'bureaucratic' control exercised in large modern corporations, where effort is secured by payment systems allowing a steady progression of earnings for loyal employees (Edwards 1979).

This more recent work is a revision, as well as an extension, of Marx's own analysis. In his conception of 'modern industry' control over the pace of work was exercised by the machine itself, which carried out the operations on the materials automatically, leaving the worker as a simple machine minder who fed the machine and dealt with minor malfunctions. This pattern, which Marx saw in contemporary developments in the textile industry, has not become the universal one. For in many types of production the worker still carries out operations on the materials. This has made it necessary for the employers to attempt to gain control over the speed of work by mechanical contrivance (the production line which obliges the worker to carry out tasks at a set speed) or organizational means (scientific management). Moreover, it has been more recently argued that 'Fordist' systems of mass production, where there is a minute division of labour, are giving way to more flexible systems where workers perform a greater range of tasks (Aglietta 1979). This reflects the trend towards more sophisticated consumer goods, which demand shorter production runs and more model changes, and also the problems of overcoming the employee dissatisfaction with mindless and repetitive work which exploded in a number of countries at the end of the 1960s.

Marx's fundamental insight remains, however, the inspiration of this whole body of work, focusing on an issue of tremendous contemporary significance as employers struggle with the necessity of restructuring production in the fiercely competitive conditions of the 1980s (see as an example Willman and Winch 1985). Only very recently has mainstream economics begun to address the problem of controlling work, and even then, as argued by Bowles (1985), from a less compelling perspective.

Value, Profits and Exploitation

Critics of Marx, from Böhm-Bawerk (1896) onwards, have always contended that his theory of profits and exploitation was fatally flawed by his reliance on a simplistic 'labour theory of value' – that commodities exchange in proportion to the amount of labour time required to produce them. If the price of a commodity was determined directly by this 'embodied labour', then the wage would directly measure the labour time required to produce the goods which workers bought in order to maintain themselves (the *value of labour power* in Marx's terminology). Profit, being the difference between the value added by the worker and the wage, would similarly measure directly the excess of time worked over the value of labour power, that is the surplus value produced by the worker while under the employer's control. At the level of society as a whole, total profits would be a direct measure of the surplus labour performed by the whole working class, that is the time worked beyond that necessary to reproduce the means of subsistence. Marx's *rate of exploitation*, the ratio of surplus value to the value of labour power, would be directly reflected in the ratio of profits to wages. Marx's insistence that the source of profit was the capitalist's ability to control the labour process, and thus force the working class to perform surplus labour, would receive a clear expression.

Marx himself was quite aware that the assumption he employed in *Capital*, Volume I, that

commodities exchange at their values, that is, in proportion to the labour required to produce them, was a simplification designed to highlight the overall relation between capital and labour. In Volume III he explains that this assumption will only hold when the *organic composition of capital*, that is the ratio between the value of outlays on machinery and materials (*constant capital*) and on wages (the value of labour power), is equal across industries. Where the organic composition differs across industries, then the surplus value produced by workers in a particular industry would represent a greater or lesser rate of profit on total capital employed depending on whether the organic composition was low or high. But exchange in proportion to labour time would inevitably mean that the capitalists within an industry received surplus value equal to that produced by their workers. This is because the commodities they received in exchange would be of equal value to those produced, thus leaving a surplus value for the capitalists, after setting aside what was required to pay for constant and variable capital, just equal to the surplus value their workers produced. Accordingly exchange in proportion to labour time would imply unequal profit rates across sectors, which is impossible under competitive conditions.

Marx's own solution was to propose that commodities exchange not at their values, but at their prices of production. These represented a modification or transformation of values in order to ensure equal rates of profit across sectors despite unequal organic compositions of capital. It was simple for him to show that such prices of production implied that industries with a high organic composition, and which therefore needed to appropriate more surplus value than its workers produced to compensate for the bigger outlays on constant capital, would have to have a higher than average ratio of price of production to value (and vice versa for low organic composition sectors). So Marx's solution to the transformation problem involved a simple redistribution of total surplus value away from labour intensive industries.

As von Bortkiewicz (1906) was the first to point out, Marx's solution to the transformation problem was incorrect. When constructing his prices of production Marx adds the average rate of profit applied to the values of the inputs. But if commodities do not sell at their values then capitalists are not purchasing their inputs at their values but at their prices of production. So correct prices of production have to be calculated on the basis of a simultaneous transformation of inputs *and* outputs from values to prices of production. Marx was actually aware that this further step was necessary but thought, not unreasonably, that it would make no important difference. Unfortunately he was wrong.

For the 'correct' solution to the transformation problem makes it impossible to maintain Marx's equality between such value aggregates as surplus value and the total value of output on the one hand, and their price correlates, profits and total output in money prices. Much subsequent literature (see von Bortkiewicz (1906) and the later generalization by Seton (1957) concentrated on describing the circumstances under which at least one of the 'invariances' between the price and value systems would hold. It can be argued, however, following the Uno school of Japanese Marxists (see Itoh 1980), that this search for numerical equality between surplus value and profit is wholly misconceived, stemming from Marx's failure to maintain consistently his Volume I distinction between the *substance* of value (labour time) and its *form* (money prices). Any attempt to force numerical equality is artificial and thus misleading.

Even so this does not dispose of the 'problem'. For the correct, simultaneous solution also makes the rate of profit on capital employed different from Marx's general rate of profit, calculated as the ratio of surplus value to the value of capital employed (see von Bortkiewicz 1906, and Steedman 1977). What might seem more damaging still is that the rate of exploitation in value terms is not in general equal to the ratio of profits to wages. So Marx's basic expression of the extent of capitalist domination does not find a direct reflection in the money aggregates.

This in fact does not damage Marx's theory at all. The ratio of profits to wages reflects the ratio of surplus product to the bundle of wage goods as manifested in the exchange process (aggregate wages must represent the price of production of

all wage goods and aggregate profits the price of production of the surplus product). The rate of exploitation is the ratio of the work done to produce the two bundles. These two ratios will only be equal when the organic compositions in the sectors producing the wage goods and surplus products are equal. Clearly there is no theoretical necessity for this to hold, though empirical estimates by Woolf (1979) suggest that the deviation of relative prices from relative values for these bundles of commodities may be rather small.

This divergence between the form of exploitation (the ratio of profits to wages) and its real substance (the ratio of surplus value to the value of labour power) can be readily accepted Using Sraffa's construction of a standard commodity to show what pattern of industries would ensure equality between the two ratios seems to add rather little (see Medio 1972). Retreating to the rather grandly named Fundamental Marxian Theorem, that positive profits require positive surplus value (Morishima 1973), also seems unnecessarily defensive in that it fails to explain clearly the relationship between the price and value dimensions. It is important to emphasize that this interpretation of the transformation problem does not establish the case *for* analysis in terms of values. It merely shows how the value categories can be reconciled with the surface phenomena of profits and prices.

Further controversy over the adequacy and usefulness of Marx's theory of value has revolved around two further issues. The whole 'transformation problem' assumed that the values of commodities can be unambiguously defined as the labour time socially necessary for the production of a commodity at prevalent degrees of mechanization, skill, and intensity of work. But critics from Böhm-Bawerk onwards have disputed that differnt types of labour can be 'reduced' to simple labour (see Rowthorn 1980, ch. 6). It has further been argued (Steedman 1977) that in situations of joint production labour values may not be determinable at all. If the output of shepherds is mutton and wool, how can their labour be allocated between the two products? If the employers used the wool and the shepherds ate the mutton it would not be possible to divide the shepherds' total working day into the necessary labour worked to produce the means of subsistence and the surplus labour worked for the employers. More generally, where there are different methods of joint production, the standard method of deriving labour values can lead to their being negative. Negative surplus value has been shown to coexist with positive profits (Steedman 1977), though not uncontroversially (King 1982).

These criticisms have at least made Marxists accept that there are real analytical difficulties in drawing up consistent value schema. The riposte of some (e.g. Himmelweit and Mohun 1981 drawing on the work of I.I. Rubin 1928) that the whole project of deducing values prior to their reflection in market prices in a misguided 'neo-Ricardian' exercise has not found much favour. It seems to abandon any *quantitative* aspect to value theory, leaving simply a *qualitative* emphasis on understanding exchange as an exchange of labours (see Hilferding's reply in Böhm-Bawerk [1896]; Sweezy 1942; Rubin 1928).

The conceptual problems in formalizing value theory hardly differentiate it from other theoretical constructs. The most serious attack on it has come from those claiming that it is *redundant*, that it adds nothing to the conceptualization of equilibrium prices and profits based on physical quantities. This criticism goes back at least to Joan Robinson (1942), was formalized by Samuelson (1971) and re-emphasized by Steedman (1977). Following Sraffa (1960), it is argued that prices and profits can be derived directly from knowledge of the real wage and the requirements of labour and means of production required to produce commodities, and that values can only be derived from the same data. Thus it is said that it is unnecessary to go via values to reach profits (even assuming values can be unambiguously defined). This attack has confronted Marxists with the question – what precisely is it that values are designed to do?

The justifications for using labour as the central conceptual category, and thus analysing exchange and exploitation in terms of embodied labour time have ranged from rather abstract statements of the fundamental role played by labour in Marx's whole theory of society (Shaikh 1981), to the

claim that working with values focuses the analysis on labour's part in production (Dobb 1937). Sen (1978) points out that we naturally focus on the human contribution to production just as we focus on an artist's part in a sculpture. Indeed, critics of value theory never stop to question why they are perfectly happy to regard labour productivity as a vital concern (over time, across countries etc.) but object to the concept of value (which is just the inverse of labour productivity). Certainly for those who accept the central role of the economic surplus produced by the working class in the development of society, and the relations on the factory floor as the key to the production of this surplus, then analysis in terms of labour time is clear and simple. If we want a vivid and forceful way of analysing the relation between capital and labour then labour time seems the obvious category to use. After all what capitalists make workers do is *work*.

Accumulation and Crises

Marx's *Capital* was aimed not only at uncovering the basis of capitalist exploitation but above all at revealing capitalism's 'laws of motion'. Marx argued that competition between capitalists was fought out by their investing in new, more efficient techniques of production and that the economies of scale which this brought acted as a pressure forcing individual capitalists to accumulate (a very different conception from the neoclassical idea of accumulation as trading off present for future consumption – see Marglin 1984). The outcome of this process was the increased concentration of industry (termed centralization by Marx), which was further accelerated by the development of the credit system. Many Marxist writers, from Hilferding (1910) to post-war Marxists (Mandel 1962) have documented this trend, with the conclusion being drawn on occasions that the extent of monopolization was actually destroying the pressure to accumulate (Baran and Sweezy 1966). This seemed to be contradicted, however, by the great boom of the 1950s and 1960s in Europe and Japan, and the spread of international competition which it brought.

For Marx the impact of accumulation, both on the working class and on profits, was dominated by its presumed labour-saving form. Marx argued that higher productivity required an increased volume of constant capital per worker (what later economists have called the capital–labour ratio). While this is not necessarily the case, since new techniques may economize on constant capital, subsequent experience has entirely vindicated Marx's view. What has been more controversial are the implications of this for employment, wages and the rate of profit.

A rising mass of constant capital per worker implies that employment grows more slowly than the capital stock. But whether or not this leads to a rising or falling *reserve army of labour* depends on the strength of accumulation, the rate at which technical progress is labour saving, and the growth of the labour force. In the advanced countries at least, the trend has indeed been for the capitalist sector to overcome pre-capitalist sectors like peasant agriculture, but for those 'set free' to be absorbed into wage labour. It is important here to distinguish the impact of the trend of accumulation on employment (at full utilization of capacity), from periods of 'cyclical' unemployment, which may be of extended duration of course, resulting from the underutilization of capacity during crises. The mass unemployment of the 1970s and 1980s in Europe, for example, is obviously due mainly if not wholly to the crisis of accumulation (that is, the lack of it), rather than to the form accumulation has been taking.

Despite periodic bouts of unemployment there has been a tendency for real wages to grow in line with labour productivity in the advanced countries, that is, for the profit share to be roughly constant over time or even to decline. Despite measurement complications concerning the treatment of self-employment, this suggests that Marx's rate of exploitation has not shown the tendency to increase which he expected would be ensured by the reserve army of labour. Some authors (Gillman 1957, for example) have sought to verify a rising rate of exploitation by reference to Marx's concept of unproductive labour (supervisory staff, bank employees etc.). If these workers are regarded as being paid out of surplus

value, rather than as constituting a cost of production which reduces surplus value, and if their relative importance in the labour force has been rising (which it has), then a rising rate of exploitation is consistent with a rising share of wages in national income. But to argue that the surplus value available to the capitalists for accumulation has declined because, given the growth of productivity of productive workers, there has been a growth in the proportion of unproductive workers, does not seem to add much to the simpler idea that the growth of productivity of all workers has been insufficiently fast relative to real wages.

The rising trend of real wages has raised the issue as to whether Marx's concept of the value of labour power, dependent on the time required to produce the 'necessaries' is still valid. The usual answer has been for Marxists to stress the 'moral and historical' element in the value of labour power as defined by Marx. Periods of strong demand for labour and the development of trade unions have allowed a widening of workers' 'needs', including the provision of more extensive state services. The difficulties that employers have found in cutting real wages, and governments in seriously eroding the welfare services despite the mass unemployment in the 1970s and 1980s, have added conviction to the idea that the current standard of living is, socially, *necessary* (Rowthorn 1980, ch. 7).

Marx argued that the trend towards a rising organic composition would allow the rate of exploitation to be increased, but would nevertheless lead to a falling *rate* of profit on total capital employed as outlays on constant capital would grow. Despite the fact that Marx regarded this Law of the Tendency of the Rate of Profit to Fall as the 'most important law of political economy' it played only rather a background role in the classic works of Marxism (Luxemburg 1913; Hilferding 1910). With the revival of interest in Marxist economics in the late 1960s it received prominence in the works of writers such as Mandel (1975). The main controversy has surrounded whether or not there is a fundamental tendency for the value of constant capital per worker to rise as the Law requires. Marx himself recognized that this was the outcome of a twosided process. The increased mass of constant capital per worker tended to drag the value of capital up. On the other hand the productivity growth which was part and parcel of the process tended to reduce the value of constant capital per worker. Whether the value of constant capital per worker rises or falls depends on whether productivity grows slower or faster than the increased mass of capital per worker. Marx himself gave no convincing reasons why productivity growth should be the slower of the two, and it has long been argued that there is no such reason (Robinson 1942; Sweezy 1942; van Parijs 1980). Attempts to argue that in some sense the rise in the mass of constant capital per worker is more fundamental and that there is a Law of the Tendency of the Rate of Profit to Fall even if it was manifested in an upward trend in the profit rate (Fine and Harris 1978) have not been found convincing. Marxists who have attempted to provide empirical evidence in support of the Law have typically confused the mass of constant capital with its value: the capital–output ratio, which is the price correlate of the value of capital per worker, has not shown an upward trend.

If this objection makes a falling profit trend contingent on the strength of productivity growth (an empirical matter), the second line of objection (originated by Okishio 1961) argues in fact that the techniques willingly introduced by capitalists will never, in and of themselves, result in a lower profit rate for the capitalist class. If can be shown that new techniques which raise the profit rate for the innovating capitalist will also imply, contrary to Marx's belief, a cost saving and thus a higher profit rate for the capitalist class. For the average profit rate to fall with the introduction of new techniques, therefore, there must have been, in addition, some increase in real wages. All this is not to say that the value of constant capital may not rise in some periods, and that it may not be associated with a falling profit rate (both were true of many countries in the early Seventies), but only that there must also be rising wages (as was also the case). It has been argued by Shaikh (1978) that oligopolists might not maximize the profit rate; but even if this were so it could not establish any necessity for the profit rate to fall.

Discussion of the Law of the Tendency of the Rate of Profit to Fall has emphasized the importance of the course of real wages for the development of capitalism. The two main schools of Marxist crisis theory have indeed placed real wages at the centre, but in very different ways. Underconsumptionist theorists (Luxemburg in the classic period, Sweezy amongst later writers) have argued that insufficient growth in real wages depresses the incentive to invest by restricting the market for consumer goods. As Tugan-Baranovsky (summarized by Sweezy 1942) pointed out with the help of Marx's reproduction schemes, it is not possible to prove the *necessity* of a crisis of underconsumptionism from a rising rate of surplus value. As Marx explained, whether or not surplus value was realized depends entirely on capitalists' spending decisions (on investment and consumption). The capitalists could realize a growing share of surplus value provided they were prepared to invest more and more in the capital goods sector (Dept I), even though this investment was destined just to produce more capital goods (Bukharin 1924). So crises of underconsumption, which would arise when capitalists failed to increase their investment in line with the potential surplus value, rely on the behavioural assumption that capitalists will actually not keep up their investment spending. The most influential postwar analysis along these lines, Baran and Sweezy's *Monopoly Capital* (1966, which acknowledges its theoretical debt to Steindl 1952), saw the growing monopolization of US capitalism enhancing the tendency for the share of surplus value to rise, while at the same time relaxing the pressure to invest.

It was something of an irony that just at the time that *Monopoly Capital* was written, Europe and Japan were enjoying a phenomenal boom. Many Marxist economists in these countries favoured an overaccumulation theory of crisis (Glyn and Sutcliffe 1972; Rowthorn 1980, chs 4–6; Itoh 1980). The strength of the boom eroded the reserve army of labour and caused tight labour markets, rising wages and thus falling profits, inflation and a recession (Armstrong et al. 1984). Also emphasized by these theories has been the role of stronger trade unions in pressing for higher state welfare spending and the difficulties that full employment brought for employers attempting to reorganize production to increase productivity (Bowles et al. 1983).

Why these difficulties should lead to a crisis, rather than simply slower growth, again depends on the central question of capitalists' investment behaviour. Precisely why and when a fall in profits leads to a precipitate decline in investment is notoriously difficult to model. Japanese Marxists (Itoh 1980) have made an important contribution by emphasizing the importance of the credit system in both prolonging a boom and initiating a collapse. Kalecki, who immortalized Marx's insight in the dictum 'workers spend what they get, capitalists get what they spend', wrote near the end of his life that the determination of investment 'remains the great *pièce de résistance* of economics' (1971, p. 165).

The recuperative role of crises in restoring the conditions for renewed accumulation has always been stressed by Marxists. It is more plausible in the case of crises due to overaccumulation (where the problem is rising wages) than for underconsumption crises (where wages have been rising too slowly). Indeed, Keynesian policies of demand expansion seem designed to meet the latter, and political difficulties have to be put forward as blocking such an obvious solution (Baran and Sweezy 1966). In crises of overaccumulation Keynesian policies are more likely to be used in reverse, in order to speed up the impact of unemployment in reducing labour's bargaining position over wages and productivity. Some French Marxists, known as the 'Regulation School' have recently emphasized the necessity for the whole pattern of institutions, state policies, technologies etc. to be reformed if a major structural crisis is to be overcome (Aglietta 1979; Boyer 1979; de Vroey 1984). Whether the microchip, decentralization of production, internationalization of production and capital markets, Japanesestyle industrial relations, more freedom for market forces and so forth provide a new 'way out' for capitalism in the 1990s is currently under intense discussion.

If this review of Marxist economics has concentrated on debates about, revisions to, and

extensions of Marx's own ideas it is to emphasize that the days of Stalinist orthodoxy and dogmatic repetition of the texts are gone. Marxist economics is again making a forceful and imaginative contribution to the analysis of contemporary society.

Edward Mason had a significant impact on the economics profession in four disparate areas: through his influence on the Harvard Economics Department; through his role in two separate subfields of the discipline – industrial and development economics; and by exemplifying the dual role of academic and practitioner.

When he came to Harvard in 1919 as a graduate student, he was not in the Harvard mould: he was from the public schools of Kansas and its University. Later, another newcomer and 'provincial', J. Kenneth Galbraith, characterized young Mason's presence by saying 'even when he was an Instructor, where Ed Mason sat there was the head of the table'. He remained a central figure in Harvard Economics for well over 50 years, his only absence a stint in Washington during the Second World War (1941–44). He was one of a handful of senior faculty who dominated the department during its glory days, when it produced about half of all economics Ph.D. degree holders in the United States and was responsible for a substantial fraction of the research produced in the country.

Mason's role at Harvard extended beyond economics. He served for 11 years (1947–58) as Dean of the School of Public Administration and for a short period was second-in-command of the university. While he was its Dean the School of Public Administration became the leading exponent of an emphasis on policy analysis, especially economic analysis, rather than administrative tools and institutions.

Mason taught many of the economists who expanded industrial economics from a preoccupation with regulation and monopoly to an analysis of markets and firms. The 'Masonic Lodge' of ex-students, together with its Grand Master, came to dominate the newly developed applied discipline of industrial organization. Mason stimulated the work by his proposition that the performance of a firm was largely explained by the structure of the market in which it operated. The controversy stimulated by this idea and by the concept of monopolistic competition to which he contributed, helped the subfield of industrial economics to flourish intellectually.

It was typical of Mason to come to research from policy concerns; he exemplified the practitioner–academician. Mason's advice was sought by governments and he was privy to their problems and the facts at their disposal. During the Second World War, he headed the economic staff of the OSS, probably the first US intelligence agency to gather economic intelligence systematically and to analyse possibilities for economic warfare. Later he was Deputy Assistant Secretary of State in charge of Economic Affairs and chief economic adviser to the US delegation at the 1947 Moscow Conference.

In the early 1950s, development economists began to apply many of the standard tools of economics to the special problems and institutions of the poor countries. Mason developed an interest in this subject in typical fashion by setting out to deal with a specific set of policy problems. After returning to Harvard at the end of the war, as Dean of Public Administration, he was asked to organize technical assistance to help Pakistan carry out the economic analysis crucial to rational government decision making. Out of that effort emerged another institution that rightfully could

be seen as created by Mason; the Development Advisory Service, later the Harvard Institute of International Development. A surprising proportion of those who consider themselves development economists had their initial field experience as an adviser, or as their local counter part, in one of the teams fielded by an organization that existed only because Mason managed to persuade Harvard to undertake the non-traditional university function of advising foreign governments.

Massé was born on 13 January 1898, the same day that Emile Zola in his 'J'accuse' revealed the truth about the Dreyfus Affair, which arouses so much passion in French political circles to this day. His family was quick to take sides – in defence of the innocent – and from them Massé quite probably inherited his deep humanism, in which realistic thought was allied with optimism in action.

In 1916, he passed the competitive entrance examinations to both the Ecole Normale Supérieure, in science, and the Ecole Polytechnique. He was a Second Lieutenant in the Artillery from 1917 to 1918, and then opted for the Polytechnique and a career as an engineer. This choice of career foreshadowed a life in which, in a happy marriage, thought and action were to mingle unceasingly. A further spell of training at the Ecole des Ponts et Chaussées, and the start of his career as a government servant, channelled him towards major civil engineering works, and then, quite soon, towards the business world and hydroelectrical improvement works.

This was a decisive turning-point for both the man of action, the builder, and for the thinking economist. Obliged to deal with the management problems raised by the water stocks accumulated in reservoirs, and also with the need to turn them to account, Massé identified the key role of reserves as the means of regulating systems in order to cope with random factors. In his first work, *Les réserves et la régulation de l'avenir*, published in 1946, whose findings had been published two years previously in a paper submitted to the Société Statistique de Paris, Pierre Massé can be seen to be a forerunner of dynamic programming and of the theory of optimum control. In particular, he set forth in this paper two rules for the optimal management of random processes: *(a)* reservoirs should be managed so as to equalize the marginal utility of the water releases and the marginal expected value of the water held in stock; and *(b)* in order to calculate that expected value a strategy for the future should be defined, that is, a sequence of conditional decisions combining at any time the impact of past decisions, the actual outcome of the random processes, and the perception of what future natural conditions will probably be. Kenneth Arrow was later to note, in 1956, that this was the earliest formulation of Richard Bellman's Optimum Principle.

Massé's work was deeply marked by the recognition that in a random world – and the more so with an uncertain future – one could not confine oneself to just a single forecast, and by the need to adopt strategies and regulate stocks. This was to be borne out 20 years later, when he was in charge of the French Commissariat au Plan (Planning Commission). The consistency of the forecasts carried out as part of the National Accounts exercise certainly went some way towards making the plan a 'reducer of uncertainties'. Moreover, under his guidance this achievement was crowned by a forecasting approach in which the seeking of a consensus on the type of development that was desirable was combined with the concern to identify 'factors with potential for the future', and by the devising of 'warning lights',as instruments for marking the

future course that were capable of setting corrective actions in motion.

He was Directeur de l'Equipement at Electricité de France in 1946 for the start of the Plan Monnet and became its Directeur Général Adjoint two-and-a-half years later, a post he held until 1959. In those 12 years he developed, and then applied, linear programming techniques for determining the overall volume of electricity generating plant, and furnished justification for using a national discount rate for setting off present and future income and expenditure against each other. He tirelessly argued with the government in favour of using these clear and rigorous tools, already finding support on the Commissariat Général du Plan. In 1957, he published *Le choix des investissements,* a work which was to become authoritative both in France and abroad.

In February 1959, General de Gaulle appointed Massé to head the Commissariat Général du Plan. He took up his duties backed by the sound experience of a microeconomist who was thoroughly at ease with the idea of maximizing the benefit to the community in managing a public service, and who was attached to the pricing system and to its role in providing guidance and regulation. He sought to make the Plan – which had been largely governed by the concern for consistency and accordingly gave pride of place to analysing interlocking strengths and weaknesses – a structure better directed towards achieving competitiveness, both domestically and on foreign markets. His aim was not only to produce more, but also to produce better quality, with consciousness of costs.

With these goals, he strove to lighten the Plan's structure and make it interlocking with, and not a substitute for, the market. Without losing the valuable contribution of a generalized market survey, backed up with the use of an input–output matrix, he endeavoured to better pinpoint future price and income trends: in this way, programming by volume was to be backed up by an early attempt at programming by value. While the market could show what present prices were, it said practically nothing about future prices, since forward markets covered only narrow sectors and near time-horizons. By the light it shed on the future, the Plan was seen to be an indispensable adjunct to a smoothly working market economy. The 'Centre' had the task of successfully conveying to the 'Periphery' the right price system, and on the basis of this information, the Periphery was able to return to the Centre information on what the intentions were of the decentralized economic agents concerning volumes of goods to be consumed or invested in, and the volumes of factors to be mobilized. In this way, consultation was established between the Centre and the Periphery, converging, after a few successive iterations, towards a dynamic equilibrium. Pierre Massé had already analysed this converging dialogue between the Centre and the Periphery as early as 1952, in 'Pratique et philosophie de l'investissement'. The Commissariat au Plan in fact organized consultations among the major socio-occupational categories; experts could intervene to put figures to the impacts from selecting the options adopted, while the representatives of the state were there to ensure observance of the major policy guidelines defined by the government in agreement with Parliament. Such at least was the theory. Certain departures from it were unavoidable in practice.

However, 'at the same time as it was an act of faith', the Plan continued to be 'an affirmation of the will'. Concerned as he was for a 'less incomplete view of man' to be taken into consideration, Massé succeeded in convincing the most influential circles in his country that a better balance should be struck between private and collective consumption. Thus, a feature of the early 1960s was a new concern for developing communal infrastructures. At the same time, while investigating various development scenarios, he concluded that it was necessary to raise the discount rate (of profitability) – an indicator of the scarcity of capital for government investors – so that it actually corresponded to the marginal efficiency of capital. He also concerned himself with disseminating the practice of constant-price calculations, so that, while changes in relative prices were not ignored, the profitability of infrastructure projects was not made attributable to inflated profits.

Having stressed future values, Massé necessarily broadened the scope of studies to cover price and income trends, and unavoidably brought discussion round to the knotty point of social

tensions. To clarify and persuade, he worked on surplus accounts, establishing a rigorous relationship between the overall productivity gains made from one year to the next, and the sum of benefits available for distribution to customers, suppliers, workers and investors. From this attempt there at least remains a learning approach which the Centre d'Etude des Revenus et des Coûts, set up in 1966 at his instigation, has been engaged in disseminating and extending.

After helping start the Fifth Plan, Massé returned to Electricité de France, of which he was chairman for three years, and secured from the political authorities a sounder channelling of the necessary efforts for investment in the generation of electricity by nuclear power. He thereupon resumed acquaintanceship with business economics, though he did not forsake reflections upon the problems of the national economy, which he was never to abandon thereafter.

In 1977, Massé was elected a member of the Institut de France, which for almost 200 years has gathered together the most eminent French personalities in the humanities, science, history, philosophy and art. He pursued research for the remainder of his life. His body of work attests to a lifelong endeavour to reconcile macro and micro-economists and to ensure the cross-fertilization of their ideas for the social good.

Massie, Joseph (Died 1794)

Murray Milgate

Joseph Massie is one of those figures of mid-18th-century economics about whose life little of real substance is known, but who has nevertheless managed to attract from quite diverse authors a degree of recognition that is not enjoyed by many much less mysterious figures. In *Theories of Surplus Value* Marx praises Massie for the subtlety of his discussion of the general rate of profit; the original edition of this *Dictionary* credits him with a decisive criticism of Locke's theory of the rate of interest; William Cunningham admired Massie's belief that 'only an exhaustive examination of the phenomena of industrial and commercial life' could yield an appropriate understanding of the principles which governed economic activity (1891, p. 81); and historians of economic thought are thankful for his extraordinary activities as a book-collector that yielded a catalogue to a personal library (containing by 1764 more than two thousand items) of economic literature prior to 1750.

From the point of view of economic theory, there would seem to be little doubt that Massie's most important contribution is to be found in his *Essay on the Governing Causes of the Natural Rate of Interest* (1750), which was reprinted with an introduction by Jacob Hollander in 1912. However, quite what it is that makes this short treatise so important is a matter of debate. Some argue that Massie's rejection of the general argument of Locke, that the money rate of interest regulates

the profits of trade, is its key feature. Certainly, the emergence of this line of criticism played a part in shifting the focus of the study of the rate of profit from the sphere of money to the sphere of trade in general – a transition which was to be important in the construction of classical economic theory by Adam Smith and others. On this point, some (like Marx) have been argued that David Hume, who published a more widely canvassed expression of the same ideas after Massie, 'borrowed' them from that author – thereby crediting Massie with a direct, if unacknowledged, influence on the development of economic theory.

However, there is another feature of Massie's discussion of the governing causes of the natural rate of interest which has caught the attention of others. This is his idea that in a competitive economy the *natural* level of the rate of profit is that to which the profits of different trades tend to conform – it was, as Smith was to put it twenty-five years later, the centre of gravitation of the system. Moreover, according to Massie, when the returns to investment in different lines of production are at this natural level, commodities sell for what he calls their *natural price*. The significance of this is, of course, not that Massie used the notion of natural price, but rather that he *defined* natural prices in terms of a general rate of profit.

Massie, however, does not seem to have appreciated that these radically new conceptualizations could provide the basis upon which to build economic arguments of a more systematic, or scientific, character than had hitherto been the case – as Smith, for example, was to do to so great an effect twenty-six years later in the *Wealth of Nations*. Indeed, Massie actually wrote on the question of systematizing economic study, and here his arguments seem to have little in common with the grand theorists. As Cunningham was the first to observe, Massie's *Representation concerning the knowledge of Commerce* (1760a) advocated instead a detailed historical investigation of the actual conditions of industry – so detailed, in fact, that in his account of each branch of industry there was to be sixteen sub-divisions into which each was to be broken. Even for Cunningham, this was pushing the historical method a little too far.

Matching

Giuseppe Moscarini

Abstract

Matching (or job-matching) is the process whereby a firm and a worker meet, learn whether their characteristics combine productively and, in light of this information, sequentially contract a wage and decide whether to separate or to continue production. This hypothesis implies that wages rise and the risk of separation declines with seniority, wage changes are unpredictable and have declining variability, and valuable specific human capital is accumulated in the form of knowledge about the quality of the match.

These and other observable implications have found strong support in available empirical evidence, and make job-matching a central theory of worker turnover.

Matching (or job-matching) is the process whereby a firm and a worker meet, learn whether their characteristics combine productively and, in light of this information, sequentially contract a wage and decide whether to separate or to continue production.

In many respects, a job is like a marriage. Two parties (a firm and a worker) engage in a long-run relationship, whose success depends on a myriad of factors, all quite difficult to describe. Only the actual outcome of the match can reveal the underlying 'fit'. If the match works, it continues; otherwise it is scrapped and the partners try their luck elsewhere.

Jovanovic (1979a) formalizes the job-matching hypothesis in a dynamic, rational-expectations context. This hypothesis hinges on two pivotal ideas: learning and selection. The emphasis on selection follows the tradition of equilibrium sorting in labour markets going back to the static Roy model (1951). Now, dynamics and imperfect information take centre stage. A job is viewed as an 'inspection' as well as an 'experience' good. The worker and the firm have to 'taste' the match to decide its value, just like two people first date (to 'inspect' the match) then possibly get married (to 'experience' the match), with varying degrees of success. Unlike in marriage markets, utility is typically transferable through the wage. The fit between firm and worker characteristics is modelled as a match-specific productivity component, a parameter of the output process, summarizing how well the innumerable relevant characteristics of the worker and of the task actually dovetail. Random noise in production creates a signal extraction problem. The firm and/or the worker continuously observe the output performance of the match, incorporate this information in wages, and reassess it against alternative opportunities offered by the market.

A Job-Matching Model

Output y_t is produced at time $t = 1, 2\ldots$ by a firm and a worker with a 1:1 Leontief technology:

$$y_t = \theta + \varepsilon_t.$$

There is no hours or effort choice. θ is average productivity or 'match quality', drawn by nature, unobserved by firm and worker, at the beginning of the match from $\theta : N(m_{-1}, 1/h_{-1})$, which are also parties' prior beliefs. $\varepsilon_t : N(0, 1/p_\varepsilon)$ is white noise, i.i.d. and independent of θ. Therefore, risk-neutral firm and worker are interested in the permanent component θ. Following the bulk of the literature, assume that firm and worker are symmetrically informed. This is not a crucial assumption: all that matters is that *some* learning drives match selection.

Upon matching at time 0, parties inspect the match and observe a signal

$$x = \theta + \eta$$

where $\eta : N(0, 1/p_\eta)$ independent of θ. By Bayes' rule, $\theta|x : N(m_0, 1/h_0)$, where $h_0 = h_{-1} + p_\eta$ and $h_0 m_0 = m_{-1}\, h_{-1} + x p_\eta$. If the match begins and output is produced at $t = 1, 2\ldots$, posterior beliefs about match quality conditional on the worker's track record are recursively updated as follows:

$$\begin{aligned} &\theta|x, y_1, y_2, \quad \ldots y_t : N(m_t, \ \ 1/h_t) \text{ where} \\ &h_t = h_{-1} + p_\eta + t p_\varepsilon \ \ h_t m_t \\ &\quad = h_{t-1} m_{t-1} + p_\varepsilon y_t. \end{aligned}$$

That is, m_t and h_t are the mean and precision of the normal posterior distribution of θ, conditional on all information available to date t. After solving

backward, m_t is an average of the prior expectation m_{-1}, the initial signal x and the history of output $\sum_{s=1}^{t} y_s$, weighted by their respective precisions. Given the model's parameters, history and beliefs are summarized by expected productivity m_t and by tenure t, which jointly measure the specific human capital accumulated in the relationship.

With no uncertainty and perfect information ($h_{-1} = \infty$ and/or $p_\eta = \infty$), workers and firms would immediately discard unpromising matches and keep drawing better and better outcomes. With imperfect information, equilibrium behaviour is 'sequential' and non-trivial. Equilibrium cannot be perfectly competitive, due to the specificity of match quality and consequently of human capital. Nonetheless, with free entry, no mobility and no capital costs, there is a contracting equilibrium where the wage offered by the firm to the worker equals the worker's expected (marginal) productivity m_t, and firms break even. The worker captures the entire option value of learning. By Bayes's rule, the distribution of the future wage m_{t+1}, unconditional on unknown match quality θ but conditional on current beliefs $\{m_t, t\}$, is normal with

$$\begin{aligned} \mathrm{E}[m_{t+1}|m_t,t] &= m_t \text{ and } Var[m_{t+1}|m_t,t] \\ &= \frac{p_\varepsilon}{\left[h_{-1}+p_\eta+(t+1)p_\varepsilon\right]\left(h_{-1}+p_\eta+tp_\varepsilon\right)} \end{aligned} \tag{1}$$

The worker's value of employment solves the Bellman equation

$$\begin{aligned} V(m_t,t) = \max\langle &\beta \mathrm{E}[V(\tilde{m}_0,0)], \\ &m_t + \beta \mathrm{E}[V(m_{t+1},t+1)|m_t,t\rangle \end{aligned} \tag{2}$$

for some discount factor $\beta \in [0,1]$. At each point in time, including $t = 0$ right after observing the initial signal x and before starting production, the worker decides whether to quit this match at once and to inspect another one next period (expected value $E[V(\tilde{m}_0,0)]$, independent of $\{m_t, t\}$ because θ is match-specific) or to accept the wage m_t, produce, observe the output realization y_t, update beliefs to $\{m_{t+1}, t+1\}$, and decide again.

The worker's employment value $V(m, t)$ is increasing in expected match quality m and decreasing in tenure t. The first effect is obvious. Formally, an increase in m_t raises the right-hand side of (2) directly and, by (1), the normal distribution of future wages in a first-order stochastic dominance sense. Standard dynamic programming arguments establish monotonicity of V. To see why the value V is also decreasing in tenure t, consider the following thought experiment. Before deciding whether to quit or to produce y_{t+1}, the worker is provided with a free signal υ which has the same distribution as y_{t+1}, and is then informative about match quality. After observing this signal, the worker cannot do worse, because he or she can always ignore it. So, before observing υ, she must value this additional information:

$$\begin{aligned} \mathrm{E}_\upsilon[\mathrm{E}[V(m_{t+1},t+1)|\upsilon,m_t,t]] &\geq V(m_t,t) \\ = V(\mathrm{E}_\upsilon[\mathrm{E}[m_{t+1}|\,m_t,t,\upsilon]],t) & \end{aligned}$$

where the equality follows from $\upsilon : y_{t+1}$ and then $\mathrm{E}_\upsilon[\mathrm{E}[m_{t+1}|\mathrm{m}_t, t, \upsilon]] = \mathrm{E}[m_{t+1}|m_t,t] = m_t$. The inequality implies that V is convex in m. Since tenure t reduces the variance of m from (1), it follows from Jensen's inequality that $V(m,t)$ declines in t for given m. Intuitively, a match of equally expected but more uncertain productivity is more valuable: there is some chance it will turn out to be great, otherwise it can always be scrapped.

Testable Implications and Empirical Evidence

The key implications of the model derive from selection and learning, and those implications that are testable have indeed found strong empirical support.

Selection

Given the properties of V, the worker quits as soon as the wage falls short of a reservation wage, which is increasing in tenure. As the option value of learning is consumed, a given expected match quality is no longer sufficient to support the

match. Reservation wages are not directly observable, but the resulting selection does have indirect, testable implications. Only promising matches survive, so the average m_t (wage) in continuing jobs increases (cross-sectionally) with tenure t. Indeed, seniority has modest but consistently positive wage returns (Altonji and Williams 2005). As better matches are less likely to end, the hazard rate of separation, after an initial 'discovery' phase, declines with tenure, a very robust stylized fact (Farber 1994). Finally, censoring bad matches skews the distribution of wage residuals, conditional on observable worker and firm exogenous characteristics: a symmetric and thin-tailed Gaussian distribution of output turns into a distribution of 'unexplained' wages with a thick Pareto upper tail (Moscarini 2005), as in a typical empirical wage distribution.

Learning

From (1), unconditional on the unobserved quality of the match, the wage m_t is a martingale, with variance of innovations declining with tenure t. Beliefs updated in a Bayesian fashion cannot be expected to drift in any direction, for the same reason that asset prices are a random walk in efficient financial markets. Thus, unconditionally on tenure, within-job wage changes are uncorrelated and, as uncertainty about match quality is resolved, have declining variance (Mortensen 1988). Wage growth slows down over the course of a career. Indeed, the search for serial correlation in wage changes has been inconclusive, but the slowdown of wage growth is prevalent (Topel and Ward 1992). The wages of a cohort of workers 'fan out', as some workers are luckier than others and find earlier a good match that pays a high wage, and as commonly observed empirically. When a match separates due to an exogenous layoff (not modelled here, but easy to accommodate), the worker loses the entire match-specific human capital, so she suffers a persistent wage loss. This fully agrees with the available evidence (Jacobson et al. 1993). More problematic is the prediction (Mortensen 1988) that, as $V(m,t)$ falls with t, separation rises with tenure given the wage: empirical evidence (Topel and Ward 1992) suggests the opposite.

Alternative Hypotheses About Worker Turnover

In light of its intuitive appeal and empirical success, job-matching has become the benchmark model of worker turnover. It has in part inspired the canonical search- and-matching model of the labour market (Mortensen and Pissarides 1994), where *ex post* idiosyncratic uncertainty drives job flows while search frictions account for involuntary unemployment. But, despite its vast influence, the job-matching approach still faces alternative and competing views of worker turnover, which provide conceptually quite different explanations for the same set of stylized facts. The starker contrast is with pure search models, which may dispose of heterogeneity altogether. In the search literature, wage dispersion and dynamics originate from firms' power of monopsony and commitment to contracts, due to purely strategic considerations. Retention concerns and counter-offers (Burdett and Mortensen 1998; Burdett and Coles 2003) explain returns to seniority, declining separations rate and so forth. Closer to the job-matching approach is a class of models that retain heterogeneity and selection, but allow for the quality of the job to change physically over time, while in the job-matching model everything is predetermined, and parties only have to learn their fate. Notable examples are firm-specific training (Jovanovic 1979b) and learning-by-doing, as well as stochastic match-specific productivity shocks (Mortensen and Pissarides 1994). In these models, general properties of Bayesian learning, like the declining variance of innovations, must be assumed as ad hoc properties of the productivity process. Nonetheless, this lack of identification poses a formidable challenge, and motivates an ongoing research effort.

Matching and Market Design

Muriel Niederle, Alvin E. Roth and Tayfun Sönmez

Abstract

Matching is the part of economics concerned with who transacts with whom, and how. Models of matching, starting with the Gale–Shapley deferred acceptance algorithm, have been particularly useful in studying labour markets and in helping design clearing houses to fix market failures. Studying how markets fail also gives us insight into how marketplaces work well. They need to provide a thick, uncongested market in which it is safe to participate. Clearing houses that do this have been designed for many entry-level professional labour markets, for the assignment of children to public schools, and for exchange of live-donor kidneys for transplantation.

'Matching' is the part of economics that focuses on the question of who gets what, particularly when the scarce goods to be allocated are heterogeneous and indivisible; for example, who works at which job, which students go to which school, who receives which transplantable organ, and so on. Studying how particular matching markets succeed at creating efficient matches, or fail to do so, has yielded insights into how markets in general work well or badly.

Because market failures have sometimes been successfully fixed by devising new rules for both centralized and decentralized market organization, matching has been a major focus of the emerging field of market design. Some designs by economists have included labour market clearing houses for doctors and other health-care workers in the United States, both for their first jobs and as they enter specialties. Clearing houses have also been implemented in less traditional markets, which cannot adjust prices or wages to help clear the market, such as the matching of students to schools in New York City and in Boston. And new clearing houses are being

implemented for the organization of live-donor kidney exchanges among patients in need of a kidney transplant who have willing donors with whom they are incompatible.

In the next section we review some studies of matching, including some market failures that have been addressed either by introducing appropriate rules to a decentralized market (as in admissions to graduate programmes in American universities), or by introducing a centralized clearing house (as in the markets for new doctors in the United States, Canada, and Britain). The subsequent two sections consider the simple theory behind some clearinghouse designs. Then we return to some of the successful market design applications, which build on the theoretical models, but handle practical problems that are sometimes not yet fully understood in theory.

We focus on three kinds of market failure that sometimes impede efficient matching.

1. Failure to provide *thickness;* that is, to bring together enough buyers and sellers (or firms and workers, schools and students, and so forth) to transact with each other.
2. Failure to overcome the *congestion* that thickness can bring, that is, that can result when lots of buyers and sellers are trying to transact. That is, failure to provide enough time, or failure to make transactions fast enough so that market participants can consider enough alternative possible transactions to arrive at satisfactory ones.
3. Failure to make it *safe* for market participants to reliably reveal or otherwise act on their information.

Some Market Failures and Their Consequences

Unravelling, Congestion and Centralized Clearing Houses

A variety of professional labour markets have suffered from the *unravelling* of appointment dates: from year to year, appointments were made earlier and earlier in advance of actual employment. Markets that had once been thick, with many employers and applicants on the market at the same time, became thin, as potential employees faced early offers, dispersed in time, to which they had to respond before they could learn what other offers might be forthcoming. That is, applicants often received 'exploding' offers that had to be accepted or rejected without waiting to see whether a more desirable offer might be forthcoming. An applicant who accepts such an offer, in the case that acceptances are binding, will never learn of the more desirable offers that might have become available, but if the offer is reasonably desirable rejecting it might be very risky. And, when applicants are quickly accepting offers in this way, employers, when they make offers, have to start taking into account whether the offer is likely to be accepted, since by the time an offer is rejected other desirable applicants may have already accepted offers elsewhere. This often makes unravelling a dynamic process, with offers being made earlier and shorter in duration from year to year. This kind of unravelling has been described in detail in markets for lawyers (Avery et al. 2001), gastroenterologists (Niederle et al. 2006) and many others (see Roth and Xing 1994). A clear example is the market for new doctors (Roth 1984).

The first job for almost all new doctors in the United States and Canada is as an intern or resident at a hospital. In the early 1900s, medical graduates were hired for such jobs near the end of their fourth year of medical school, just before graduation. By the 1930s, hiring was largely completed half a year before graduation, and by the 1940s it had moved to sometimes as much as two years before graduation. That is, in the early 1940s, students were being hired long before they would begin work, at dispersed times, and without much opportunity to consider alternatives, and long before they had sufficient experience to reveal either to employers or to themselves what kinds of medicine they would most prefer and be best able to practise. There was widespread recognition among the participants that the market was often failing to create the most productive matches of doctors to hospitals, both because there was too little opportunity to consider alternatives and because the matching was being done

before important information about students became available.

One way in which many markets tried to address this failure was by attempting to establish rules concerning when offers could be made. In the market for new American doctors, the most concerted attempt at this kind of solution began in 1945 with the help of the medical schools, which agreed not to release any information to hospitals about students until a specified date.

However, the market experienced *congestion* in that hospitals found that they did not always have enough time to make all the offers they would like if their first offer was declined. Over the next few years students were called upon to make increasingly prompt decisions whether to accept offers. In 1945 offers were supposed to remain open for 10 days. By 1949 a deadline of 12 hours had been rejected as too long. Hospitals were finding that, if an offer was rejected after even a brief period of consideration, it was often too late for them to reach their next most preferred candidates before they had accepted other offers. Even when there was a long deadline much of this action was compressed into the last moments, because a student who had been offered a position that wasn't his first choice would be inclined to wait as long as possible before accepting, in the hope of eventually being offered a preferable position. So hospitals felt compelled to pressure students to reply immediately, and offers conveyed by telegram were frequently followed by phone calls requesting an immediate reply.

Congestion can be a problem in any market in which transactions take some time, but it is especially visible in entry-level professional labour markets in which many workers and jobs become available at the same time (for example, after graduation from university, medical school, law school, and so on).

In the face of congestion, many markets unravel, as employers try to gain more time to make offers by starting to do so earlier (Roth and Xing 1994). But the market for new doctors found a solution in the form of a centralized clearing house. Starting in the early 1950s, the various medical groups organized a centralized clearing house, which remains in use today, having undergone some changes over the years. Nowadays, a medical student applies to hospitals and goes on interviews in the winter of the final year of medical school, and then in February submits an ordered preference list of positions to the centralized clearing house, the National Resident Matching Program (NRMP). At the same time, the residency programmes (the employers) submit an ordered preference list of candidates. Once all the preference lists are collected, the clearing house uses an algorithm to produce a match, and residency programmes and applicants are informed to whom they have been matched. Although this clearing house began as an entirely voluntary one, it has been so successful that today it is virtually the only way that most residencies are filled. As we will see below, that success depends critically on the matching algorithm.

The NRMP, and clearing houses like it, also make very clear the kinds of issues involved for a marketplace to make it safe for participants to reveal their information. In a clearing house in which you are asked to state your preferences, the question is simply: is it a good idea to state your true preferences, or would you do better otherwise? For the NRMP we'll see that stating true preferences is indeed both safe and sensible. We'll also discuss clearing houses that failed this test, like the one for placing students into schools in Boston that consequently failed to accomplish their objectives in other ways also, and were redesigned.

Before presenting some formal models that will allow us to start to explain which matching algorithms and clearing houses have been successful and which have failed, it will be helpful to think about several different kinds of matching markets.

Two-Sided and One-Sided Matching Markets

Labour markets, like the market for new doctors, are usually modelled as two-sided markets, in which agents on one side of the market (workers) need to be matched with agents on the other side (employers), and each agent has preferences over possible matches. We'll see below that this two-sided structure allows strong

conclusions to be drawn about the properties of matchings and matching mechanisms.

In many markets this two-sided structure is absent. One way this occurs is when any participant in the market can be matched with any other. For example, if a group of people want to form pairs to be roommates or bridge partners, any one of them can in principle be matched with any other, although not all matchings would be efficient. We encounter markets of this kind when we speak of kidney exchange.

Another way in which markets can be one-sided is if the agents in the market need to be matched to objects, for example when people need to be assigned rooms in a dormitory, or places in a public school that doesn't itself have preferences or take strategic actions (unlike in a two-sided matching market). That is, such a market matches people to places, but only one side, the people, are active participants in the market. Some markets can also be hybrids, with both two and one-sided properties (as when schools aren't strategic players, but still have priorities over students).

Below we consider some static models of two and one-sided matching that have proved useful in the design of clearing houses, and in understanding what they do. In the section on design, we'll also speak about some decentralized design solutions to various market failures, such as unravelling. While there has been some good initial progress on formal models of decentralized markets, and dynamic models in which phenomena like unravelling can play out over time (see for example, Li and Rosen 1998), these areas are still in need of development, and have not yet received the theoretical attention commensurate with their importance in the study of markets generally (though see Niederle and Yariv 2007).

Formal Models of Matching

Two-Sided Matching Models

The workhorse models of two-sided matching come in several varieties. The simplest, presented in detail below, is the 'marriage model' in which each firm seeks to hire only a single worker, and wages and other kinds of price adjustment are represented simply in the preferences that workers and firms have for each other (for example, in these models, wages are part of the job description that determines preferences). However the kinds of results we present here generalize to models in which wage and price formation is explicitly included, some pointers to such models are included in the references.

The marriage model consists of two disjoint sets of agents, men $= \{m_1,\ldots, m_n\}$ and women $= \{w_1, \ldots, w_p\}$, each of whom has complete and transitive preferences over the agents on the other side (and the possibility of being unmatched, which we model as being 'matched to yourself'). Preferences can be represented as rank order lists, for example, if man m_i's first choice is w_3, his second choice w_2 [$w_3 > m_i\ w_2$] and so on, until at some point he prefers to remain unmatched, that is $P(m_i) = w_3, w_2, \ldots m_i \ldots$. If agent k (on either side of the market) prefers to remain single rather than be matched to agent j, that is, if $k > k\ j$, then j is said to be *unacceptable* to k. If an agent is not indifferent between any two acceptable mates, or between being matched and unmatched, we'll say he/she has *strict* preferences.

An outcome of the game is a *matching:* μ: M ∪ W → M ∪ W such that $w = \mu(m)$ iff $\mu(w) = m$, and for all m and w either $\mu(w)$ is in M or $\mu(w) = w$, and either $\mu(m)$ is in W or $\mu(m) = m$. That is, a matching matches agents on one side to agents on the other side, or to themselves, and if w is matched to m, then m is matched to w.

A matching μ is *blocked by an individual* k if k prefers being single to being matched with $\mu(k)$, that is, $k > k\ \mu(k)$. A matching μ is *blocked by a pair of agents* (m,w) if they each prefer each other to the partner they receive at μ, that is, $w > m\ \mu(m)$ and $m > w\ \mu(w)$.

A matching μ is *stable* if it isn't blocked by any individual or pair of agents.

A stable matching is Pareto efficient, and in the core, and in this simple model the set of (pairwise) stable matchings equals the core.

Theorem 1 (Gale and Shapley 1962) A stable matching exists for every marriage market.

Gale and Shapley approached this problem from a purely theoretical perspective, but proved this theorem via a constructive algorithm of the kind that has subsequently turned up at the heart of a variety of clearing houses.

Deferred Acceptance Algorithm, with Men Proposing

(roughly the Gale and Shapley 1962 version).

Step 0. If some preferences are not strict, arbitrarily break ties (for example, if some m is indifferent between wi and wj, order them consecutively in alphabetical order. Different agents may break ties differently: that is, tie-breaking can be decentralized by having each agent fill out a strict preference list...).

Step 1(a). Each man m proposes to his 1st choice (if he has any acceptable choices).

Step1(b). Each woman rejects any unacceptable proposals and, if more than one acceptable proposal is received, 'holds' the most preferred and rejects all others. . . .

Step k(a). Any man who was rejected at step k-1 makes a new proposal to its most preferred acceptable mate who hasn't yet rejected him. (If no acceptable choices remain, he makes no proposal.)

Step k(b). Each woman holds her most preferred acceptable offer to date, and rejects the rest. STOP: when no further proposals are made, and match each woman to the man (if any) whose proposal she is holding.

Note that the proof of the theorem now follows from the observation that the matching produced in this way is itself stable. If some man would prefer to be matched to a woman other than his assigned mate, he must, according to the algorithm, have already proposed to her, and she has rejected him, meaning she has a man she strictly prefers, hence they cannot form a blocking pair.

Roth (1984) showed that the algorithm adopted by the medical clearing house in the 1950s was equivalent to the hospital proposing deferred acceptance algorithm. Gale and Shapley observed that which side of the market proposes in a deferred acceptance algorithm has consequences.

Theorem 2 (Gale and Shapley 1962) When all men and women have strict preferences, there always exists an M-optimal stable matching (that every man likes at least as well as any other stable matching), and a W-optimal stable matching. Furthermore, the matching μ M produced by the deferred acceptance algorithm with men proposing is the M-optimal stable matching. The W-optimal stable matching is the matching μ W produced by the algorithm when the women propose.

Note that the algorithm has been stated as if people take actions in the course of the algorithm, and we can ask whether those actions would best serve their interests. To put it another way, is it possible to design a clearing house in which a matching is produced from participants' stated rank order lists in such a way that it will never be in someone's interest to submit a rank order list different from their true preferences? The following theorem answers that question in the negative.

Theorem 3 Impossibility Theorem (Roth – see Roth and Sotomayor 1990) No stable matching mechanism exists for which stating the true preferences is a dominant strategy for every agent.

However it is possible to design the mechanism so that one side of the market can never do any better than to state their true preferences.

Theorem 4 (Dubins and Freedman, Roth – see Roth and Sotomayor 1990)

The mechanism that yields the M-optimal stable matching (in terms of the stated preferences) makes it a dominant strategy for each man to state his true preferences.

The conclusions of Theorems–3 also hold for a variety of related models (in which firms employ multiple workers, and wages are explicitly allowed to vary; see, for example, Shapley and Shubik 1971; Kelso and Crawford 1982, for notable early models of matching with money, and see Roth and Sotomayor 1990; Hatfield and Milgrom 2005). However, when we look at many-to-one matching models (in which firms employ multiple workers but workers seek just one job), we have to be careful. It turns out that no procedures exist that give firms a dominant strategy, but that a worker proposing deferred acceptance algorithm still

makes it a dominant strategy for workers to state their true preferences (see Roth and Sotomayor 1990 for more details and further references). (These results are closely connected to related results in auction theory; see in particular Hatfield and Milgrom 2005; Milgrom 2004.)

When the market for medical residents was redesigned Roth and Peranson (1999), a number of practical complications had to be dealt with, such as the fact that about 1000 graduates a year go through the match as couples who wish to be matched to nearby jobs, and hence have joint preferences over pairs of residency programmes. While this can cause the set of stable matchings to be empty, in practice this has not proved to be a significant problem (see also Roth 2002, on engineering aspects of economic design).

One-Sided Matching Models

Shapley and Scarf's 'House' Markets

Another basic model of matching markets was introduced by Shapley and Scarf (1974). They model a simple barter economy in which each one of n agents owns an indivisible good (which they call a house) and has preferences over all houses in the economy. Each agent has use for only one house and trade is only feasible in houses (that is, there is no money in their model). An allocation μ in this context is a matching of houses and agents so that each agent receives one and only one house. An exchange in this market does not need to be bilateral. An allocation μ is in the core if no coalition (including single agent coalitions) of agents can improve upon it (in the sense that all are weakly better off and at least one is strictly better off) by swapping their own houses. Shapley and Scarf attribute to David Gale the following *top trading cycles* algorithm (TTC) which can be used to find a core allocation for any housing market:

Step 1: Each agent points to the owner of her most preferred house (which could possibly be herself). Since there are finite number of agents there is at least one *cycle* (where a cycle is an ordered list (i_1, i_2, …, i_k) of agents with each agent pointing to the next agent in the list and agent *ik* pointing to agent i_1). In each cycle the implied exchange is carried out and the procedure is repeated with the remaining agents.

In general, at.

Step k: Each remaining agent points to the owner of her most preferred house among the remaining houses. There is at least one cycle. In each cycle the implied exchange is carried out and the procedure is repeated with the remaining agents.

The algorithm terminates when each agent receives a house.

Theorem 5 (Shapley and Scarf 1974) The TTC algorithm yields an allocation in the core for each housing market.

The core has some remarkable properties in the context of housing markets. The following propositions summarize the most notable of these results.

While exchange is feasible only in houses, a *competitive allocation* of a housing market can be defined via 'token money'. There is an important relation between the core and the competitive allocation for this very basic barter economy.

Theorem 6 (Roth and Postlewaite 1977) There is a unique allocation in the core (which can be obtained with the TTC algorithm) when agents have strict preferences over houses. Moreover the unique core allocation coincides with the unique competitive allocation.

Another remarkable feature of this model is that the top trading cycles mechanism makes it safe for agents to reveal their true preferences.

Theorem 7 (Roth 1982) The core as a mechanism is *strategy-proof* when agents have strict preferences over houses. That is, truth-telling is a dominant strategy for all agents in the preference revelation game in which TTC is applied to the stated preferences to produce an allocation.

Moreover, it is essentially the only mechanism that is strategy-proof among those that are Pareto efficient and *individually rational* (in the sense that an agent never receives a house inferior to her own).

Theorem 8 (Ma 1994) The core is the only mechanism that is Pareto efficient, individually rational and strategy-proof.

House Allocation Problems

Hylland and Zeckhauser (1979) introduced the *house allocation problem* which only differs from housing markets in *property rights*: There are n houses to be allocated for n agents where each agent has use for only one house and has strict preferences over all houses. Unlike in housing markets, no agent owns a specific house. The mechanism known as *random serial dictatorship* (RSD) is widely used in real-life allocation problems of this sort, such as assigning students to dormitory rooms.

Under RSD agents are randomly ordered (from a uniform distribution) in a list and the first agent in the list is assigned her top choice house, the next agent is assigned her top choice among the remaining houses, and so on. In addition to its popularity in practice, RSD has good incentive and efficiency properties.

Theorem 9 RSD is *ex post* Pareto efficient and strategy-proof.

Recall that the only difference between house allocation problems and housing markets is the initial property rights, and the core is very well-behaved in the context of the latter. This observation motivates the mechanism *core from random endowments* (CRE): randomly assign houses to agents with uniform distribution, interpret the resulting matching as the initial allocation of houses, and pick the core of the resulting housing market. It turns out, CRE is equivalent to RSD.

Theorem 10 (Abdulkadiroglu and Sönmez 1998) For any house allocation problem CRE and RSD yield the same lottery and hence they are equivalent mechanisms.

House Allocation with Existing Tenants

Housing markets and house allocation problems have very different property rights. The former is a pure private ownership economy where each house 'belongs' to a specific agent, whereas in the latter no strict subset of the grand coalition has claims on any house. Abdulkadiroglu and Sönmez (1999) introduced the following hybrid *house allocation with existing tenants* model. There are two kinds of agents: *existing tenants* each of whom owns a house, and *newcomers* none of whom has claims on a specific house. In addition to the *occupied houses* owned by existing tenants, there are also *vacant houses*. As in house allocation problems no specific person or group has claims on any vacant house. Suppose that the number of newcomers is equal to the number of vacant houses and hence the number of agents is equal to the number of houses. Agents have strict preferences over all houses and each existing tenant is allowed to keep her current house.

Abdulkadiroglu and Sönmez introduced the following *you request my house −1 get your turn* algorithm (YRMH–IGYT) which generalizes TTC as well as RSD. Under YRMH–IGYT, agents are randomly ordered in a line and initially only the vacant houses are *available.* The first agent in the line is assigned her top choice provided that it is either her own house or an available house (in which case her own house becomes available) and the process continues with the next agent in the line.

If, however, her top choice is an occupied house, the line is adjusted and the owner of the requested house is moved right in front of the requester. The process continues in a similar way with either the owner of the requested house getting assigned his own house or an available house (making his own house available), or otherwise his requesting an occupied house and upgrading its owner to the top of the line. When the process continues in a similar way there will either be a *cycle* of existing tenants (as in TTC) who can swap their own houses or a *chain* $(i_1, i_2, \ldots, i_k)$ of agents where agent i_1 is assigned an available house and each of the following agents is assigned the preceding agent's house.

The resulting mechanism inherits the attractive properties of its 'parents'.

Theorem 11 (Abdulkadiroglu and Sönmez 1999) The YRMH–IGYT mechanism is strategy-proof, *ex post* Pareto efficient, and individually rational (in the sense that no existing tenant receives a house inferior to her own).

Kidney Exchange

Living donors are an important source of kidneys for transplantation. But a patient with a willing living donor may not be able to receive a transplant because of a blood-type or immunologic incompatibility between her and her donor. Recently transplant centres around the world developed the possibility of *pairwise kidney exchange* in which two such pairs can exchange donors in case the donor in each pair is compatible with the patient in the other. Another interesting option is *indirect kidney exchange* in which the patient of an incompatible pair receives priority in the deceased donor waiting list if her incompatible donor donates a kidney to that waiting list. However, prior to 2004 only a very few exchanges had been accomplished, in large part because the market wasn't thick, and no databases were being maintained of incompatible patient–donor pairs. In an effort to organize kidney exchange on a larger scale, Roth et al. (2004) introduced the following *kidney exchange* model. There are a number of patients each with a (possibly) incompatible donor. For each patient a subset of donors can feasibly donate a kidney and the patient has strict preferences over these donors and his own donor (who may or may not be compatible with him). In addition to ranking all compatible donors, each patient also ranks a 'waiting list option' which represents trading his donor's kidney with a priority in the waitlist. An *allocation* in this context is a matching of patients and donors such that:

- each patient is matched with either a donor or the waiting list option, and
- each donor can be matched with at most one patient while the waiting list option may be matched with multiple patients.

(The donors who remain unmatched are offered to the waitlist in exchange for the equal number of priorities awarded by the allocation). We are only interested in *individually rational* allocations where patients receive neither a donor nor the waiting list option unless it is indicated to be at least as good as his donor's kidney. If the waiting list option is ranked inferior to his donor for a patient, that means the patient is not interested in such an exchange. As in the case of house allocation with existing tenants model, an allocation consists of cycles and chains where

- each patient in a cycle receives a kidney from the donor of the next patient in the cycle, and
- all but the last patient in a chain receive a kidney from the donor of the next patient in the chain whereas the last patient in the chain receives a priority in the waiting list.

If the waiting list option is infeasible, then the resulting problem is formally equivalent to a housing market and therefore has a unique allocation in the core which can be obtained via the TTC algorithm. In this simpler model an allocation (including the one in the core) consists of only cycles. When the waiting list option is feasible an allocation can also have chains (which are indirect exchanges and their more elaborate versions). In this more general model Roth et al. (2004) introduce a class of *top trading cycles and chains* (TTCC) algorithms each of which extend the TTC. Among these algorithms Roth et al. (2004) identify one that is Pareto efficient and strategy-proof:

Theorem 12 (Roth et al. 2004) There exists a TTCC mechanism that is Pareto efficient and strategy-proof.

In practice, as kidney exchanges have become organized on a larger scale in New England and elsewhere (see Roth et al. 2005a, b, 2007), there has been a focus, for logistical reasons, on cycles and chains that are relatively short, typically only involving exchanges among two or three patient–donor pairs.

The deferred acceptance algorithm (for two-sided markets) also has some uses in

one-sided allocation problems in which children are to be allocated to schools, if the schools, although not active strategic players, have priorities over students that need to be treated like preferences (Abdulkadiroglu and Sönmez 2003).

Design and Engineering

Introducing a Centralized Stable Match

Of the several dozen markets and submarkets we know of that established clearing houses in response to unravelling in a (two-sided) labour market, those that produce stable matchings have been most successful. Of particular note in this regard are the markets used in the various regions of the British National Health Service. In the 1960s, these markets suffered from the same kind of unravelling that had afflicted the American medical market in the 1940s. A Royal Commission recommended that each region organize a centralized clearing house (see Roth 1991), and the various regions each invented their own matching algorithms, some of which were stable and some of which were not (an example of such unstable algorithms will be given later). Those clearing houses that produced stable matches succeeded, while those that did not most often failed and were abandoned. But over a broad range of markets, the correlation between stability and success in halting unravelling isn't perfect; some unstable mechanisms remain in use, and some stable mechanism have occasionally failed, as we will discuss later. And there are other differences between markets than the way their clearing houses are designed. This is why, in order to establish that producing a stable outcome is an important feature for the success of a match, controlled experiments in the laboratory can be informative.

The laboratory experiments reported by Kagel and Roth (2002) help to verify the influence of a stable or unstable matching mechanism. After unravelling had begun in a small laboratory market, a clearing house was introduced using either the stable deferred acceptance algorithm or the unstable algorithms that failed in various regions of the British National Health service (Roth 1991). In the lab, as in the field, participants learned to wait for and use the stable algorithm, but learned to arrange their matches early and thus avoid using the unstable algorithm. Note that a laboratory market is quite different from a naturally occurring labour market, but it has the advantage that it allows the effect of the different algorithms to be observed in an environment in which everything else is the same.

Centralized clearing houses that yield stable outcomes have sometimes been introduced to organize markets suffering from failures other than unravelling (and the resulting lack of thickness), but related to congestion or the safety of revealing private information.

Examples of algorithms that produce unstable outcomes, but have been used in a number of market clearing houses, are so called priority algorithms, used for example by some British clearing houses, and also in several school choice problems in the United States. A priority algorithm classifies different matches in terms of priorities, based on the rank orders submitted, and then makes feasible matches in order of priority. In Boston, for example, the centralized system attempted to give as many students as possible their first choice school. The difficulty with the system was that students who did not get assigned to their first choice were much less likely to be assigned to the school they had listed as their second choice than they would have been if they had listed it as their first choice, since those schools often get filled by students who list them as their first choice. This means participants have strong incentives to not report their preferences truthfully, if there is a good chance that they would not be admitted to their true first choice school; it might be wiser to list their second-choice school as their first choice. The newly adopted Boston clearing house fixes this problem using a deferred acceptance algorithm (Abdulkadiroglu et al. 2005, 2006).

Some markets manage to halt unravelling, but still suffer from congestion. The market for clinical psychologists (before it reorganized through a modified deferred acceptance algorithm, see Roth and Xing 1997) and the match of students to New York City high schools before it was redesigned

(Abdulkadiroglu et al. 2005, 2006) are good examples. Clinical psychologists tried to run a deferred acceptance algorithm over the phone in the course of a day, 'match day,' from 9:00 a.m. to 4:00 p.m. All offers had to remain open until 4 p.m., and students were supposed to hold only one offer at a time. Even though turnaround time in this market was very fast (offers took about five minutes, rejections about one minute), simulating a deferred acceptance algorithm in real time, for a market with about 2000 positions in 500 programmes, takes much longer than the seven hours of match day. (And making the market longer may increase the effects of congestion, if it means that participants can no longer stay by the phone for the whole market, so that the time for an offer to be made and rejected becomes disproportionately longer.) Congestion is an issue whenever a large number of offers have to be made. The system used to assign students to New York City high schools used to be carried out through the mails, and over 30,000 students a year were 'stranded' on waiting lists and had to be assigned to a school for which they had expressed no preference. The new New York City clearing house is able to process preferences quickly, and in the four years following its adoption in 2003 fewer than 3000 students had to be assigned each year to a school for which they had expressed no preference.

What Are the Effects of a Centralized Match?

Centralized clearing houses can help make markets thick and uncongested, and avoid unravelling. Studying their effect on various markets can also help us understand how clearing houses and the timing of the market (for example, how far a labour market operates in advance of employment) influence the outcome of the market in other respects. For example, the market for gastroenterology fellows provides us with a natural case study of the effects of a clearing house not only on hiring practices (namely the timing of the market, and the kinds of offers that are made), but also employment opportunities, job placement and the potential impact on wages.

Gastroenterology fellows are doctors who have completed three years of residency in internal medicine, and are now employed in a fellowship that will result in their becoming board certified sub-specialists in gastroenterology. The market in which gastroenterology fellows are hired operated in a decentralized way for many years, and experienced the problems of congestion, unravelling and exploding offers, as described above in connection with the market for medical residents. In 1986, various internal medicine sub-specialties organized a clearing house called the Medical Specialties Matching Program (MSMP), sponsored by and organized along the same lines as the NRMP (which operates the resident match). But in the mid-1990s, gastroenterology fellowship programmes, and applicants, started to defect from the match, and the gastroenterology market again unravelled. A match was successfully re-established only in 2006 (Niederle et al. 2006). In those intervening years, as the market unravelled, the national market broke up into more local markets (Niederle and Roth 2003b). Fellowship programmes, particularly smaller ones, had a larger tendency to hire their own residents than under a centralized match.

A second aspect of the outcome that received prominence in 2002 is the question of whether a match affects wages. An antitrust lawsuit against the NRMP and numerous other defendants was brought in 2002 by 16 law firms on behalf of three former residents seeking to represent the class of all former residents (and naming as defendants a class including all hospitals that employ residents).

Niederle and Roth (2003a) showed empirically that in fact there is no difference in wages between medicine sub-specialties that use a match and those that don't. The suit was dismissed in 2004 following legislation intended to clarify that the medical match is a marketplace and does not violate antitrust laws.

The theory of the complaint was that a match holds down wages for residents and fellows. Bulow and Levin (2006) present a very stylized theoretical model providing some logical support for this possibility, by comparing a market with impersonal prices (to represent the NRMP) with perfectly competitive prices at which each worker is paid his or her marginal product. Subsequent

theoretical papers have shown that the conclusion about wage suppression doesn't necessarily follow if the model is expanded to include the possibility of firms hiring more than one worker (Kojima 2007), or when the model incorporates the actual procedures by which the medical match is conducted (Niederle 2007). Furthermore, decentralized markets may often fail to achieve stable outcomes (Niederle and Yariv 2007).

Beyond Centralized Matching. Why Do Some Markets Work Well, While Others Do Not?

We have seen that stability is an important feature for a centralized match to remain in use. However, the history of the gastroenterology market shows that producing a stable outcome is not sufficient to guarantee a successful clearing house. For a centralized match to work well, participants need to have incentives to participate in the match. McKinney et al. (2005) observed that the collapse of the gastroenterology fellowship match seems to have been caused by an unusual shock to the supply of highly qualified gastroenterology fellows, a kind of shock that was not observed in other internal medicine sub-specialties that continued to use a match. Furthermore, market conditions seemed to have stabilized, so that a centralized match would work well once again, if it could be successfully reinstated.

However, many gastroenterology fellowship programmes, when they considered reinstituting a match, were concerned that, while they were willing to refrain from making the early offers that had become customary, and wait for the match, their main competitors would continue to make early exploding offers to promising applicants. Such concerns could effectively prevent a successful restart of a centralized clearing house.

This raises the more general question as to why some markets unravel and experience congestion problems in the first place, while others do not. Empirically, most markets that experience congestion also experience that employers (hospitals, federal judges, colleges...) make short-term offers, with a binding deadline, and in which the acceptance of an offer is often effectively binding (Niederle and Roth 2007, for descriptions in the markets for law graduates, and for college admissions, see for example, Avery et al. 2001, 2003, 2007).

On the other hand there are markets that do not unravel, such as the market for graduate school admission. In this market, a policy (adopted by the large majority of universities) states that offers of admission and financial support to graduate students should remain open until 15 April. Furthermore, a student faced with an earlier deadline is explicitly encouraged to accept this offer, and, in case a better one is received before 15 April, to renege on that former acceptance. This of course makes early exploding offers much less attractive to make. Niederle and Roth (2007) explore environments in which either eliminating the possibility of making exploding offers or making early acceptances non-binding helps prevents markets from operating inefficiently early.

These insights were used to help reorganizing the gastroenterology fellowship match. To reduce the concerns of programmes that their competitors would start making exploding offers before the match, a resolution was adopted by the four main professional gastroenterology organizations that stated that acceptances made before the match were not to be considered binding, and such applicants could still change their minds and participate in the match. For an account of the effects of a centralized clearinghouse on the outcomes of a market, and the experience of the gastroenterology fellowship market, see Niederle and Roth (2008).

Directions for Future Research

As economists' understanding of the matching function of markets increases, and as economists are more often called upon to help design markets, one challenge will be to understand better how decentralized markets work well or badly, and not only in the final transactions.

For example, a common problem in many entry-level labour markets (and in dating and marriage markets) is that participants do not have well formed preferences over potential matching partners, and forming those preferences is often very costly. For example, in the American market for assistant professors, economics departments

receive hundreds of applications for any position, but in general interview only about 30 candidates at the annual winter meetings. From among those they interview, they must decide whom to fly out for extended campus visits and seminars, and it is from among this latter set of candidates that they eventually choose to whom to make an offer. Because this is a time-consuming and costly process many departments have to take care to interview applicants who not only have a good chance of being desirable colleagues, but who also have a good chance of accepting an offer if one is made. This often amounts to a coordination problem: not all departments should interview the same applicants. Allowing applicants to credibly submit information about their interest in particular schools can help alleviate this coordination problem, and in 2007 the American Economic Association implemented a signalling mechanism of this sort in the market for economists.

In general, the study of the matching function of markets has directed attention at the design of rules and procedures of both centralized and decentralized markets. The goal of the growing interest among economists in matching and market design is to understand the operation of markets, both centralized and decentralized, well enough so we can fix them when they're broken.

Matching Estimators

Petra E. Todd

Abstract

Matching methods are a popular method for evaluating the effects of programme or other treatment interventions. This article reviews recent developments in the econometric literature on matching estimators, including the assumptions required to justify their application, different ways of implementing the estimators and some recent empirical applications.

Introduction

Matching is a widely used non-experimental method of evaluation that can be used to estimate

the average effect of a treatment or programme intervention. The method compares the outcomes of programme participants with those of matched non-participants, where matches are chosen on the basis of similarity in observed characteristics. One of the main advantages of matching estimators is that they typically do not require specifying the functional form of the outcome equation and are therefore not susceptible to misspecification bias along that dimension. Traditional matching estimators pair each programme participant with a single matched non-participant (see, for example, Rosenbaum and Rubin 1983), whereas more recently developed estimators pair programme participants with multiple non-participants and use weighted averaging to construct the matched outcomes.

We next define some notation and discuss how matching estimators solve the evaluation problem. Much of the treatment effect literature is built on the potential outcomes framework of Fisher (1935), exposited more recently in Rubin (1974) and Holland (1986). The framework assumes that there are two potential outcomes, denoted (Y_0, Y_1) that represent the states of being without and with treatment. An individual can be in only one state at a time, so only one of the outcomes is observed. The outcome that is not observed is termed a *counterfactual outcome*. The treatment impact for an individual is

$$\Delta = Y_1 - Y_0,$$

which is not directly observable. Assessing the impact of a programme intervention requires making an inference about what outcomes would have been observed in the no-programme state. Let $D = 1$ for persons who participate in the programme and $D = 0$ for persons who do not. The $D = 1$ sample often represents a select group of persons who were deemed eligible for a programme, applied to it, got accepted into it and decided to participate in it. The outcome that is observed is $Y = DY_1 + (1 - D)Y_0$.

Before considering different parameters of interest and their estimation, we first consider what is available directly from the data. The conditional distributions $F(Y_1|\, X, D = 1)$ and $F(Y_0|\, X, D = 0)$ can be recovered from the observations on Y_1 and Y_0, but not the joint distributions $F(Y_0, Y_1|\, X, D = 1)$, $F(Y_0, Y_1|\, X)$ or the impact distribution, $F(\Delta|\, X, D = 1)$. Because of this missing data problem, researchers often aim instead on recovering some features of the impact distribution, such as its mean. The parameter that is most commonly the focus of evaluation studies is the *mean impact of treatment on the treated*, $TT = E(Y_1 - Y_0|\, D = 1)$, which gives the benefit of the programme to programme participants. (If the outcome were earnings and the TT parameter exceeded the average cost of the programme, then the programme might be considered to at least cover its costs.)

Matching estimators typically assume that there exist a set of observed characteristics Z such that outcomes are independent of programme participation conditional on Z. That is, it is assumed that the outcomes (Y_0,Y_1) are independent of participation status D conditional on Z,

$$(Y_0, Y_1) \perp\!\!\!\perp D|Z. \tag{1}$$

The independence condition can be equivalently represented as $\Pr(D = 1|\, Y_0, Y_1, Z) = \Pr(D = 1|\, Z)$, or $E(D|\, Y_0, Y_1, Z) = E(D|\, Z)$. In the terminology of Rosenbaum and Rubin 1983, treatment assignment is 'strictly ignorable' given Z. It is also assumed that for all Z there is a positive probability of either participating ($D = 1$) or not participating ($D = 0$) in the programme: that is,

$$0 < \Pr(D = 1|\, Z) < 1. \tag{2}$$

This assumption is required so that matches for $D = 0$ and $D = 1$ observations can be found. If assumptions (1) and (2) are satisfied, then the problem of determining mean programme impacts can be solved by substituting the Y_0 distribution observed for matched on Z non-participants for the missing participant Y_0 distribution.

The above assumptions are overly strong if the parameter of interest is the mean impact of treatment on the treated (TT), in which case a weaker conditional mean independence assumption on Y_0 suffices (see Heckman et al. 1998a, b):

$$E(Y_0|Z,D=1) = E(Y_0|Z,D=0) = E(Y_0|Z). \quad (3)$$

Furthermore, when TT is the parameter of interest, the condition $0 < \Pr(D=1|Z)$ is also not required, because that condition is only needed to guarantee a participant analogue for each non-participant. The TT parameter requires only

$$\Pr(D=1|Z) < 1. \quad (4)$$

Under these assumptions, the mean impact of the programme on programme participants can be written as

$$\begin{aligned}\Delta_{TT} &= E(Y_1 - Y_0|D=1)\\ &= E(Y_1|D=1) - E_{Z|D=1}\{E_Y(Y|D=1,Z)\}\\ &= E(Y_1|D=1) - E_{Z|D=1}\{E_Y(Y|D=0,Z)\},\end{aligned}$$

where the second term can be estimated from the mean outcomes of the matched on Z comparison group. (The notation $E_{Z|D=1}$ denotes that the expectation is taken with respect to the $f(Z|D=1)$ density.)

Assumption (3) implies that D does not help predict values of Y_0 conditional on Z which rules out selection into the programme directly on values of Y_0. However, there is no similar restriction imposed on Y_1, so the method does allow individuals who expect to experience higher levels of Y_1 to select into the programme on the basis of that information. For estimating the *TT* parameter, matching methods allow selection into treatment to be based on possibly unobserved components of the anticipated programme impact, but only in so far as the programme participation decisions are based on the unobservable determinants of Y_1 and not those of Y_0.

Second, the matching method also requires that the distribution of the matching variables, Z, not be affected by whether the treatment is received. For example, age, gender, and race would generally be valid matching variables, but marital status may not be if it were potentially affected by receipt of the programme. To see why this assumption is necessary, consider the term

$$\begin{aligned}&E_{Z|D=1}\{E_Y(Y|D=0,Z)\}\\ &= \int_{z\in Z}\int_{y\in Y} y f(y|D=0,z) f(z|D=1)\mathrm{d}z.\end{aligned}$$

It uses the $f(z|D=1)$ conditional density to represent the density that would also have been observed in the no treatment ($D=0$) state, which rules out the possibility that receipt of treatment changes the density of Z. Variables that are likely to be affected by the treatment or programme intervention cannot be used in the set of matching variables.

With non-experimental data, there may or may not exist a set of observed conditioning variables for which (1) and (2), or (3) and (4), hold. A finding of Heckman et al. (1997) and Heckman et al. (1996, 1998a, b) in their application of matching methods to data from the Job Training and Partnership Act (JTPA) programme is that (2) and (4) were not satisfied, because no match could be found for a fraction of the participants. If there are regions where the support of Z does not overlap for the $D=1$ and $D=0$ groups, then matching is justified only when performed over the *region of common support*. The estimated treatment effect must then be defined conditionally on the region of overlap. Some methods for empirically determining the overlap region are described below.

Matching estimators can be difficult to implement when the set of conditioning variables Z is large. If Z are discrete, small-cell problems may arise. If Z are continuous and the conditional mean $E(Y_0|D=0,Z)$ is estimated nonparametrically, then convergence rates will be slow due to the so-called *curse of dimensionality* problem. Rosenbaum and Rubin (1983) provide a theorem that can be used to address this dimensionality problem. They show that for random variables Y and Z and a discrete random variable D

$$\begin{aligned}&E(D|Y,P(D=1|Z))\\ &\quad = E(E(D|Y,Z)|Y,\Pr(D=1|Z)),\end{aligned}$$

so that

$$\begin{aligned}&E(D|Y,Z) = E(D|Z)\\ &\Rightarrow E(D|Y,\Pr(D=1|Z) = E(D|\Pr(D=1|Z)).\end{aligned}$$

This result implies that, when Y_0 outcomes are independent of programme participation conditional on Z, they are also independent of participation conditional on the probability of participation, $P(Z) = \Pr(D = 1|\, Z)$. That is, when matching on Z is valid, matching on the summary statistic $\Pr(D = 1|\, Z)$ (the *propensity score*) is also valid. Provided that $P(Z)$ can be estimated parametrically (or semiparametrically at a rate faster than the nonparametric rate), matching on the propensity score reduces the dimensionality of the matching problem to that of a univariate problem. For this reason, much of the literature on matching focuses on propensity score matching methods. (Heckman et al. 1998a, b, and Hahn 1998, consider whether it is better in terms of efficiency to match on $P(X)$ or on X directly.) With the use of the Rosenbaum and Rubin (1983) theorem, the matching procedure can be broken down into two stages. In the first stage, the propensity score $\Pr(D = 1|\, Z)$ is estimated, using a binary discrete choice model. (Options for first the stage estimation include, for example, a parametric logit or probit model or a semiparametric estimator, such as semiparametric least squares – Ichimura 1993 – maximum score – Manski 1973 – smoothed maximum score – Horowitz 1992 – or semiparametric maximum likelihood – Klein and Spady 1993. If $P(Z)$ were estimated using a fully nonparametric method, then the curse of dimensionality problem would reappear.) In the second stage, individuals are matched on the basis of their predicted probabilities of participation.

We next describe a simple model of the programme participation decision to illustrate the kinds of assumptions needed to justify matching. (This model is similar to an example given in Heckman et al. 1999.) Assume that an individual chooses whether to apply to a training programme on the basis of the expected benefits. He or she compares the expected earnings streams with and without participating, taking into account opportunity costs and net of some random training cost ε, which may include a psychic component expressed in monetary terms. The participation decision is made at time $t = 0$ and the training programme lasts for periods 1 through τ, during which time earnings are zero. The information set used to determine expected earnings is denoted by W, which might include, for example, earnings and employment history. The participation model is

$$D = 1 \text{ if } E\left(\sum_{j=\tau}^{T} \frac{Y_{1j}}{(1+r)^j} - \sum_{k=1}^{T} \frac{Y_{0k}}{(1+r)^k} \,|\, W\right) > \varepsilon + Y_{00}, \text{ else } D = 0.$$

The terms in the right-hand side of the inequality are assumed to be known to the individual but not to the econometrician.

$$\begin{aligned} &\text{If} f(Y_{0k}|\, \varepsilon + Y_{00}, X) = f(Y_{0k}|\, X), \\ &\quad \text{then } E(Y_{0k}|\, X, D = 1) \\ &\quad = E(Y_{0k}|\, X, \varepsilon + Y_{00} < \eta(W)) \\ &\quad = E(Y_{0k}|\, X), \end{aligned}$$

which would justify application of a matching estimator. This assumption places restrictions on the correlation structure of the earnings residuals. For example, the assumption would not be plausible if $X = W$ and $Y_{00} = Y_{0k}$, because knowing that a person selected into the programme ($D = 1$) would likely be informative about subsequent earnings. We could assume, however, a model for earnings

$$Y_{0k} = \varphi(X) + v_{0k},$$

such as where v_{0k} follows an MA(q) process with $q < k$, which would imply that Y_{0k} and Y_{00} are uncorrelated conditional on X. The matching method does not require that everything in the information set be known, but it does assume sufficient information to make the selection on observables assumption plausible.

Cross-Sectional Matching Methods

For notational simplicity, let $P = P(Z)$. A prototypical propensity score matching estimator takes the form

$$\begin{aligned} \hat{\alpha}_M &= \frac{1}{n_1} \sum_{i \in I_1 \cap S_P} \left[Y_{1i} - \hat{E}(Y_{0i}|\, D = 1, P_i)\right] \\ \hat{E}(Y_{0i}|\, D = 1, P_i) &= \sum_{j \in I_0} W(i,j) Y_{0j}, \end{aligned} \tag{5}$$

where I_1 denotes the set of programme participants, I_0 the set of non-participants, S_P the region of common support (see below for ways of constructing this set). n_1 is the number of persons in the set $I_1 \cap S_P$. The match for each participant $I \in I_1 \cap S_P$ is constructed as a weighted average over the outcomes of non-participants, where the weights $W(i, j)$ depend on the distance between P_i and P_j. Define a neighbourhood $C(P_i)$ for each i in the participant sample. Neighbours for i are non-participants $j \in I_0$ for whom $P_j \in C(P_i)$. The persons matched to i are those people in set A_i where $A_i = \{j \in I_0 | P_j \in C(P_i)\}$. We describe a number of alternative matching estimators below, that differ in how the neighbourhood is defined and in how the weights $W(i, j)$ are constructed.

Alternative Ways of Constructing Matched Outcomes

Nearest-Neighbour Matching

Traditional, pairwise matching, also called *nearest-neighbour matching*, sets:

$$C(P_i) = \min_j \left\| P_i - P_j \right\|, j \in I_0.$$

That is, the non-participant with the value of P_j that is closest to P_i is selected as the match and A_i is a singleton set. The estimator can be implemented either matching with or without replacement. When matching is performed with replacement, the same comparison group observation can be used repeatedly as a match. A drawback of matching without replacement is that the final estimate will usually depend on the initial ordering of the treated observations for which the matches were selected.

Caliper matching (Cochran and Rubin 1973) is a variation of nearest neighbour matching that attempts to avoid 'bad' matches (those for which P_j is far from P_i) by imposing a tolerance on the maximum distance $\|P_i - P_j\|$allowed. That is, a match for person i is selected only if $\|P_i - P_j\| < \varepsilon$, $j \in I_0$, where ε is a pre-specified tolerance. Treated persons for whom no matches can be found within the caliper are excluded from the analysis, which is one way of imposing a common support condition. A drawback of caliper matching is that it is difficult to know a priori what choice for the tolerance level is reasonable.

Stratification or Interval Matching

In this variant of matching, the common support of P is partitioned into a set of intervals, and average treatment impacts are calculating through simple averaging within each interval. A weighted average of the interval impact estimates, using the fraction of the $D = 1$ population in each interval for the weights, provides an overall average impact estimate. Implementing this method requires a decision on how wide the intervals should be. Dehejia and Wahba (1999) implement interval matching using intervals that are selected such that the mean values of the estimated P_i and P_j are not statistically different from each other within intervals.

Kernel and Local Linear Matching

More recently developed matching estimators construct a match for each programme participant using a weighted average over multiple persons in the comparison group. Consider, for example, the nonparametric *kernel matching estimator*, given by

$$\hat{\alpha}_{KM} = \frac{1}{n_1} \sum_{i \in I_1} \left\{ Y_{1i} - \frac{\sum_{j \in I_0} Y_{0j} G\left(\frac{P_j - P_i}{a_n}\right)}{\sum_{k \in I_0} G\left(\frac{P_k - P_i}{a_n}\right)} \right\}$$

where $G(\ )$ is a kernel function and an is a bandwidth parameter. (See Heckman et al. 1997a, b, 1998a, b and Heckman et al., 1998a, b.) In terms of Eq. (5), the weighting function, $W(i,j)$, is equal to

$$\frac{G\left(\frac{P_j - P_i}{a_n}\right)}{\sum_{k \in I_0} G\left(\frac{P_k - P_i}{a_n}\right)}.$$

For a kernel function bounded between -1 and 1, the neighbourhood is

$$C(P_i) = \left\{ \left| \frac{P_i - P_j}{a_n} \right| \leq 1 \right\}, j \in I_0.$$

M

Under standard conditions on the bandwidth and kernel,

$$\frac{\sum_{j\in I_0} Y_{0j} G\left(\frac{P_j - P_i}{a_n}\right)}{\sum_{k\in I_0} G\left(\frac{P_k - P_i}{a_n}\right)}$$

is a consistent estimator of $E(Y_0|\ D = 1, P_i)$. (Specifically, we require that $G(\cdot)$ integrates to one, has mean zero and that $a_n \to 0$ as $n \to \infty$ and $na_n \to \infty$: One example of a kernel function is the quartic kernel, given by $G(s) = \frac{15}{16}(s^2 - 1)^2$ if $|s| < 1$, $G(s) = 0$ otherwise.)

Heckman et al. (1997) also propose a generalized version of kernel matching, called local linear matching. Recent research by Fan 1992a, b, demonstrated advantages of local linear estimation over more standard kernel estimation methods. These advantages include a faster rate of convergence near boundary points and greater robustness to different data design densities; see Fan 1992a, b.) The local linear weighting function is given by

$$W(i,j) = \frac{G_{ij}\sum_{k\in I_0} G_{ik}(P_k - P_i)^2 - \left[G_{ij}(P_j - P_i)\right]\left[\sum_{k\in I_0} G_{ik}(P_k - P_i)\right]}{\sum_{j\in I_0} G_{ij}\sum_{k\in I_0} G_{ij}(P_k - P_i)^2 - \left(\sum_{k\in I_0} G_{ik}(P_k - P_i)\right)^2}. \tag{6}$$

As demonstrated in research by Fan (1992a, b), local linear estimation has some advantages over standard kernel estimation. These advantages include a faster rate of convergence near boundary points and greater robustness to different data design densities (see Fan 1992a, b). Thus, local linear regression would be expected to perform better than kernel estimation in cases where the non-participant observations on P fall on one side of the participant observations.

To implement the matching estimator given by Eq. (5), the region of common support S_P needs to be determined. The common support region can be estimated by

$$\hat{S}_P = \left\{P : \hat{f}(P|D=1) > 0 \text{ and} \hat{f}(P|D=0) > c_q\right\},$$

where $\hat{f}(P|D=d), d \in \{0,1\}$ are standard non-parametric density estimators. To ensure that the densities are strictly greater than zero, it is required that the densities be strictly positive (that is, exceed zero by a certain amount), determined using a 'trimming level' q. That is, after excluding any P points for which the estimated density is zero, an additional small percentage of the remaining P points is excluded for which the estimated density is positive but very low. The set of eligible matches is thus given by

$$\hat{S}_q = \left\{P \in \hat{S}_P : \hat{f}(P|D=1) > c_q \text{ and} \hat{f}(P|D=0) > c_q\right\},$$

where c_q is the density cut-off level that satisfies

$$\sup_{c_q} \frac{1}{2J} \sum_{\{i\in I_1 \cap \hat{S}\}} \left\{1\left(\hat{f}(P|D=1)\right) < c_q + 1\left(1\left(\hat{f}(P|D=0)\right) < c_q\right)\right\} \le q.$$

Here, J is the cardinality of the set of observed values of P that lie in $I_1 \cap \hat{S}_P$. That is, matches are constructed only for the programme participants for which the propensity scores lie in $\hat{S}_q$.

The above estimators are representations of matching estimators and are commonly used. They can be easily adapted to estimate other parameters of interest, such as the average effect of treatment on the untreated (UT = $E(Y_1 - Y_0|\ D = 0, X)$), or the average treatment effect (ATE = $E(Y_1 - Y_0|\ X)$), which is just a weighted average of treatment on the treated (TT) and treatment on the untreated (UT).

The recent literature has also developed alternative matching estimators that employ different weighting schemes to increase efficiency. See, for example, Hahn (1998) and Hirano et al. (2003) for

estimators that attain the semiparametric efficiency bound. The methods are not described in detail here, because those studies focus on the ATE and not on the average effect of treatment on the treated (TT) parameter. Heckman, Ichimura and Todd (1998) develop a regression-adjusted version of the matching estimator, which replaces Y_{0j} as the dependent variable with the residual from a regression of Y_{0j} on a vector of exogenous covariates. The estimator uses a Robinson (1988) type estimation approach to incorporate exclusion restrictions: that is, that some of the conditioning variables in an equation for the outcomes do not enter into the participation equation or vice versa. In principle, imposing exclusion restrictions can increase efficiency. In practice, though, researchers have not observed much gain from using the regression-adjusted matching estimator. Some alternatives to propensity score matching are discussed in Diamond and Sekhon (2005).

When Does Bias Arise in Matching?

The success of a matching estimator depends on the availability of observable data to construct the conditioning set Z, such that (1) and (2) are satisfied. Suppose only a subset $Z_0 \subset Z$ of the required variables is observed. The propensity score matching estimator based on Z_0 then converges to

$$\alpha'_M = E_{P(Z_0)|D=1}(E(Y_1|P(Z_0), D=1) - E(Y_0|P(Z_0), D=0)). \quad (7)$$

The bias for the parameter of interest, $E(Y_1 - Y_0|\ D=1)$, is

$$\text{bias}_M = E(Y_0|D=1) - E_{P(Z_0)|D=1}\{E(Y_0|P(Z_0), D=0)\}.$$

There is no way of a priori choosing the set of Z variables to satisfy the matching condition or of testing whether a particular set meets the requirements. In rare cases, where data are available on a randomized social experiment, it is sometimes possible to ascertain the bias (see, for example, Heckman et.al 1997a, b; Dehejia and Wahba 1999, 2002; Smith and Todd 2005).

Difference-in-Difference Matching Estimators

The estimators described above assume that, after conditioning on a set of observable characteristics, outcomes are conditionally mean independent of programme participation. However, for a variety of reasons there may be systematic differences between participant and non-participant outcomes, even after conditioning on observables, which could lead to a violation of the identification conditions required for matching. Such differences may arise, for example, because of programme selectivity on unmeasured characteristics or because of levels differences in outcomes that might arise when participants and non-participants reside in different local labour markets or if the survey questionnaires used to gather the data differ in some ways across groups.

A difference-in-differences (DID) matching strategy, as defined in Heckman et al. (1997) and Heckman et al. (1998a, b), allows for temporally invariant differences in outcomes between participants and non-participants. This type of estimator matches on the basis of differences in outcomes using the same weighting functions described above. The propensity score DID matching estimator requires that

$$E(Y_{0t} - Y_{0t'}|P, D=1) = E(Y_{0t} - Y_{0t'}|P, D=0),$$

where t and t' are time periods after and before the programme enrolment date. This estimator also requires the support condition given above, which must now hold in both periods t and t'. The local linear difference-in-difference estimator is given by

$$\hat{\alpha}_{DM} = \frac{1}{n_1} \sum_{i \in I_1 \cap S_P} \left\{ (Y_{1ti} - Y_{0t'i}) - \sum_{j \in I_0 \cap S_P} W(i,j)(Y_{0tj} - Y_{0t'j}) \right\},$$

where the weights correspond to the local linear weights defined above. If repeated cross-section data are available, instead of longitudinal data, the estimator can be implemented as

M

$$\hat{\alpha}_{DM} = \frac{1}{n_{1t}} \sum_{i \in I_{1t} \cap S_P} \left\{ \left(Y_{1ti} - \sum_{j \in I_{0t} \cap S_P} W(i,j) Y_{0tj} \right\} - \frac{1}{n_{1t'}} \sum_{i \in I_{1t'} \cap S_P} \left\{ \left(Y_{1t'i} - \sum_{j \in I_{0t'}} W(i,j) Y_{0t'j} \right\},$$

where $I_{1t}, I_{1t'}, I_{0t}, I_{0t'}$ denote the treatment and comparison group data-sets in each time period.

Finally, the DID matching estimator allows selection into the programme to be based on anticipated gains from the programme in the sense that D can help predict the value of Y_1 given P. However, the method assumes that D does not help predict changes $Y_{0t} - Y_{0t'}$ conditional on a set of observables (Z) used in estimating the propensity score. In their analysis of the effectiveness of matching estimators, Smith and Todd (2005) found difference-in-difference matching estimators to perform much better than cross-sectional methods in cases where participants and non-participants were drawn from different regional labour markets and/or were given different survey questionnaires.

Matching When the Data are Choice-Based Sampled

The samples used in evaluating the impacts of programmes are often choice-based, with programme participants oversampled relative to their frequency in the population of persons eligible for the programme. Under choice-based sampling, weights are generally required to consistently estimate the probabilities of programme participation. (See, for example, Manski and Lerman 1977, for discussion of weighting for logistic regressions.) When the weights are unknown, Heckman and Todd (1995) show that with a slight modification matching methods can still be applied, because the odds ratio $(P/(1-P))$ estimated using a logistic model with incorrect weights (that is, ignoring the fact that samples are choice-based) is a scalar multiple of the true odds ratio, which is itself a monotonic transformation of the propensity scores. Therefore, matching can proceed on the (misweighted) estimate of the odds ratio (or on the log odds ratio).

Using Balancing Tests to Check the Specification of the Propensity Score Model

As described earlier, the propensity score matching estimator requires the outcome variable to be mean independent of the treatment indicator conditional on the propensity score, $P(Z)$. An important consideration in implementation is how to choose Z. Unfortunately, there is no theoretical basis for choosing a particular set Z to satisfy the identifying assumptions, and the set is not necessarily the most inclusive one.

To guide in the selection of Z, there is some accumulated empirical evidence on how bias estimates depended on the choice of Z in particular applications. For example, Heckman et al. (1998a, b), Heckman et al. (1997) and Lechner (2001) show that the choice of variables included in Z can make a substantial difference to the estimator's performance. These papers found that biases tended to be higher when the participation equation was estimated using a cruder set of conditioning variables. One approach adopted is to select the set Z to maximize the percentage of people correctly classified under the model. Another finding in these papers is that the matching estimators performed best when the treatment and control groups were located in the same geographic area and when the same survey instrument was administered to both treatments and controls to ensure comparable measurement of outcomes.

Rosenbaum and Rubin (1983) suggest a method to aid in the specification of the propensity score model. The method does not provide guidance in choosing which variables to include in Z, but can help to determine which interactions and higher-order terms to include in the model for a given Z set. They note that for the true propensity score, the following holds:

$$Z \perp\!\!\!\perp D | \Pr(D = 1 | Z),$$

or equivalently $E(D|\ Z; \Pr(D = 1|\ Z)) = E(D|\ \Pr(D = 1|\ Z))$. The basic intuition is that, after conditioning on $\Pr(D = 1|Z)$, additional conditioning on Z should not provide new information about D. If after conditioning on the estimated

values of $P(D = 1|Z)$ there is still dependence on Z, this suggests misspecification in the model used to estimate $\Pr(D = 1|Z)$. The theorem holds for any Z, including sets Z that do not satisfy the conditional independence condition required to justify matching. As such, the theorem is not informative about what set of variables to include in Z.

This result motivates a specification test for $\Pr(D = 1|Z)$, that is a test whether or not there are differences in Z between the $D = 1$ and $D = 0$ groups after conditioning on $P(Z)$. The test has been implemented in the literature a number of ways (see, for example Eichler and Lechner 2002; Dehijia and Wahba 1999, 2002; Smith and Todd 2005; Diamond and Sekohn 2005).

Assessing the Variability of Matching Estimators

The distribution theory for the cross-sectional and difference-in-difference kernel and local linear matching estimators described above is derived in Heckman et al. (1998). However, implementing the asymptotic standard error formulae can be cumbersome, so standard errors for matching estimators are often instead generating using bootstrap resampling methods. (See Efron and Tibshirani 1993, for an introduction to bootstrap methods, and Horowitz 2003, for a recent survey of bootstrapping in econometrics.) A recent paper by Abadie and Imbens (2006a) shows that standard bootstrap resampling methods are not valid for assessing the variability of nearest neighbour estimators, but can be applied to assess the variability of kernel or local linear matching estimators for a suitably chosen bandwidth. Abadie and Imbens (2006b) present alternative standard error formulae for assessing the variability of nearest neighbour matching estimators.

Applications

There have been numerous evaluations of matching estimators in recent decades. For a survey of many applications in the context of evaluating the effects of labour market programmes (see Heckman et al. 1999). More recently, propensity score matching estimators have been used in evaluating the impacts of a variety of programme interventions in developing countries. Jalan and Ravallion (1999) assess the impact of a workfare programme in Argentina (the *Trabajar* programme), and Jalan and Ravallion (2003) study the effects of public investments in piped water on child health outcomes in rural India. Galiani et al. (2005) use difference-in-difference matching methods to analyse the effects of privatization of water services on child mortality in Argentina. Other applications include Gertler et al. (2004) in a study of the effects of parental death on child outcomes, Lavy (2004) in a study of the effects of a teacher incentive programme in Israel on student performance, Angrist and Lavy (2001) in a study of the effects of teacher training on children's test scores in Israel, and Chen and Ravallion (2003) in a study of a poverty reduction project in China.

Behrman et al. (2004) use a modified version of a propensity score matching estimator to evaluate the effects of a preschool programme in Bolivia on child health and cognitive outcomes. They identify programme effects by comparing children with different lengths of duration in the programme, using matching to control for selectivity into alternative durations. Also, see Imbens (2000) and Hirano and Imbens (2004) for an analysis of the role of the propensity score with continuous treatments. Lechner (2001) extends propensity score analysis for the case of multiple treatments.

Matching Models: Empirics

Jeremy T. Fox

Abstract

A matching model takes a set of payoffs or outputs for all possible matches and produces a set of matches where no couple would prefer to deviate and become matched, instead of their assigned matches. Matching models are increasingly being estimated in empirical work in industrial organization, labour economics, public economics, and other fields. This article surveys methods for and applications of structural estimation for two-sided matching games.

Economists often observe data on relationships. We see who is in a relationship with whom: which firms merged with each other, which men are married to which women, and which bidders won which items in an auction. A matching model or matching game is one theoretical framework for modelling the equilibrium formation of these relationships. A relationship is termed a match. A matching model takes a set of payoffs or outputs for all possible matches and produces a set of matches where no couple would prefer to deviate and become matched, instead of their assigned matches. The robustness of the equilibrium to deviation by any potential couple suggests 'pairwise stability' as the term for an equilibrium.

The key economic idea in matching models is the rivalry to match with the most attractive partners. In marriage, men compete with each other to marry the most attractive women while women compete with each other to marry the most attractive men. There is scarcity on both sides of the market.

This entry focuses on research that formally estimates the parameters of a matching model using data on who matches with whom. Economists adopting this structural approach typically observe data on who matches with whom as well as exogenous characteristics of each agent. For example, economists studying marriage will observe the race, schooling level, religion, physical attractiveness and wage of each man and each women. The data also record which men married which women. Economists are willing to assume that the data represent a pairwise stable outcome to a particular matching game.

The structural approach means that researchers impose the structural model and estimate unknown parameters in the model. The advantages of the structural approach apply to more economic situations than just matching models, and have been explored elsewhere (Reiss and Wolak 2007). A quick summary is that the structural approach allows the computation of counterfactuals and the measurement of economic parameters that cannot be directly observed. Using the example of marriage, one type of counterfactual would be to explore how the equilibrium set of matches is altered as demographics change. Measurement is also important: if men and women each have several characteristics, how important are each of the characteristics in the payoffs to a match?

This article focuses on the use of matching games in structural empirical work. Other literatures have focused on centralized market design (for example the medical resident matching programme in the United States) and the descriptive interpretation of matching patterns.

Two-sided Matching Games

Most but not all empirical work has focused on two-sided matching games: agents can be divided into two sides, say men and women. Roth and Sotomayor (1990) is a useful text that explains simple matching games.

For the purposes of this article, I divide two-sided matching games into models with and without transfers. Gale and Shapley (1962) introduced the model where agents do not exchange money: men have preferences over women and women have preferences over men. Generically there will be a lattice of multiple pairwise stable outcomes in this model. Koopmans and Beckmann (1957), Shapley and Shubik (1972), and Becker (1973) study models where matched agents can exchange money and where agents have transferable utility. For one-to-one matching games such as marriage, generically there will be one set of pairwise stable physical matches in these models; there may be a continuum of transfers that support these physical matches. The choice of modelling framework depends on the researcher's understanding of the market in question.

The above papers allow each man, say, to marry at most one woman. There are extensions to many-to-one and many-to-many two-sided matching games. Complementarities between multiple matches involving the same agent are key to some of the empirical applications below (Fox 2009a; Fox and Bajari 2009). There are also one-sided and many-sided matching games.

There are more general matching games where other contract elements, such as the hours of work in a labour market, are determined as part of the pairwise stable outcome (Crawford and Knoer 1981; Kelso and Crawford 1982; Hatfield and Milgrom 2005). Matching games are mathematically linked to hedonic equilibrium models, although I will not explore the link here (Rosen 1974). There is also a clear link to models of frictions, such as search models, that also have observed agent heterogeneity (Shimer and Smith 2000; Atakan 2006).

Estimation Methods

Matching games share many similarities with the literature on estimating static, discrete Nash games, such as the well-known entry models of Berry (1992) and Bresnahan and Reiss (1991).

Matching games use pairwise stability and not Nash equilibrium, but many estimation challenges are similar. A key difficulty in matching games is that the number of agents in a market can be in the hundreds or thousands, compared to the three or four firms deciding to enter a market in some entry applications. The number of agents in matching empirical applications can make some estimators computationally infeasible.

Nested Solution Methods

The most straightforward way to estimate a matching game is to use simulated maximum likelihood or the simulated method of moments. These estimators require solving the model a fixed number of times for each iteration of an outer optimization routine. Simulation estimators are

conceptually straightforward but computationally burdensome.

Boyd and colleagues (2003) use the simulated method of moments to study the matching of public school teachers to schools in New York state. They use data on wages and assume the wages are exogenously determined. Their model without endogenous transfers has multiple stable matches, and they use the lattice structure of the equilibria to impose an equilibrium selection rule in estimation.

Full Likelihood Methods

In many cases, the full likelihood can be written down. In a study of the matching of venture capitalists to entrepreneurs, Sørensen (2007) uses an augmented likelihood approach where the unobserved payoffs of each match are treated as nuisance parameters and integrated out using a blocking structure in a Markov Chain Monte Carlo (MCMC) procedure. Sørensen does not use endogenous transfers and hence imposes an aligned preferences assumption that he proves generates a unique pairwise stable outcome.

The full likelihood approach can be computationally intractable in large matching markets. In a study of the matching between investment banks and firms undertaking an initial public offering, Akkus (2008) shows that the likelihood simplifies if the values of realized matches are recorded in the data. By using data on the payoffs of matches, estimation becomes easier.

Inequality Methods

With an application to automotive suppliers and automotive assemblers, Fox (2009a) introduces a maximum score estimator to estimate a many-to-many matching game where transfers are endogenous, but not in the data. The maximum score estimator maximizes the number of inequalities implied by pairwise stability that hold true. This approach breaks the computational curse of dimensionality because not all inequalities need to be included for the estimator to be consistent.

Logit Methods

Dagsvik (2000) and Choo and Siow (2006) study games with transfers, and assume that the payoffs to matches have error terms that satisfy the parametric logit property. To a large degree, the logit assumption allows researchers to derive closed-form equations that allow estimation, especially for very large markets that plausibly have a continuum of agents, such as the US national marriage market.

Identification

In matching games, agents on the same side of the market are rivals to match with agents on the other side of the market. The fact that a man did not match with the most attractive woman does not mean that the man did not prefer that woman to his actual wife. The equilibrium budget set of each agent is unobserved. Thus, it is not clear what can be learned (identified) from data on who matches with whom.

Fox (2009b) studies identification in matching games with transfers and finds two sets of results. First, the relative importance of complementarities in payoffs for say schooling, compared with say wealth, is identified using data on matches but not the equilibrium transfers that are present in the model. Second, the ordering of production levels (which matches give higher payoffs) is identified using the same data.

Selection Correcting Outcome Equations

Sørensen (2007) explores the use of a matching model to parametrically selection correct an auxiliary outcome equation. The outcome, the success of an investment in his application, is not determined as part of the matching game, but the outcome is only observed in the data for realized matches. Sørensen's approach is analogous to using a single agent decision model to selection correct an outcome equation (Heckman 1979). Sørensen (2009) extends the framework of Heckman (1990) to study identification in selection models where selection is induced by a matching game.

Empirical Applications

I now catalogue some of the many empirical applications of matching games.

Marriage and Family Economics

Choo and Siow (2006) explore whether changing matching patterns in the US marriage market are due to changes in preferences or changes in the exogenous characteristics of potential spouses. They also explore the effects of the legalization of abortion. There have been a large number of marriage and family economics papers following up on the Choo and Siow framework, many by the original authors. See Siow (2008) for a complete survey of this material.

Bruze (2009) estimates a matching game where labour supply and the split of consumption between men and women are part of the pairwise stable contract terms. He explores the return to an agent for finding a higher-earning spouse in college.

Hitsch et al. (2009) use revealed preference information from an online dating site to avoid the need to use an equilibrium model to estimate preferences. They use the preference estimates to simulate a pairwise stable outcome and find it matches well with actual sorting on the site.

Industrial Organization, Corporate Finance and Marketing

Hall (1988) is an early paper that emphasizes the need for matching models to study mergers. She did not estimate a full matching game because of computational concerns.

It is common to have data on realized interfirm relationships. Sørensen (2007) studies the matching of venture capitalists to entrepreneurs with a focus on selection correcting an outcome equation where the success of an investment is regressed upon the experience of the venture capitalist. The basic approach of Sørensen allows for match-specific error terms, and he can allow for time-invariant characteristics of a venture capitalist by using fixed effects/panel data. Chen (2009) uses a similar selection-correction framework where the outcome equation of interest is the price of a bank loan. Akkus (2008) uses the selection-correction approach to regress the degree of first-day underpricing on the experience of an investment bank. Park (2008) uses a similar MCMC estimator to investigate the decision of a mutual fund manager to engage in a merger as a function of past returns.

Fox and Bajari (2009) was the first paper to estimate a many-to-one matching game where complementarities across multiple matches were allowed for. The authors look at auctions of multiple heterogeneous items, where each bidder can win multiple items. They study FCC spectrum auctions, where complementarities between the geographic territories being auctioned are estimated to be important for the efficient operation of the mobile phone industry. A key methodological challenge is showing how a potentially inefficient, dynamic Nash game could result in equilibria that satisfy pairwise stability. The estimator used is that of Fox (2009a) for matching games with transfers. Fox (2009a) studies the many-to-many matching of automotive suppliers to automotive assemblers, and measures the relative importance of specialization by suppliers in particular corporations, brands and car models. Further, Fox measures a potential benefit of suppliers matching with high-quality Asian assemblers, such as Toyota.

Levine (2008) uses the estimator of Fox (2009a) to explore the matching of biotechnology innovations to marketing firms. She explores whether the returns to scale of marketers might decrease the returns to innovators. Yang et al. (2009) use the same estimator to explore the matching of professional athletes to teams, with a focus on the potential marketing complementarities between players and teams from different-sized cities. Akkus and Hortaçsu (2007) extend the maximum score estimator to use data on equilibrium transfers. Akkus and Hortaçsu investigate geographic complementarities in the market for bank mergers after the removal of prohibitions against interstate banks. Mindruta (2009) studies the matching of university researchers and private firms.

Development, Public Finance, Labour Economics and Other

Boyd and colleagues (2003) investigate the matching of teachers to public schools, with a focus on learning how to attract qualified teachers to schools in impoverished areas.

Gordon and Knight (2009) investigate the consolidation decisions of Iowa school districts after the state passed incentives inducing such consolidation.

Ahlin (2009) uses the estimator of Fox (2009a) to study the matching of Thai villagers to other villagers in risk-sharing groups. He investigates whether villagers match by risk type or seek to diversify risk.

Fox (2008) estimates a repeated matching model for the labour market for engineers in Sweden. Each period state variables evolve, a matching model opens, prices are formed to equate supply and demand and workers choose jobs. The model is dynamic in that both firms and workers are forward looking: they consider the effect of the decision to switch today on future outcomes.

Baccara and colleagues (2009) study the matching of professors to offices, and estimate the importance of various types of professional networks in payoffs.

Material Balances

A material balance is a simple planning device developed (if not originated) early in Soviet planning for the purpose of equating prospective availabilities of a given good and its prospective requirements over the plan period (or at some target date in case of a stock). It occupies a central role in Soviet-type planning. The phrase, a literal rendering of the Russian *material'nyi balans*, is somewhat inexact and possibly confusing inasmuch as each of the two words has a variety of meanings in English. A more exact term would be 'sources-and-uses account' for a flow or 'balance sheet' for a stock. As such, material balances have counterparts in planning and management the world over.

In Soviet-type planning, a material balance is typically constructed *ex ante*. It can pertain to any good or resource requiring planners' attention or administrative disposition; thus, 'balance' is drawn up not only for material products, but also for labour, capacity, foreign exchange, and so on. While it can be drawn up at any level of the hierarchy of a command economy and by any relevant organizational entity, these alternatives carry important economic, bureaucratic and even political implications in a Soviet-type economy. 'In the course of preparing the annual plan ... the USSR State Planning Commission draws up [some] 2,000 single-product balances, the State Commission for Supply – up to 15,000, and the ministries – up to 50,000' (*EKO*, August, 1983, p. 26). Though there may be some duplication in terms of goods between these figures, they nonetheless do suggest the magnitude of the annual task, especially if one bears in mind the interconnections.

In Soviet-type practice a material balance not only has the passive purpose of checking requirements against availabilities, but forms the operational basis for specific production or import directives to designated organizations and firms, and for specific acquisition permits to designated users of the good. Note that nearly all producer goods are administratively allocated (rationed) to users Table 1.

A material balance may take the following form (adapted from Levine, 1959):

Two kinds of questions arise: (*a*) operational – how is the balance initially compiled and 'balanced', and later adjusted for outside effects (from other balances) and the extent to which successive iterations are required to converge?

Material Balances, Table 1

Material balance for good X for (year)	
Sources	Uses (distribution)
1. Current production – by major producing organizations, firms	1. For production – by organizations, firms
2. Imports	2. For construction – by organizations, firms
3. Other sources	3. For household sector('market fund')
4. Beginning-year stocks – by organizations	4. For export
5. Total sources	5. To central reserve stocks
	6. End-year stocks at suppliers – by organizations, firms
	7. Total uses (distribution)

and (*b*) policy – the bounds and degree of aggregation of a 'good', the organizational locus and level of compilation, and so on?

Little is known about the initial compilation. There must be serious problems of the requisite detailed information in the case of many goods, given that the preparation of the annual plan extends over most of the pre-plan year (and often into the plan year). Thus, the database may anticipate the plan year by one-and-a-half to two years whose projection is obviously subject to uncertainty. A common problem is the uncertainty of going-on-stream of capacity under construction. Also, the data may not be very accurate to start with, given the cat-and-mouse game that firms and other subordinates play with their superiors. What is more, thousands of balances are being drawn up simultaneously, often by different organizations or subdivisions, with the obvious difficulty of mutual coordination.

The 'balancer' must take into account – in addition to technical parameters – political and other high-level decisions, existing economic programmes, bureaucratic politics, and the usual pressure to squeeze more out of the economy's resources. Corruption is not unknown. The work is largely done manually and inevitably to some extent subjectively. While computers are beginning to be used, the input–output technique – which in principle is eminently suitable for the purpose – seems to be applied for the grosser computations and checks, not for the drawing up of operational, short-term material balances. The main reasons are that the sectors in even the largest matrices are too aggregative for the material balances, and the data underlying the technical coefficients are not current enough.

Among the balancer's technical parameters, pride of place is occupied by the 'norm' – a disaggregated input–output ratio, which assists the compiler in filling in parts of both sides of the account. Much effort goes into computation of the norms, given their crucial role in the preparation of plans and the issuing of specific assignments. They are supposed to be 'scientific', that is, representing the best applicable engineering practice (note: for technical rather than economic efficiency), but given their enormous number and informational problems, this remains an ideal. In the event, the balancer must employ short-cuts and resort to optimistic assumptions in order to achieve equality of requirements and availabilities while under pressure to deliver high ('taut') production targets. A common and much criticized short-cuts is simply to raise output targets of all producers by a uniform percentage, with corresponding adjustments of the norms.

The weakest link in the material balance method is coordination among the many balances to achieve a reasonably internally consistent plan for the whole economy or a sector thereof. (Montias, 1959, discusses this at length.) Even if the implicit inter-industry matrix is close to triangular, every iteration is a major undertaking under the actual conditions. Aggregating the goods would simplify the iteration process, but would not suit well the demands posed by detailed production assignments and allocation orders. So would the holding of ample reserve stocks, which are not always there or accessible. In fact,

adjustments and corrections tend ordinarily to be carried to only a few adjoining balances.

The overall annual plan that emerges is typically of low internal consistency (not to say, economic efficiency), causing considerable difficulties to those charged with its implementation and necessitating continual further correction and adjustment during the plan year, with the same effect.

Mathematical Economics

Gerard Debreu

Abstract

A summary of the emergence and triumph of mathematical economics. The modern phase was deeply influenced by John von Neumann's article of 1928 on games and his paper of 1937 on economic growth. His 1944 *Theory of Games and Economic Behavior*, coauthored by Oskar Morgenstern, went beyond differential calculus and linear algebra and paved the way for the axiomatization of economic theory. This has enabled researchers to use precisely stated and flawlessly proved results, in the quest for the most direct link between the assumptions and the conclusions of a theorem. Economic theory is fated for a long mathematical future.

I. The steady course on which mathematical economics has held for the past four decades sharply contrasts with its progress during the preceding century, which was marked by several major scientific accidents. One of them occurred in 1838, at the beginning of that period, with the publication of Augustin Cournot's *Recherches sur les principes mathématiques de la théorie des richesses.* By its mathematical form and by its economic content, his book stands in splendid isolation in time; and in explaining its data historians of economic analysis in the first half of the 19th century must use a wide confidence interval.

The University of Lausanne was responsible for two other of those accidents. When Léon Walras delivered his first professorial lecture

there on 16 December 1870, he had held no previous academic appointment; he had published a novel and a short story but he had not contributed to economic theory before 1870; and he was exactly 36. The risk that his university took was vindicated by the appearance of the *Eléments d'économie politique pure* in 1874–7. For Vilfredo Pareto, who succeeded Walras in his chair in 1893, it was also a first academic appointment; he had not contributed to economic theory before 1892; and he was 45. This second gamble of the University of Lausanne paid off when Pareto's *Cours d'économie politique* appeared in 1896–97, followed by his *Manuel d'économie politique* in 1909, and by the article 'Economie mathématique' in 1911.

In the contemporary period of development of mathematical economics, profoundly influenced by John von Neumann, his article of 1928 on games and his paper of 1937 on economic growth also stand out as major accidents, even in a career with so many facets.

The preceding local views would yield a distorted historical perception, however, if they were not complemented by a global view which sees in the development of mathematical economics a powerful, irresistible current of thought. Deductive reasoning about social phenomena invited the use of mathematics from the first. Among the social sciences, economics was in a privileged position to respond to that invitation, for two of its central concepts, commodity and price, are quantified in a unique manner, as soon as units of measurement are chosen. Thus for an economy with a finite number of commodities, the action of an economic agent is described by listing his input, or his output, of each commodity. Once a sign convention distinguishing inputs from outputs is made, the action of an agent is represented by a point in the commodity space, a finite-dimensional real vector space. Similarly the prices in the economy are represented by a point in the price space, the real vector space dual of the commodity space. The rich mathematical structure of those two spaces provides an ideal basis for the development of a large part of economic theory.

Finite dimensional commodity and price spaces can be, and usually are, identified and treated as a Euclidean space. The stage is thus set for geometric intuition to take a lead role in economic analysis. That role is manifest in the figures that abound in the economics literature, and some of the great theorists have substituted virtuosity in reasoning on diagrams for the use of mathematical form. As for mathematical economists, geometric insight into the commodity-price space has often provided the key to the solution of problems in economic theory.

The differential calculus and linear algebra were applied to that space at first as a matter of course. By the time John Hicks's *Value and Capital* appeared in 1939, Maurice Allais' *A la recherche d'une discipline économique* in 1943, and Paul Samuelson's *Foundations of Economic Analysis* in 1947, they had both served economic theory well. They would serve it well again, but the publication of the *Theory of Games and Economic Behavior* in 1944 signalled that action was also going to take new directions. In mathematical form, the book of von Neumann and Oskar Morgenstern set a new level of logical rigour for economic reasoning, and it introduced convex analysis in economic theory by its elementary proof of the MiniMax theorem. In the next few years convexity became one of the central mathematical concepts, first in activity analysis and in linear programming, as the *Activity Analysis of Production and Allocation* edited by Tjalling Koopmans attested in 1951, and then in the mainstream of economic theory. In consumption theory as in production theory, in welfare economics as in efficiency analysis, in theory of general economic equilibrium and in the theory of the core, the picture of a convex set supported by a hyperplane kept reappearing, and the supporting hyperplane theorem supplied a standard technique for obtaining implicit prices. The applications of that theorem to economics were a ready consequence of the real vector space structure of the commodity space; yet they were made more than thirty years after Minkowski proved it in 1911.

Algebraic topology entered economic theory in 1937, when von Neumann generalized Brouwer's fixed point theorem in a lemma devised to prove the existence of an optimal growth path in his model. The lag from Brouwer's

result of 1911 to its first economic application was shorter than for Minkowski's result. It should, however, have been significantly longer, for von Neumann's lemma was far too powerful a tool for his proof of existence. Several authors later obtained more elementary demonstrations, and David Gale in particular based his in 1956 on the supporting hyperplane theorem. Thus von Neumann's lemma, reformulated in 1941 as Kakutani's fixed point theorem, was an accident within an accidental paper. But in a global historical view, the perfect fit between the mathematical concept of a fixed point and the social science concept of an equilibrium stands out. A state of a social system is described by listing an action for each one of its agents. Considering such a state, each agent reacts by selecting the action that is optimal for him given the actions of all the others. Listing those reactions yields a new state, and thereby a transformation of the set of states of the social system into itself is defined. A state of the system is an equilibrium if, and only if, it is a fixed point of that transformation. More generally, if the optimal reactions of the agents to a given state are not uniquely determined, one is led to associate a set of new states, instead of a single state, with every state of the system. A point-to-set transformation of the set of states of the social system into itself is thereby defined; and a state of the system is an equilibrium if, and only if, it is a fixed point of that transformation. In this view, fixed point theorems were slated for the prominent part they played in game theory and in the theory of general economic equilibrium after John Nash's one-page note of 1950.

A perfect fit of mathematical form to economic content was also found when the traditional concept of a set of negligible agents was formulated exactly. In 1881, in *Mathematical Psychics,* Francis Edgeworth had studied in his box the asymptotic equality of the 'contract curve' of an economy and of its set of competitive allocations. Basic to his proof of convergence is the fact that in his limiting process every agent tends to become negligible. A long period of neglect of his contribution ended in 1959, when Martin Shubik brought out the connection between the contract curve and the game theoretic concept of the core. After the second impulse given in 1962 by Herbert Scarf's first extension of Edgeworth's result, a new phase of development of the economic theory of the core was under way; and in 1964 Robert Aumann formalized the concept of a set of negligible agents as the unit interval of the real line with its Lebesgue measure. The power of that formulation was demonstrated as Aumann proved that in an exchange economy with that set of agents, the core and the set of competitive allocations coincide. Karl Vind then gave, also in 1964, a different formulation of this remarkable result in the context of a measure space of agents without atoms, and showed that it is a direct consequence of Lyapunov's theorem of 1940 on the range of an atomless vector measure. The convexity of that range explains the convexing effect of large economies. In the important case of a set of negligible agents, it justifies the convexity assumption on aggregate sets to which economic theory frequently appeals. A privileged place was clearly marked for measure theory in mathematical economics.

An alternative formulation of the concept of a set of negligible agents was proposed by Donald Brown and Abraham Robinson in 1972 in terms of Non-standard Analysis, created by Robinson in the early 1960s. Innovations in the mathematical tools of economic theory had not always been immediately and universally adopted in the past. In this case the lag from mathematical discovery to economic application was exceptionally short, and Non-standard Analysis had not been widely accepted by mathematicians themselves. Predictably the intrusion of this strange, sophisticated new tool in economic theory was greeted mostly with indifference or with scepticism. Yet it led to the form given by Robert Anderson to inequalities on the deviation of core allocations from competitive allocations, which are central to the theory of the core. In the article published by Anderson in 1978 those inequalities are stated and proved in an elementary manner, but their expression was found by means of Non-standard Analysis.

The differential calculus, which had been used earlier on too broad a spectrum of economic problems, turned out in the 1970s to supply the proper mathematical machinery for the study of the set of competitive equilibria of an economy. A partial

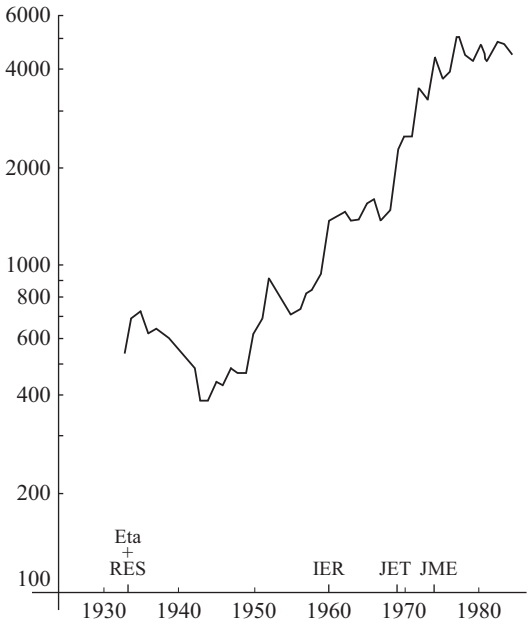
explanation of the observed state of an economic system had been provided by proofs of existence of equilibrium based on fixed point theorems. A more complete explanation would have followed from persuasive assumptions on a mathematical model of the economy ensuring uniqueness of equilibrium. Unfortunately the assumptions proposed to that end were excessively stringent, and the requirement of global uniqueness had to be relaxed to that of local uniqueness. Even then an economy composed of agents on their best mathematical behaviour (for instance each having a concave utility function and a demand function both indefinitely differentiable) may be ill-behaved and fail to have locally unique equilibria. If one considers the question from the generic viewpoint, however, one sees that the set of those ill-behaved economies is negligible. This time the ideal mathematical tool for the proof of that assertion is Sard's theorem of 1942 on the set of critical values of a differentiable function. By providing appropriate techniques for the study of the set of equilibria, differential topology and global analysis came to occupy in mathematical economics a place that seemed to have been long reserved for them.

As new fields of mathematics were introduced into economic theory and solved some of its fundamental problems, a growth-generating cycle operated. The mathematical interest of the questions raised by economic theory attracted mathematicians who in turn made the subject mathematically more interesting. The resulting expansion of mathematical economics was unexpectedly rapid. Attempting to quantify it, one can use as an index the total number of pages published yearly by the five main periodicals in the field: *Econometrica* and the *Review of Economic Studies* (which both started publishing in 1933), the *International Economic Review* (1960), the *Journal of Economic Theory* (1969), and the *Journal of Mathematical Economics* (1974). The graph of that index is eloquent. It shows a first phase of decline to 1943, followed by a 33-year period of exuberant, nearly exponential growth. The annual rate of increase that would carry the index exponentially from its 1944 level to its 1977 level is 8.2 per cent, a rate that implies doubling in slightly less than nine years and that cannot easily be sustained. The years 1977–84 have indeed marked a pause that will soon resemble a stagnation phase if it persists. Among its imperfections the index gives equal weights to *Econometrica*, the *Review of Economic Studies,* and the *International Economic Review,* all of which publish articles on econometrics as well as on mathematical economics, and to the *Journal of Economic Theory* and the *Journal of Mathematical Economics*, which do not. But given lower relative weights to the first three yields even higher annual rates of exponential growth of the index for the period 1944–77.

The sweeping movement that took place from 1944 to 1977 suggests an inevitable phase in the evolution of mathematical economics. The graph illustrating that phase hints at the deep transformation of departments of economics during those 33 years. It also hints at the proliferation of discussion papers and at the metamorphosis of professional journals like the *American Economic Review*, which was almost pure of mathematical symbols in 1933 but had lost its innocence by the late 1950s (Fig. 1).

II. As a formal model of an economy acquires a mathematical life of its own, it becomes the object of an inexorable process in which rigour, generality and simplicity are relentlessly pursued.

Before 1944, articles on economic theory only exceptionally met the standards of rigour common in mathematical periodicals. But several of the exceptions were outstanding, among them the two papers of von Neumann of 1928 and of 1937, and the three papers of Abraham Wald of 1935–6 on the existence of a general economic equilibrium. In 1944 the *Theory of Games and Economic Behavior* gained full rights for uncompromising rigour in economic theory and prepared the way for its axiomatization. An axiomatized theory first selects its primitive concepts and represents each one of them by a mathematical object. For instance the consumption of a consumer, his set of possible consumptions and his preferences are represented respectively by a point in the commodity space, a subset of the commodity space and a binary relation in that subset. Next, assumptions on the objects representing the primitive concepts are specified,



Mathematical Economics, Fig. 1 Number of pages published yearly by the leading journals in mathematical economics (Econometrica (abbr. Eta), *Review of Economic Studies*, (For the first 29 years the *Review of Economic Studies* was published on an academic rather than on a calendar year basis. As a result, only one issue appeared in 1933, compared with three in 1934; hence the spurious initial increase in the graph.) *International Economic Review, Journal of Economic Theory, Journal of Mathematical Economics*)

and consequences are mathematically derived from them. The economic interpretation of the theorems so obtained is the last step of the analysis. According to this schema, an axiomatized theory has a mathematical form that is completely separated from its economic content. If one removes the economic interpretation of the primitive concepts, of the assumptions and of the conclusions of the model, its bare mathematical structure must still stand. This severe test is passed only by a small minority of the papers on economic theory published by *Econometrica* and by the *Review of Economic Studies* during their first decade.

The divorce of form and content immediately yields a new theory whenever a novel interpretation of a primitive concept is discovered. A textbook illustration of this application of the axiomatic method occurred in the economic theory of uncertainty. The traditional characteristics of a commodity were its physical description, its date, and its location when in 1953 Kenneth Arrow proposed adding the state of the world in which it will be available. This reinterpretation of the concept of a commodity led, without any formal change in the model developed for the case of certainty, to a theory of uncertainty which eventually gained broad acceptance, notably among finance theorists.

The pursuit of logical rigour also contributed powerfully to the rapid expansion of mathematical economics after World War II. It made it possible for research workers to use the precisely stated and flawlessly proved results that appeared in the literature without scrutinizing their statements and their proofs in every detail. Another cumulative process could thus gather great momentum.

The exact formulation of assumptions and of conclusions turned out, moreover, to be an effective safeguard against the ever-present temptation to apply an economic theory beyond its domain of validity. And by the exactness of that formulation, economic analysis was sometimes brought closer to its ideology-free ideal. The case of the two main theorems of welfare economics is symptomatic. They respectively give conditions under which an equilibrium relative to a price system is a Pareto optimum, and under which the converse holds. Foes of state intervention read in those two theorems a mathematical demonstration of the unqualified superiority of market economies, while advocates of state intervention welcome the same theorems because the explicitness of their assumptions emphasizes discrepancies between the theoretic model and the economies that they observe.

Still another consequence of the axiomatization of economic theory has been a greater clarity of expression, one of the most significant gains that it has achieved. To that effect, axiomatization does more than making assumptions and conclusions explicit and exposing the deductions linking them. The very definition of an economic concept is usually marred by a substantial margin of ambiguity. An axiomatized theory substitutes for that ambiguous concept a mathematical object that is subjected to definite rules of reasoning. Thus an

axiomatic theorist succeeds in communicating the meaning he intends to give to a primitive concept because of the completely specified formal context in which he operates. The more developed this context is, the richer it is in theorems, and in other primitive concepts, the smaller will be the margin of ambiguity in the intended interpretation.

Although an axiomatic theory may flaunt the separation of its mathematical form and its economic content in print, their interaction is sometimes close in the discovery and elaboration phases. As an instance, consider the characterization of aggregate excess demand functions in an l-commodity exchange economy. Such a function maps a positive price vector into an aggregate excess demand vector, and Walras' Law says that those two vectors are orthogonal in the Euclidean commodity-price space. That function is also homogeneous of degree zero. For a mathematician, these are compelling reasons for normalizing the price vector so that it belongs to the unit sphere. Then aggregate excess demand can be represented by a vector tangent to the sphere at the price vector with which it is associated. In other words, the aggregate excess demand function is a vector field on the positive unit sphere. Hugo Sonnenschein conjectured in 1973 that any continuous function satisfying Walras' Law is the aggregate excess demand function of a finite exchange economy. A proof of that conjecture (Debreu 1974) was suggested by the preceding geometric interpretation since any vector field on the positive unit sphere can be written as a sum of l elementary vector fields, each one obtained by projecting a positive vector on one of the l coordinate axes into the tangent hyperplane. There only remains to note that every continuous elementary vector field is the excess demand function of a mathematically well-behaved consumer. Mathematical form and economic content alternately took the lead in the development of this proof.

The pursuit of generality in a formalized theory is no less imperative than the pursuit of rigour, and the mathematician's compulsive search for ever weaker assumptions is reinforced by the economist's awareness of the limitations of his postulates. It has, for example, expurgated superfluous differentiability assumptions from economic theory, and prompted its extension to general commodity spaces.

Akin in motivation, execution and consequences is the pursuit of simplicity. One of its expressions is the quest for the most direct link between the assumptions and the conclusions of a theorem. Strongly motivated by aesthetic appeal, this quest is responsible for more transparent proofs in which logical flaws cannot remain hidden, and which are more easily communicated. In extreme cases the proof of an economic proposition becomes so simple that it can dispense with mathematical symbols. The first main theorem of welfare economics, according to which an equilibrium relative to a price system is a Pareto optimum, is such a case.

In the demonstration, we study an economy consisting of a set of agents who have collectively at their disposal positive amounts of a certain number of commodities and who want to allocate these total resources among themselves. By the consumption of an agent, we mean a list of the amounts of each commodity that he consumes. And by an allocation, we mean a specification of the consumption of each agent such that the sum of all those individual consumptions equals the total resources. Following Pareto, we compare two allocations according to a unanimity principle. We say that the second allocation is collectively preferred to the first allocation if every agent prefers the consumption that he receives in the second to the consumption that he receives in the first. According to this definition, an allocation is optimal if no other allocation is collectively preferred to it. Now imagine that the agents use a price system, and consider a certain allocation. We say that each agent is in equilibrium relative to the given price system if he cannot satisfy his preferences better than he does with his allotted consumption unless he spends more than he does for that consumption. We claim that an allocation in which every agent is in equilibrium relative to a price system is optimal. Suppose, by contradiction, that there is a second allocation collectively preferred to the first. Then every agent prefers his consumption in the second allocation to his consumption in the first. Therefore the consumption of every agent in the second allocation is more

expensive than his consumption in the first. Consequently the total consumption of all the agents in the second allocation is more expensive than their total consumption in the first. For both allocations, however, the total consumption equals the total resources at the disposal of the economy. Thus we asserted that the value of the total resources relative to the price system is greater than itself. A contradiction has been obtained, and the claim that the first allocation is optimal has been established.

This result, which provides an essential insight into the role of prices in an economy and which requires no assumption within the model, is remarkable in another way. The two concepts that it relates might have been isolated, and its symbol-free proof might have been given early in the history of economic theory and without any help from mathematics. In fact that demonstration is a late by-product of the development of the mathematical theory of welfare economics. But to economists who have even a casual acquaintance with mathematical symbols, the previous exercise is not more than an artificial *tour de force* that has lost the incisive conciseness of a proof imposing no bar against the use of mathematics. That conciseness is one of the most highly prized aspects of the simplicity of expression of a mathematized theory.

In close relationship with its axiomatization, economic theory became concerned with more fundamental questions and also more abstract. The problem of existence of a general economic equilibrium is representative of those trends. The model proposed by Walras in 1874–7 sought to explain the observed state of an economy as an equilibrium resulting from the interaction of a large number of small agents through markets for commodities. Over the century that followed its publication, that model came to be a common intellectual framework for many economists, theorists as well as practitioners. This eventually made it compelling for mathematical economists to specify assumptions that guarantee the existence of the central concept of Walrasian theory. Only through such a specification, in particular, could the explanatory power of the model be fully appraised. The early proofs of existence of Wald in 1935–6 were followed by a pause of nearly two decades, and then by the contemporary phase of development beginning in 1954 with the articles of Arrow and Debreu, and of Lionel McKenzie.

In the reformulation that the theory of general economic equilibrium underwent, it reached a higher level of abstraction. From that new viewpoint a deeper understanding both of the mathematical form and of the economic content of the model was gained. Its role as a benchmark was also perceived more clearly, a role which prompted extensions to incomplete markets for contingent commodities, externalities, indivisibilities, increasing returns, public goods, temporary equilibrium, ...

In an unanticipated, yet not unprecedented, way greater abstraction brought Walrasian theory closer to concrete applications. When different areas of the field of computable general equilibrium were opened to research at the University of Oslo, at the Cowles Foundation, and at the World Bank, the algorithms of Scarf included in their lineage proofs of existence of a general economic equilibrium by means of fixed point theorems. This article has credited the mathematical form of theoretic models with many assets. Their sum is so large as to turn occasionally into a liability, as the seductiveness of that form becomes almost irresistible. In its pursuit, research may be tempted to forget economic content and to shun economic problems that are not readily amenable to mathematization. No attempt will be made here, however, to draw a balance sheet, to the debit side of which justice would not be done. Economic theory is fated for a long mathematical future, and in other editions of Palgrave authors will have the opportunity, and possibly the inclination, to choose as a theme 'Mathematical Form vs. Economic Content'.

The idea of applying mathematics to human affairs may appear at first sight an absurdity worthy of Swift's Laputa. Yet there is one department of social science which by general consent has proved amenable to mathematical reasoning – statistics. The operations not only of arithmetic, but also of the higher calculus, are applicable to statistics. What has long been admitted with respect to the average results of human action has within the last half-century been claimed for the general laws of political economy. The latter, indeed, unlike the former, do not usually present numerical constants; but they possess the essential condition for the application of mathematics: constancy of *quantitative* – though not necessarily numerical – relations. Such, for example, is the character of the law of Diminishing Returns: that an increase in the capital and labour applied to land is (tends to be) attended with a less than proportionate increase in produce. The language of Functions is well adapted to express such relations. When, as in the example given, and frequently in economics (see Marshall, *Principles,* 5th edn, Preface, p. xix), the relation is between *increments* of quantities, the differential calculus is appropriate. In the simpler cases the geometrical representations of functions and their differentials may with advantage be employed.

Among the branches of the economic calculus *simultaneous equations* are conspicuous. Given several quantitative – though not in general numerical – relations between several variable quantities, the economist needs to know whether the quantities are to be regarded as *determinate*, or not. A beautiful example of numerous prices determined by numerous conditions of supply and demand is presented by Professor Marshall in his 'bird's-eye view of the problems of joint demand, composite demand, joint supply, and composite supply' (*Principles,* Mathematical Appendix, note xxi). 'However complex the problem may become, we can see that it is theoretically determinate' (ibid., cf. Preface, p. xx). When we have to do with only *two* conditions, two *curves*

may be advantageously employed instead of two *equations.*

The mathematical operations which have been mentioned, and others – in particular the integral calculus, are all contained in the calculus of *maxima* and *minima*, or, as it is called, of *variations;* which seems to comprehend all the higher problems of abstract economics. For instance, Prof. Marshall, after writing out a number of equations 'representing the causes that govern the investment of capital and effort in any undertaking', adds, 'they may all be regarded as mathematically contained in the statement that H–V [the net advantages] is to be made a maximum' (*Principles,* Mathematical Appendix, 2nd and later editions, note xiv). It was profoundly said by Malthus, 'Many of the questions both in morals and politics seem to be of the nature of the problems *de maximis et minimis* in fluxions.' The analogy between economics and mechanics in this respect is well indicated by Dr Irving Fisher in his masterly *Mathematical Investigations*.

The property of dealing with quantities not expressible in numbers, which is characteristic of mathematical economics, is not to be regarded as a degrading peculiarity. It is quite familiar and allowed in ordinary mathematics. For instance, if one side of a plane triangle is greater than another, the angle opposite the greater side is greater than the angle opposite the less side (*Euclid*, Book I). Quantitative statements almost as loose as those employed in abstract economics occur in the less perfectly conquered portions of mathematical physics, with respect to the distances of the fixed stars, for instance (see Sir Robert Ball, *Story of the Heavens*, ch. xxi); e.g. before 1853 it was only known that 'the distance of 61 Cygni could not be *more* than sixty billions of miles'. It is really less than forty billions.

The instance of astronomy suggests a secondary or indirect use of mathematical method in economics, which physical science has outgrown. As the dawn of the Newtonian, or even of the Copernican, theory put to flight the vain shadows of astrology, so the mere statement of an economic problem in a mathematical form may correct fallacies. Attention is directed to the data which would be required for a scientific solution of the problem. Variable quantities expressed in symbols are less liable to be treated as constant. This sort of advantage is obtained by formulating the relation between quantity of precious metal in circulation and the general level of prices, as Sir John Lubbock (senior) has done in his pamphlet *On currency* (anonymous, 1840). Thus the mathematical method contributes to that negative or dialectic use of theory which consists in meeting fallacious arguments on their own ground of abstract reasoning (see some remarks on this use of theory by Prof. Simon Newcomb in the June number of the *Quarterly Journal of Economics,* 1893; and compare Prof. Edgeworth, *Economic Journal,* vol. i, p. 627). The mathematical method is useful in clearing away the rubbish which obstructs the foundation of economic science, as well as in affording a plan for the more regular part of the structure.

The modest claims here made for the mathematical method of political economy may be illustrated by comparing it with the literary or classical method in the treatment of some of the higher problems of the science. The fundamental principle of supply and demand has been stated by J.S. Mill with much precision in ordinary language (*Political Economy,* book iii, ch. 2, §§ 4, 5, and, better, review of Thornton, *Dissertations*, vol. iv). But he is not very happy in indicating the distinction between a rise of price which is due to a diminution of supply – the dispositions of the buyers, the Demand Curves remaining constant – and the rise of price which is due to a displacement of the demand curve. He appears not to perceive that the position of equilibrium between supply and demand is *determinate*, even where it is not *unique* – a conception supplied by equations with multiple roots or curves intersecting in several points. The want of this conception seems to involve even Mill's treatment of the subject in obscurity (*Political Economy,* book iii, ch. 18, § 6).

The use of simultaneous equations or intersecting curves facilitates the comprehension of the 'fundamental symmetry' (Marshall) between the forces of demand and supply; the littérateurs lose themselves in wordy disputes as to which of the two factors 'regulates' or 'determines' value.

The disturbance of the conditions of supply by a tax or bounty, or other impediment or aid, gives rise to problems too complicated for the unaided intellect to deal with. Prof. Marshall, employing the mathematical theory of Consumers' rent, reaches the conclusion that it might *theoretically* be advantageous to tax commodities obeying the law of decreasing returns in order with the proceeds to give bounty to commodities following the opposite law (*Principles,* book v, ch. xiii, § 7). The want of the theory of consumer's rent renders obscure Mill's treatment of the 'gain' which a country may draw to itself by taxing exports or imports (*Political Economy,* book v, ch. 4, § 6; cf. book iii, ch. 18, § 5). This matter is much more clearly expressed by the curves of Messrs. Auspitz and Lieben (*Untersuchungen*, Article 81).

The preceding examples presuppose free competition; the following relate to monopoly. The relation between the rates and the traffic of a railway is shown with remarkable clearness by the aid of a diagram in the appendix to Prof. Hadley's *Railroad Transportation.* By means of elaborate curves Prof. Marshall shows that a government having regard to the interest of the consuming public, as well as to its revenue, may fix a much lower price than a monopolist actuated by mere self-interest. The taxation of monopolies presents problems which require the mathematical method initiated by Cournot. His reasoning convinces of error the following statement made by Mill (book v, chs 4, 6) and others: 'A tax on rare and high-priced wines will fall only on the owners of the vineyard,' for 'when the article is a strict monopoly . . . the price cannot be further raised to compensate for the tax'. Cournot obtains by mathematical reasoning the remarkable theorem that in cases where there is a joint demand for articles monopolized by different individuals, the purchaser may come off worse than if he had dealt with a single monopolist. This case is more important than at first appears (Marshall, *Principles,* 2nd edn, book v, ch. x, § 4; 5th edn, book v, ch. xi, § 7).

Under the head of monopoly may be placed the case of two individuals or corporate units dealing with each other. The indeterminateness of the bargain in this case is perhaps best contemplated by the aid of diagrams.

These examples, which might be multiplied, seem to prove the usefulness of the mathematical method. But the estimate would be imperfect without taking into account the abuses and defects to which the method is liable. One of these is common to every *organon* – especially new ones – liability to be overrated. As Prof. Marshall says, 'When the actual conditions of particular problems have not been studied, such [mathematical] knowledge is little better than a derrick for sinking oil-wells where there are no oil-bearing strata.' Again, the mathematical method is a machinery, the use of which is very liable to be overbalanced by the cost to others than the maker of acquiring it. Not only is mathematics a foreign language 'to the general'; but even to mathematicians a new notation is an unknown dialect which it may not repay to learn. As Prof. Marshall says, 'It seems doubtful whether any one spends his time well in reading lengthy translations of economic doctrines into mathematics that have not been made by himself.'

This estimate of the uses and dangers of mathematical method may be confirmed by reference to the works in the subjoined list; which does not pretend to be exhaustive.

Mathematics and Economics

E. R. Weintraub

Abstract

The interconnection of mathematics and economics reflects changes in both the mathematics and economics communities over time. The respective histories of these disciplines are intertwined, so that both changes in mathematical knowledge and changing ideas about the nature of mathematical knowledge have effected changes in the methods and concerns of economists.

Understanding the connection between mathematics and economics is not the same as understanding the nature and role of mathematical economics. 'Mathematical economics' is the employment of mathematics in economics itself. Explaining or justifying mathematical economics often involves essentialist arguments concerning the true nature of economic objects and the true nature of the economy, as well as arguments suggesting that employing mathematics is appropriate since the underlying 'economy' is quantitative in nature. Consequently, an historical discussion of mathematical economics will be a narrative of increased sophistication over time in economics, as mathematical tools, techniques and methods move into economic discourse and enrich economic analysis.

Alternatively, one can discuss the relation between mathematics and economics in terms of separate intellectual activities performed in separate intellectual communities, and in that case one will wish to look over time at the interpenetration of the ideas and practices of the two communities across their highly permeable boundaries. The history of mathematics concerns the changing body of mathematical knowledge such as new theorems proved, new research areas opened, and new techniques developed. But the history also involves changing images of mathematical knowledge: changing perspectives and understandings, for example, about the nature of mathematical objects, what constitutes a proof, what constitutes rigour, what constitutes useful versus not useful mathematics, and so forth (see Corry 1996, p. 3). Similarly the history of economics involves a history of not only the development of economic knowledge, but the development and changes in images of economic knowledge: what constitutes the economy, what constitutes a good explanation in economics, what constitutes serious empirical work in economics, what a good model is, and so on. Consequently a discussion of the interconnection of mathematics and economics requires not just attention to the interconnection of the bodies of knowledge, as is reflected in the historical discussion of mathematical economics, but a historical discussion of the interconnection of their respective images of knowledge. Put another way, a discussion of the connection of mathematics and economics must reflect economists' changing conceptions of the image of mathematical knowledge and not just their changing understandings of the body of mathematical knowledge.

This distinction between the body of knowledge and the images of knowledge provides a different perspective on the relation between

mathematics and economics. The central point for economists to understand is that there were three distinct shifts in the image of mathematics from the beginning of the nineteenth century to the end the twentieth century.

From Geometry to Mechanics

As a starting point, consider the conditions and perspectives under which mathematics was produced early in the nineteenth century. Looking closely, we see, particularly in England, the importance of both Euclid's *Elements* and Newton's *Principia*. That is, from relatively early in the nineteenth century, through the modifications of the Cambridge Tripos in 1849, and on through the middle third of the nineteenth century at Cambridge, mathematics was understood as flowing, in its purpose and nature, from both Euclid and Newton. From Euclid one understood that geometry was the paradigm of mathematics, and that it was a path to truth. Theorems were derived from assumptions called axioms, where the truth of those assumptions was self-evident from our understanding of the physical world. To learn geometry was to understand how rigorous arguments could lead to truth. One studied mathematics, specifically geometry, as an exemplar of how one deduced truths about the world, and thus mathematics was the paradigm of deductive thought and logical ratiocination. Parallel to this view of how deductive reasoning from true premises could lead to true conclusions, Newton's *Principia* (his mathematical proofs of course were all based on Euclidian geometry – even the calculus derivations were geometrical), suggested how this kind of mathematics could also open up an understanding of the physical world. Students were required to study mathematics because it provided a way of achieving truth.

This image of mathematics is at the root of Ricardo's arithmetical models, and is present in Whewell's papers (Whewell 1829, 1831, 1850) on economics using mathematics, for Whewell himself was central in reconstructing the Cambridge Tripos around Euclidean geometry and Newton's *Principia* at mid-nineteenth century. Economics was to employ a particular kind of mathematics, Euclidean geometry, to demonstrate its propositions. Just as Newton employed geometrical proofs of his propositions, so too did Marshall. It is an interesting exercise to open Alfred Marshall's *Principles* next to the Newton's *Principia* and see the physical similarity of the proofs or demonstrations of the propositions in each book. Marshall, as Second Wrangler in the Mathematical Tripos of January 1865, had had to master both Euclid and Newton.

The first change in the image of mathematics was developed from a new conception of what mathematical truth might mean. It occurred over the second third of the nineteenth century and was then well incorporated in the Continental tradition in mathematics. That is, outside Britain there was a change in the image of mathematics between the time of Whewell's defence of mathematics in the educational process, a defence based in the notion that mathematics (*vide* Euclid, Newton) was the paradigm of certain and secure knowledge (the time of Marshall's student days), and Marshall's later time as Professor of Political Economy. The emergence of non-Euclidean geometries had made Whewell's argument about axiomatics, and inevitable truth, ring hollow long before the turn of the twentieth century. In the time of the new geometries, the difficulty of linking mathematical truth to a particular (Euclidean) geometry produced a real crisis of confidence for Victorian educational practice (Richards 1988). This first crisis prepared the late Victorian mind for the new idea that mathematical rigour had to be associated with physical argumentation. And it was this new image of mathematics in science that helps us to understand the concerns of individuals like Edgeworth and Pareto.

An emergent set of themes in mathematics developed from the increased awareness of alternatives to Euclidean geometry, and the recognition that no one set of axioms could be selected for demonstrating the truth of all mathematical propositions. Thus the success of the new rational mechanics (Lagrange's programme of applying techniques of advanced calculus to the study of motions of solids and liquids) in making sense of the world of physical systems encouraged a

refinement of the truth-producing view of mathematics. That is, in the last third of the nineteenth century, in Britain as well as Italy, France and Germany, a rigorous mathematical argument began to be seen as one based on a substrate of physical reasoning. For an argument to be rigorous, and thus believable, the mathematical structure had to be founded generally on the most successful of applied mathematical practices, namely, rational mechanics. *A valid and good and useful mathematical model was a model that had physical interpretations*. The 'marginal revolution' in economics was precisely this new understanding. One sees this very clearly in Marshall, who was at the cusp of this changed image of mathematics, for his derivations were offered using Euclidian geometry, but whose mathematical arguments about equilibrium and stability are instantiations of mechanical devices like an egg in a bowl, or a pair of scissors. Put another way, through much of the nineteenth century in British mathematics, and thus to a degree among insular British economists for whom British mathematics *was* mathematics, rigour in argument was associated with geometric proofs based on assumptions, called axioms, that could be linked to constrained optimization processes associated with particular physical systems. Rational mechanics was taken as a paradigm for what economists came to call the marginal revolution, which, however, was hardly revolutionary but rather the migration of rational mechanical ideas into economic discourse (Mirowski 1989). Thus, by the last decades of the nineteenth century one finds economists employing specific mechanical models of economic behaviour. Walras, Pareto, Marshall, Edgeworth and Fisher were producing rigorous mathematical models of economic processes, where rigour was associated with a mathematics tied to physical processes.

From Mechanics to Axiomatics

But by 1900 the images of, and styles of doing, mathematics were beginning to change again in response to new challenges in mathematics and physics. In mathematics, there were problems associated with the foundations of mathematics. There were apparent inconsistencies in set theory associated with Georg Cantor's new ideas on 'infinity' (that is, transfinite cardinals, and the continuum of real numbers), and apparent inconsistencies in the foundations of arithmetic and logic, associated with work by Frege and Peano. Similarly troubling was the failure of physics, particularly rational mechanics, to solve the new problems associated with black-body radiation, quanta and relativity. If the deterministic mechanical mode of physical argumentation was to be replaced by an alternative physical theory, what constituted a rigorous mathematical argument had to be re-described. In any event, some established areas of mathematics were no longer connected to a canonical physical model (Weintraub 2002).

Consequently, around the end of the nineteenth century, just as economists had begun to understand that constructing a mathematical science required basing argumentation of the physical reasoning of rational mechanics, and the measurement of quantities to further ground those reasoning chains, the image of mathematical knowledge was again changing. Modelling the concerns of the new physics appeared to require a new mathematics, based less on deterministic dynamical systems and more on statistical argumentation, algebra, and new beliefs about appropriate axioms for logic and arithmetic.

Just as the objects of the physical world appeared changed – gone were billiard balls, newly present were quanta – the recognition that the paradoxes of set theory and logic were intertwined led mathematicians to seek new foundations for their subject. Analysis of those foundations of set theory, logic and arithmetic, and thus the foundations of sciences based on mathematics, were now to be based on axiomatic thinking. A rigorous argument was to be one built on strong foundations, and axiomatizing the structure of theories, in both physics and mathematics, was a path to the development of those theories (Hilbert 1918). Thus, following a late nineteenth century period in which mathematical rigour was to be established by basing the mathematics on physical reasoning, around 1900 – as understanding of the physical world became less

secure – *mathematical truth was to be established not relative to physical reasoning but relative to other mathematical theories and objects*. From a physical reductionism mathematics moved to a mathematical reductionism, in the guise of one or another set of ideas about formalism: problems and paradoxes and confusions in turn-of-the-century mathematics were to be resolved by a re-conceptualization of the nature of the fundamental objects of mathematics. The images of mathematical knowledge and ideas of rigour, truth, formalization and proof all changed over this period.

It took a number of decades for this new image of mathematics to become securely established in the mathematical community. From Hilbert's 1918 call for axiomatization as the road to knowledge in mathematics and science, through the interwar years, mathematicians were slow to reframe their working concerns. So too did economists' use of mathematics in the interwar period reflect the earlier perspectives of modelling economic problems as constrained optimization demonstrations imitating nineteenth century mechanics. Beginning in the 1930s, however, a group of French mathematicians, collectively called 'Nicholas Bourbaki', began rewriting mathematics from the foundationalist perspective (Weintraub and Mirowski 1994). Mathematics was conceived of, in their project, as growing organically from very basic ideas about sets, which led inexorably to the identification of a small number of 'mother structures' (algebraic, order, and topological) from which other structures, other branches of mathematics, could be derived. Rigorous mathematics was not grounded in physical models but rather in mathematics itself. Mathematics was to concern itself with analyses of mathematical structures. Over the next few decades pure mathematics, or mathematics uncontaminated by applications and disengaged from the world of applications, gained sway in the mathematics community. It was in this period that the eminent mathematician Paul Halmos (1981) famously titled an article 'Applied mathematics is bad mathematics'. In economics, this concatenation of ideas moved into mainstream theory with the work of Gerard Debreu, Kenneth Arrow and Tjalling Koopmans. The Cowles Commission, in the 1940s at the University of Chicago, became the site for production of this kind of work in mathematical economic theory, particularly general equilibrium theory.

Yet, even as a pure mathematics was taking hold in economics, the exigencies of the Second World War and economists' involvement with scientists, engineers, and other social scientists, moved mathematical economists' concerns back from axiomatization and into what would become operations research. This, of course, was not 'pure' at all, but based on concrete problems of real systems. As Amy Dahan Dalmedico, the historian of mathematics, noted:

> The second World War initiated what I shall call 'image war' or 'representation war' concerning what mathematics was about, what it dealt with, and how. Over the course of the 1950s and 1960s, this 'war' was progressively developed until the balance of power began to shift perceptibly at the end of the 1970s and during the 1980s. This 'war' was focused mainly on the cleavage between pure and applied mathematics, and on the tacit hierarchy – of concepts as much as of values – informing these categories of 'pure' and 'applied'. (Dalmedico 2001, p. 224)

Thus, Bourbakist images of mathematics were becoming dominant in economics at the same time as the major challenge to those ideas was forming outside 'pure' theory. The image of mathematics as a discipline concerned with understanding the structures of mathematical objects was indeed dominant in the 1950s and 1960 s, not only in the United States but in a number of other countries. Yet, from the Second World War on through the cold war, applied mathematics was taking root in disparately profound ways, and was attracting more and more support in the form of grants and contracts and students. New fields of statistics, computer science and operations research flourished. Consequently, economists' ideas about mathematics began to undergo changes, as usual with some time lag, mirroring the changing images of mathematics that were reshaping interests and methods in the mathematics community itself. 'While *structure* was the emblematic term of the 1960s, *model* has now taken its place. In the physical sciences,

climatology, engineering science, economics, and the social sciences, the practice of model-building has gradually dominated the terrain. It is today absolutely massive and intrinsically bound up with numerical experimentation and simulation' (Dalmedico 2001, 249).

If the important lesson from mathematics in the first third of the nineteenth century was that economics needed to become a deductive science (as geometry was), in the late nineteenth century the lesson from mathematics was that economics needed to model itself on rational mechanics. Over the first two thirds of the 20th century the lesson was that economics was to become scientific by grounding its models and theories on a modest set of axioms concerning pure economic agents' preferences and choices. But, beginning nearly at mid-century, mathematics was re-imagining itself as a discipline that historically had developed by solving real problems presented to it from other sciences. And in a similar fashion, and partially in response to that changing image of mathematical knowledge, the notion of a serious economic science, connected to data-based reasoning, was reshaping the idea of rigorous argumentation in economics. Econometrics and applied microeconomics were to form the reconstructed core of economic science much as work in algorithmics and applied mathematics were re-commanding attention in the mathematics community. 'At the Berlin International Congress of Mathematicians in August 1998, the old opposition between the pure and the applied – still widely shared in the community – has been formulated in quite different terms: "mathematicians who build models versus those who prove theorems". (Mumford 1998). But the respect enjoyed by the former is now definitely as high as that of the latter' (Dalmedico 2001, p. 249). So too in economics, as the prestige accorded 'good work' in applied economics now rivals that accorded to work in pure theory.

Mathematics of Networks

M. E. J. Newman

Abstract

The patterns of interactions, both economic and otherwise, between individuals, groups or corporations form social networks whose structure can have a substantial effect on economic outcomes. The study of social networks and their implications has a long history in the social sciences and more recently in applied mathematics and related fields. This article reviews the main developments in the area

with a focus on practical applications of network mathematics.

In much of economic theory it is assumed that economic agents interact, directly or indirectly, with all others, or at least that they have the opportunity to do so in order to achieve a desired outcome for themselves. In reality, as common sense tells us, things are quite different. Traders in a market have preferred trading partners, perhaps because of an established history of trust, or simply for convenience. Buyers and sellers have preferred suppliers and customers. Consumers have preferred brands and outlets. And most individuals limit their interactions, economic or otherwise, to a select circle of partners or acquaintances. In many cases partners are chosen not on economic grounds but for social reasons: individuals tend overwhelmingly to deal with others who revolve in the same circles as they do, socially, intellectually or culturally.

The patterns of connections between agents form a social network (Fig. 1), and it is intuitively clear that the structure of such networks must affect the pattern of economic transactions, not to mention essentially every other type of social interaction among human beings. Any theory of interaction that ignores these networks is necessarily incomplete. In the last few decades, therefore, researchers have conducted extensive investigations of networks in economics, mathematics, sociology and a number of other fields, in an effort to understand and explain network effects.

The study of social (and other) networks has three primary components. First, empirical studies of networks probe network structure using a variety of techniques such as interviews, questionnaires, direct observation of individuals, use of archival records, and specialist tools like 'snowball sampling' and 'ego-centred' studies. The goal of such studies is to create a picture of the connections between individuals, of the type shown in Fig. 1. Since there are many different kinds of possible connections between people – business relationships, personal relationships, and so forth – studies must be designed appropriately to measure the particular connections of interest to the experimenter.

Second, once one has empirical data on a network, one can answer questions about the community the network represents using mathematical or statistical analyses. This is the domain of classical social network analysis, which focuses on issues such as: who are the most central members of a network and who are the most peripheral? Which people have most influence over others? Does the community break down into smaller groups, and if so what are they? Which connections are most crucial to the functioning of a group?

And third, building on the insights obtained from observational data and its quantitative analysis, one can create models, such as mathematical models or computer models, of processes taking place in networked systems – the interactions of traders, for example, or the diffusion of information or innovations through a community. Modelling work of this type allows us to make predictions about the behaviour of a community as a function of the parameters affecting the system.

After a brief historical review, the primary purpose of this article is to describe the mathematical techniques involved in the second and third of these three components: the quantitative analysis of network data and the mathematical modelling of networked systems. Necessarily, this review is short. Much more substantial coverage can be found in the many books and review articles in the field (Wasserman and Faust 1994; Scott 2000; West 1996; Harary 1995; Ahuja et al. 1993; Dorogovtsev and Mendes 2003; Albert and Barabási 2002; Newman 2003).

History of Social Network Analysis

The study of social networks has roots in the 19th-century beginnings of sociology, especially the 'gestalt' tradition of Koehler and others, but is widely regarded as having begun in earnest in the 1930s with the work of psychologist Jacob Moreno, a Romanian immigrant to the United States who had spent a number of years in Vienna and was influenced there by the work of Freud. Moreno advocated an approach to psychoanalysis that involved participants discussing or physically enacting issues that concerned them in front of the analyst. Another approach, which Moreno employed with schoolchildren among others, involved the analyst passively watching participants' interactions with one another and recording their nature and pattern. In the process of his studies he developed a new tool, the sociogram, which was a map of interactions between individuals drawn on paper as a set of points and lines (Moreno 1934, p. 38).

In 1933 Moreno presented some of his sociograms during a lecture at a medical conference in New York City, and the work attracted sufficient interest to be featured in the *New York Times*. In everything but name, Moreno's sociograms were what we would now call social networks, and his methods, although strange by today's standards, were the intellectual precursor of social network analysis, which is now a flourishing branch of the social sciences (Wasserman and Faust 1994). (The term 'social network' was not invented until some years later; it is usually credited to John Barnes 1954.)

Apart from a gap during the war years, social network analysis was pursued vigorously following its early popularization. Particularly well-known studies include the 'southern women' study of Davis et al. (1941), Anatol Rapoport's investigations of friendship networks among school children in the 1950s (Rapoport and Horvath 1961), Pool and Kochen's (1978) mathematical models of social networks that circulated widely in the 1950s and 1960s (although they were not published until much later), and Stanley Milgram's (1967) famous 'small world' experiments. Today, social network analysis is one of the standard quantitative tools in the social science toolbox, finding use both in academia and in the business world as a microscope with which to view the details of social interactions.

Mathematics of Networks

Turning to the mathematical methods of network analysis, which are the principal focus of this article, let us begin with some simple definitions. A network – also called a *graph* in the mathematics literature – is made up of points, usually called *nodes* or *vertices*, and lines connecting them, usually called *edges*. Mathematically, a network can be represented by a matrix called the *adjacency matrix* $\mathbf{A}$, which in the simplest case is an $n \times n$ symmetric matrix, where n is the number of vertices in the network. The adjacency matrix has elements

$$A_{ij} = \begin{cases} 1 & \text{if there is an edge between vertices } i \text{ and } j, \\ 0 & \text{otherwise.} \end{cases} \tag{1}$$

The matrix is symmetric since if there is an edge between i and j then clearly there is also an edge between j and i. Thus $A_{ij} = A_{ji}$.

In some networks the edges are *weighted*, meaning that some edges represent stronger connections than others, in which case the nonzero elements of the adjacency matrix can be generalized to values other than unity to represent stronger and weaker connections. Another variant is the *directed network*, in which edges point in a particular direction between two vertices. For instance, in a network of cash sales between buyers and sellers the directions of edges might represent the direction of the flow of goods (or conversely of money) between individuals. Directed networks can be represented by an asymmetric adjacency matrix in which $A_{ij} = 1$ implies the existence (conventionally) of an edge pointing from j to i (note the direction), which will in general be independent of the existence of an edge from i to j.

Networks may also have *multiedges* (repeated edges between the same pair of vertices), *self-edges* (edges connecting a vertex to itself), *hyper-edges* (edges that connect more than two vertices together) and many other features. We here concentrate primarily on the simplest networks, having undirected, unweighted single edges between pairs of vertices.

Centrality Measures

Now let us consider the analysis of network data. We start by looking at *centrality measures*, which are some of the most fundamental and frequently used measures of network structure. Centrality measures address the question, 'Who is the most important or central person in this network?' There are many answers to this question, depending on what we mean by 'important'. Perhaps the simplest of centrality measures is *degree centrality*, also called simply *degree*. The degree of a vertex in a network is the number of edges attached to it. In mathematical terms, the degree k_i of a vertex i is

$$k_i = \sum_{j=1}^{n} A_{ij}. \tag{2}$$

Though simple, degree is often a highly effective measure of the influence or importance of a node: in many social settings people with more connections have more power.

A more sophisticated version of the same idea is the so-called *eigenvector centrality*. Where degree centrality gives a simple count of the number of connections a vertex has, eigenvector centrality acknowledges that not all connections are equal. In general, connections to people who are themselves influential will lend a person more influence than connections to less influential people. If we denote the centrality of vertex i by x_i, then we can allow for this effect by making x_i proportional to the average of the centralities of i's network neighbours:

$$x_i = \frac{1}{\lambda}\sum_{j=1}^{n} A_{ij}x_j, \tag{3}$$

where λ is a constant. Defining the vector of centralities $\mathbf{x} = (x_1, x_2,..)$, we can rewrite this equation in matrix form as

$$\lambda\mathbf{x} = \mathbf{A}\cdot\mathbf{x}, \tag{4}$$

and hence we see that $\mathbf{x}$ is an eigenvector of the adjacency matrix with eigenvalue λ. On the assumption that we wish the centralities to be non-negative, it can be shown (using the Perron–Frobenius theorem) that λ must be the largest eigenvalue of the adjacency matrix and $\mathbf{x}$ the corresponding eigenvector.

The eigenvector centrality defined in this way accords each vertex a centrality that depends on both the number and the quality of its connections: having a large number of connections still counts for something, but a vertex with a smaller number of high-quality contacts may outrank one with a larger number of mediocre contacts. Eigenvector centrality turns out to be a revealing measure in many situations. For example, a variant of eigenvector centrality is employed by the well-known Web search engine Google to rank Web pages, and works well in that context.

Two other useful centrality measures are *closeness centrality* and *betweenness centrality*. Both are based upon on the concept of network paths. A path in a network is a sequence of vertices traversed by following edges from one vertex to another across the network. A *geodesic path* is the shortest path, in terms of number of edges traversed, between a specified pair of vertices. (Geodesic paths need not be unique; two or more paths can tie for the title of shortest.) The closeness centrality of vertex i is the mean geodesic distance (that is, the mean length of a geodesic path) from vertex i to every other vertex. Closeness centrality is *lower* for vertices that are more central in the sense of having a shorter network distance on average to other vertices. (Some writers define closeness centrality to be the reciprocal of the average so that higher numbers indicate greater centrality. Also, some vertices may not be reachable from vertex i – two vertices can lie in separate 'components' of a network, with no connection between the components at all. In this case closeness as above is not well defined. The usual solution to this problem is simply to define closeness to be the average geodesic distance to all *reachable* vertices, excluding those to which no path exists.)

The betweenness centrality of vertex i is the fraction of geodesic paths between other vertices that i lies on. That is, we find the shortest path (or paths) between every pair of vertices, and ask on what fraction of those paths vertex i lies. Betweenness is a crude measure of the control i exerts over the flow of information (or any other commodity) between others. If we imagine information flowing between all pairs of individuals in the network and always taking the shortest possible path, then betweenness centrality measures the fraction of that information that will flow through i on its way to wherever it is going. In many social contexts a vertex with high betweenness will exert substantial influence by virtue not of being in the middle of the network (although it may be) but of lying 'between' other vertices in this way. It is in most cases only an approximation to assume that information flows along geodesic paths; normally it will not, and variations of betweenness centrality such as 'flow betweenness' and 'random walk betweenness' have been proposed to allow for this. In many practical cases, however, the simple (geodesic path) betweenness centrality gives quite informative answers.

Other Network Properties

The study of shortest paths on networks also leads to another interesting network concept, the *small-world effect*. It is found that in most networks the mean geodesic distance between vertex pairs is small compared with the size of the network as a whole. In a famous experiment conducted in the 1960s, the psychologist Stanley Milgram (1967) asked participants (located in the United States) to get a message to a specified target person elsewhere in the country by passing it from one acquaintance to another, stepwise through the population. Milgram's remarkable finding that the typical message passed though just six people on its journey between (roughly) randomly chosen initial and final individuals has been immortalized in popular culture in the phrase 'six degrees of separation', which was the title of a 1990 Broadway play by John Guare in which one of the characters discusses the small-world effect. Since Milgram's experiment, the small-world effect has been confirmed experimentally in many other networks, both social and nonsocial.

Other network properties that have attracted the attention of researchers in recent years include network *transitivity* or *clustering* (the tendency for triangles of connections to appear frequently in networks – in common parlance, 'the friend of my friend is also my friend'), vertex similarity (the extent to which two given vertices do or do not occupy similar positions in the network), communities or groups within networks and methods for their detection, and, crucially, the distribution of vertex degrees, a topic discussed in more detail below.

Models of Networks

Turning to models of networks and of the behaviour of networked systems, we find that perhaps the simplest useful model of a network (and one of the oldest) is the *Bernoulli random graph*, often called just the *random graph* for short (Solomonoff and Rapoport 1951; Erdős and Rényi 1960; Bollobás 2001). In this model one takes a certain number of vertices n and creates edges between them with independent probability p for each vertex pair. When p is small there are only a few edges in the network, and most vertices exist in isolation or in small groups of connected vertices. Conversely, for large p almost every possible edge is present between the $\binom{n}{2}$ possible vertex pairs, and all or almost all of the vertices join together in a single large connected group. One might imagine that for intermediate values of p the sizes of groups would just grow smoothly from small to large, but this is not the case. It is found instead that there is a *phase transition* at a special value $p = 1/n$ above which a *giant component* forms, a group of connected vertices occupying a fixed fraction of the whole network, i.e., with size varying as n. For values of p less than this, only small groups of vertices exist of a typical size that is independent of n. Many real-world networks show behaviour reminiscent of this model, with a large component of connected vertices filling a sizable fraction of the entire network, the remaining vertices falling in much smaller components that are unconnected to the rest of the network.

The random graph has a major shortcoming, however: the distribution of the degrees of the vertices is quite unlike that seen in most real-world networks. The fraction p_k of vertices in a random graph having degree k is given by the binomial distribution, which becomes Poisson in the limit of large n:

$$p_k = \binom{n-1}{k} p^k (1-p)^{n-1-k} ; \frac{z^k e^{-z}}{k!}, \qquad (5)$$

where $z = (n-1)p$ is the mean degree. Empirical observations of real networks, social and otherwise, show that most have highly non-Poisson distributions of degree, often heavily right-skewed with a fat tail of vertices having unusually high degree (Albert and Barabási 2002; Dorogovtsev and Mendes 2003). These high-degree nodes or 'hubs' in the tail can, it turns out, have a substantial effect on the behaviour of a networked system.

To allow for non-Poisson degree distributions, one can generalize the random graph, specifying a

particular, arbitrary degree distribution p_k and then forming a graph that has that distribution but is otherwise random. A simple algorithm for doing this is to choose the degrees of the n vertices from the specified distribution, draw each vertex with the appropriate number of 'stubs' of edges emerging from it, and then pick stubs in pairs uniformly at random and connect them to create complete edges. The resulting model network (or more properly the ensemble of such networks) is called the *configuration model*.

The configuration model also shows a phase transition, similar to that of the Bernoulli random graph, at which a giant component forms. To see this, consider a set of connected vertices and consider the 'boundary vertices' that are immediate neighbours of that set. Let us grow our set by adding the boundary vertices to it one by one. When we add one boundary vertex to our set the number of boundary vertices goes down by 1. However, the number of boundary vertices also increases by the number of new neighbours of the vertex added, which is one less than the degree k of that vertex. Thus the total change in the number of boundary vertices is $-1 + (k-1) = k-2$. However, the probability of a particular vertex being a boundary vertex is proportional to k, since there are k times as many edges by which a vertex of degree k could be connected to our set than there are for a vertex of degree 1. Thus the average change in the number of boundary vertices when we add one vertex to our set is a weighted average $\Sigma_i k_i(k_i-2) = \sum_j k_j = \Sigma_i k_i(k_i-2) = (nz)$, where z is again the mean degree. If this quantity is less than zero, then the number of boundary vertices dwindles as our set grows bigger and will in the end reach zero, so that the set will stop growing. Thus in this regime all connected sets of vertices are of finite size. If on the other hand this number is greater than zero, then the number of boundary vertices will grow without limit, and hence the size of our set of connected vertices is limited only by the size of the network.

Thus, a giant component exists in the network if and only if

$$\langle k^2 \rangle - 2\langle k \rangle > 0, \tag{6}$$

where $\langle k \rangle = z = n^{-1}\Sigma_i k_i$ is the mean degree and $\langle k^2 \rangle = n^{-1}\Sigma_i k_i^2$ is the mean-square degree.

The mean-square degree appears over and over in the mathematics of networks. Another context in which it appears is in the spread of information (or anything else) over a network. Taking a simple model of the spread of an idea (or a rumour or a disease), imagine that each person who has heard an idea communicates it with independent probability q to each of his or her friends. If the person's degree is k, then there are $k-1$ friends to communicate the idea to, not counting the one from whom he or she heard it in the first place, so the expected number who hear it is $q(k-1)$. Performing the weighted average over vertices again, we find that the average number of people a person passes the idea onto, also called the *basic reproductive number* R_0, is

$$R_0 = q\frac{\sum_i k_i(k_i-1)}{\sum_i k_i} = q\frac{\langle k^2 \rangle - \langle k \rangle}{\langle k \rangle}. \tag{7}$$

If R_0 is greater than 1, then the number of people hearing the idea grows as it gets passed around and it will take off exponentially. If R_0 is less than 1 then the idea will die. Again, we have a phase transition, or *tipping point*, for the spread of the idea: it spreads if and only if

$$q > \frac{\langle k \rangle}{\langle k^2 \rangle - \langle k \rangle}. \tag{8}$$

The simple understanding behind the appearance of the mean-square degree in this expression is the following. If a person with high degree hears this idea he or she can spread it to many others, by virtue of having many friends. However, such a person is also more likely to hear the idea in the first place because of having many friends to hear it from. Thus, the degree enters twice into the process: a person with degree 10 is $10 \times 10 = 100$ times more effective at spreading the idea than a person with degree 1.

The appearance of the mean-square degree in expressions like (6) and (8) can have substantial effects. Of particular interest are networks whose degree distributions have fat tails. It is possible for

such networks to have very large values of $\langle k^2 \rangle$– in the hundreds or thousands – so that, for example, the right-hand side of Eq. (8) is very small. This means that the probability of each individual person spreading an idea (or rumour or disease) need not be large for it still to spread through the whole community.

Another important class of network models is the class of generative models, models that posit a quantitative mechanism or mechanisms by which a network forms, usually as a way of explaining how the observed structure of the network arises. The best-known example of such a model is the 'cumulative advantage' or 'preferential attachment' model (Price 1976; Barabási and Albert 1999), which aims to explain the fat-tailed degree distributions observed in some networks. In its simplest form this model envisages a network that grows by the steady addition of vertices, one at a time. Many networks, such as the World Wide Web and citation networks, grow this way; it is a matter of current debate whether the model applies to social networks as well. Each vertex is added with a certain number m of edges emerging from it, whose other ends connect to pre-existing vertices with probability proportional to those vertices' current degree. That is, the higher the current degree of a vertex, the more likely that vertex is to acquire new edges when the graph grows. This kind of rich-get-richer phenomenon is plausible in many network contexts and is known to generate Pareto degree distributions. Using a rate-equation method (Price 1976; Simon 1955; Krapivsky et al. 2000), we find that in the limit of large network size the degree distribution obeys:

$$p_k = \frac{2m(m+1)}{k(k+1)(k+2)}. \tag{9}$$

This distribution has a tail going as $p_k : k^{-3}$ in the large-k limit, which is strongly reminiscent of the degree distributions seen particularly in citation networks and also in the World Wide Web. Generative models of this type have been a source of considerable interest in recent years and have been much extended by a number of authors (Dorogovtsev and Mendes 2003; Albert and Barabási 2002) beyond the simple ideas described here.

Concepts such as those appearing in this article can be developed a great deal further and lead to a variety of useful, and in some cases surprising, results about the function of networked systems. More details can be found in the references.

Matrix Multiplier

J. R. N. Stone

The matrix multiplier is a generalization of Kahn's scalar multiplier. The term was introduced by Goodwin (1949), though similar work was done independently by Chipman (1949, 1950a, 1951).

Consider a closed set of accounts, divided into endogenous and exogenous subsets and represented by the row-and-column pairs in a matrix with money incomings in the rows and money outgoings in the columns. The first n accounts are endogenous and the remaining m are exogenous. The $n \times n$ submatrix, W say, contains transactions between endogenous accounts; the $n \times m$ submatrix, X say, contains expenditures by the exogenous accounts which are injections into the endogenous subsystem; the $m \times n$ submatrix, Z say, contains expenditures by the endogenous accounts which are leakages into the exogenous subsystem.

Writing y for the column vector of endogenous account totals, i for the unit vector, I for the unit matrix, x for Xi, and $A = W\hat{y}^{-1}$ where $\hat{y}$ denotes a diagonal matrix formed from y, then

$$y = Wi + x = Ay + x = (I - A)^{-1}x \quad (1)$$

where $(I-A)^{-1}$ is a matrix multiplier transforming the injections into the endogenous accounts into the endogenous account totals. If these accounts are restricted to the production accounts of the economy, then (1) represents Leontief's open input–output model.

Since the entries in the matrix are expressed in money terms, the vector of product prices is $p = \hat{y}^{-1}y = i$; and if we denote the vector of exogenous outgoings (primary input costs) per unit of total outgoings from the endogenous accounts (total costs = total output) by $f = \hat{y}^{-1}z$, where $z = Z'i$, then

$$y = W'i + z \quad (2)$$

and

$$p = A'p + f = (I - A')^{-1}f \quad (3)$$

where $(I - A')^{-1}$, the transpose of $(I - A)^{-1}$, transforms the cost of primary inputs per unit of output into product prices. These multipliers exist only if $A'i < i$.

Since $A^{\theta} \to 0$ as $\theta \to \infty$, we can write

$$\begin{aligned}(I - A)^{-1} &= I + A + A^2 \ldots \\ &= I + A + A^2(I - A)^{-1} \quad (4)\end{aligned}$$

where I corresponds to the output required to meet the injections of demand; A corresponds to the direct inputs into this output; and $A^2(I-A)^{-1}$ corresponds to the indirect inputs required to produce the direct outputs and so on indefinitely.

The endogenous subsystem need not be restricted to production accounts. Pyatt, Roe and associates (1977) treat as endogenous: (i) accounts for different types of factor income, (ii) accounts for the income and outlay of different sectors, and (iii) accounts for different branches of production, leaving capital and foreign accounts as exogenous. As a result, A is partitioned into three diagonal submatrices, B say, and six off-diagonal ones,

C say. Then, putting $(I - B)^{-1}C = D$, we can write

$$\begin{aligned} y &= Ay + x = (I - D)^{-1}(I - B)^{-1}x \\ &= \left(I + D + D^2\right)\left(I - D^3\right)^{-1}(I - B)^{-1}x \\ &= M_3M_2M_1x. \end{aligned} \tag{5}$$

In (5), $(I - A)^{-1}$ is partitioned into three components: M_1 arises from repercussions of the initial injection within the subsystem it initially entered; M_2 arises from its repercussions when it has completed a tour through all three subsystems and returned to the one it initially entered; and M_3 arises from its repercussions when it has completed a tour outside its original subsystem without returning to it. Thus, in terms of additive components,

$$\begin{aligned} (I - A)^{-1} = I + (M_1 - I) + (M_2 - I)M_1 \\ + (M_3 - I)M_2M_1. \end{aligned} \tag{6}$$

The multipliers are based on average propensities, which should be replaced by marginal propensities when measuring the effects of changes in injections (Pyatt and Round 1979).

Equation (5) can be extended to several regions (Round 1984), though difficulties arise if we try to apply the analysis to more than three. For two regions, r and s say, let the diagonal matrices of transactions between them be $\hat{a}_{rs}$ and $\hat{a}_{sr}$. Then, putting $(I - A_{rr})^{-1}\hat{a}_{rs} = F_{rs}$, (5) is replaced by

$$\begin{aligned} \begin{bmatrix} zy_r \\ y_s \end{bmatrix} &= \begin{bmatrix} A_{rr} & \hat{a}_{rs} \\ \hat{a}_{sr} & A_{ss} \end{bmatrix}\begin{bmatrix} y_r \\ y_s \end{bmatrix} + \begin{bmatrix} x_r \\ x_s \end{bmatrix} \\ &= \begin{bmatrix} I & -F_{rs}F_{sr} \\ -F_{sr}F_{rs} & I \end{bmatrix}^{-1}\begin{bmatrix} (I - A_{rr})^{-1} & 0 \\ 0 & (I - A_{ss})^{-1} \end{bmatrix} \\ &\times \begin{bmatrix} x_r \\ x_s \end{bmatrix} = \begin{bmatrix} (I - F_{rs}F_{sr})^{-1} & 0 \\ 0 & (I - F_{sr}F_{rs})^{-1} \end{bmatrix} \\ &\times \begin{bmatrix} I & F_{rs} \\ F_{sr} & I \end{bmatrix} \times \begin{bmatrix} (I - A_{rr})^{-1} & 0 \\ 0 & (I - A_{ss})^{-1} \end{bmatrix}\begin{bmatrix} x_r \\ x_s \end{bmatrix} \\ &= N_3N_2N_1x \end{aligned} \tag{7}$$

where $x = \{x_r\ x_s\}$. The complete matrix multiplier for the two region-system can be expressed in terms of additive components by substituting Ns for Ms in (6).

Goodwin (1949) also formulates a dynamic matrix multiplier corresponding to (1). An economy is initially in equilibrium, with $y = y_0$ and $x = x_0$. It is assumed that there is a one-period lag in all spending and that in each period $\theta > 0, x_0$ is replaced by x_1. Writing $\Lambda^\theta x(\tau) = x(\tau + \theta)$,

$$\begin{aligned} \Lambda^\tau y = A^\tau y_0 + \sum_{\theta=0}^{\tau-1} A^\theta \Lambda^{\tau-\theta-1}x_1 \\ = A^\tau y + (I - A^\tau)(I - A)^{-1}x_1 \\ = A^\tau y_0 + (I - A^\tau)y_i \end{aligned} \tag{8}$$

that is, y moves from y_0 to y_1 as a changing weighted sum of the two. Thus the dynamic matrix multiplier has the static value as a limit.

Goodwin stated that successive values of the components of y were bound to oscillate and the question was debated in Chipman (1950b) and Goodwin (1950). In fact they oscillate only if the elements of $(x_1 - x_0)$ have different signs. Since this is likely to be the case, we can only work out the future course of y from the first row of (8), which would require estimates of the future course of injections.

Maximum Likelihood

Jack R. Porter

Abstract

Maximum likelihood is a method of estimation developed for fully specified parametric likelihood settings. In smooth parametric models, maximum likelihood has a number of desirable properties, including consistency, asymptotic normality, and asymptotic efficiency. Maximum likelihood has been usefully extended to various semiparametric and nonparametric settings.

Keywords

Asymptotic normality; Bootstrap; Confidence region; Consistency; EM algorithm; Empirical likelihood; Fisher, R. A.; Generalized method of moments; Invariance; Law of large numbers; Likelihood principle; Local likelihood; Log likelihood ratio; Maximum likelihood; Nonparametric regression; Semiparametric estimation; Statistical inference; Sufficiency

JEL Classifications

C1

Given data from some member of a parametric family of distributions, maximum likelihood provides a general purpose method of estimation frequently accompanied by useful statistical properties.

In a series of papers, R.A. Fisher (1922, 1925, 1934) proposed and argued for a method of estimation he dubbed 'maximum likelihood'. The intuitive appeal and broad applicability continue to drive its use as a primary tool of statisticians. Suppose data $z = (z_1, \ldots, z_n)$ is drawn from a distribution with density $f_n(z; \theta_0)$, and further suppose that this distribution is a member of a family of parametric distributions with densities $\{f_n(z; \theta) : \theta \in \Theta \subset \mathbb{R}^k\}$ (for k finite and $\theta_0 \in \Theta$). The likelihood function is simply defined by the joint density as the function $l_n(\theta, z) = f_n(z; \theta)$ with argument θ and data z held fixed. The maximum likelihood estimator (MLE) is then defined as

$$\hat{\theta}_{ML} = \arg \min_{\theta \in \Theta} l_n(\theta, z).$$

One motivation for the MLE comes from the likelihood principle, which implies that statistical inference on θ given data z should be based solely on the likelihood function, $l_n(\theta, z)$ (Berger and Wolpert 1988). According to this principle the relative evidence on two different values of θ given by the data is fully summarized by their likelihood ratio. In this sense, the MLE is the value of θ most supported by the data. Of course, most econometric work involving maximum likelihood does not take a strict likelihood principle viewpoint, but is typically more concerned with sampling properties from a frequentist viewpoint. It is this perspective that will be our main emphasis in what follows.

It is often convenient to (equivalently) think of the MLE as maximizing the log likelihood ratio, $\mathcal{L}_n(\theta) = \ln \frac{f_n(z;\theta)}{f_n(z;\theta_0)}$. When the data is independent and identically distributed (i.i.d.) with marginal density f, the log likelihood ratio can be written $\mathcal{L}_n(\theta) = \sum_{i=1}^{n} \ln \frac{f(z_i;\theta)}{f(z_i;\theta_0)}$. By the law of large numbers, the normalized log likelihood ratio $\left(\frac{1}{n}\mathcal{L}_n(\theta)\right)$ approaches $\mathcal{L}(\theta) = E\theta_0\left[\ln \frac{f(z_i;\theta)}{f(z_i;\theta_0)}\right]$ (where the expectation is taken with respect to the 'population' density $f(z_i; \theta_0)$) asymptotically. Though–$\mathcal{L}(\theta)$ does not satisfy the formal definition of metric, it is often taken as distance measure between the densities $f(z_i; \theta)$ and $f(z_i; \theta_0)$. Not surprisingly, this distance is minimized at $\theta = \theta_0$ (when the identification condition that $f(z; \theta) \neq f(z; \theta_0)$ for $\theta \neq \theta_0$ is satisfied). The log likelihood ratio $\mathcal{L}_n(\theta)$, can be interpreted as a sample approximation to

this discrepancy measure, which is minimized at the MLE. The likelihood ratio test statistic, for testing the null hypothesis that $\theta = \theta_0$, is also based on this value.

Fisher emphasized the usefulness of the maximized likelihood itself. The density $f_n\left(z; \hat{\theta}_{ML}\right)$ provides an approximation to the population density. If, for instance, there is interest in some feature of $f_n(z; \theta_0)$, then an approximation can often be obtained from the corresponding feature $f_n\left(z; \hat{\theta}_{ML}\right)$ (as in the parametric bootstrap). More generally, Efron (1982) notes that $f_n\left(z; \hat{\theta}_{ML}\right)$ acts as a data summary.

Properties

For most commonly used parametric distributional families, the MLE is consistent. Note, for instance, that when $\mathcal{L}(\theta)$ is maximized at θ_0, and the convergence of the log likelihood ratio $\frac{1}{n}\mathcal{L}(\theta)$ mentioned above is uniform on Θ, then $\hat{\theta}_{ML}$ will correspondingly converge to θ_0. More general sufficient conditions for consistency are also available; see Ibragimov and Has'minskii (1981).

Under appropriate regularity conditions (which essentially amount to smoothness of the parametric model), the MLE is asymptotically normal.

$$\sqrt{n}\left(\hat{\theta}_{ML} - \theta_0\right) \rightarrow N\left(0, J(\theta_0)^{-1}\right)$$

where $J(\theta)$ is the Fisher information matrix, with value $E_\theta[\nabla_\theta lnf(z;\ \theta)(\nabla_\theta lnf(z;\ \theta))']$ when the data is i.i.d. and $\nabla_\theta \ \ln f(z_i;\ \theta)$ is called the 'score function'. Define the Hessian as $H(\theta) = \ E_\theta[\nabla_{\theta\theta} \ \ln \ f(z_i;\ \ \theta)]$. By the information matrix equality, $J(\theta) = \ -H(\theta)$ which adds to the variety of estimators for the information matrix. Frequentist confidence intervals are then immediately available based on the asymptotic normality property and an estimator for $J(\theta_0)$.

Other approximations for the distribution of the MLE are also available for certain statistical models. Barndorff-Nielsen (1983) provides an accurate approximation to the conditional distribution of the MLE given a maximal ancillary statistic. (An ancillary statistic is a statistic whose distribution does not depend on θ, and if every ancillary statistic is a function of a given ancillary statistic then that statistic is called maximal.) When the MLE is sufficient, Barndorff-Nielsen's formula is exact. For non-regular models, asymptotic normality may no longer hold and a general limiting distribution result is then unavailable. Ibragimov and Has'minskii (1981), for instance, characterize the asymptotic behavior of the MLE for certain non-regular classes of models.

The Fisher information matrix is additionally useful as an efficiency bound. Accordingly, the MLE itself enjoys certain optimality properties. For regular models, the MLE is asymptotically efficient under classical criteria. Hirano and Porter (2005) show that a shifted version of the MLE is asymptotically efficient for an even broader class of statistical models (and allow for asymmetric loss). Higher-order efficiency of the MLE has been established in Pfanzagl and Wefelmeyer (1978).

Intuition for the asymptotic normality and efficiency of the MLE can be gained through a consideration of the behaviour of the log likelihood ratio in the i.i.d. case. If we re-parametrize the likelihood in terms of the 'local' parameter $h = \sqrt{n}(\theta - \theta_0)$, then with enough smoothness the log likelihood ratio can be expanded as follows

$$\sum_{i=1}^{n} \ln \frac{f(z_i; \theta_0 + h/\sqrt{n})}{f(z_i; \theta_0)} \approx \frac{h'}{\sqrt{n}} \sum_{i=1}^{n} \nabla_\theta \ln f(z_i; \theta_0) + \frac{1}{2} \cdot \frac{1}{n} \sum_{i=1}^{n} h' \nabla_{\theta\theta} \ln \ f(z_i; \theta_0) h.$$

Under regularity conditions, the log likelihood ratio converges in distribution (for each h) to $N\left(-\frac{1}{2}h'J(\theta_0)h, h'J(\theta_0)h\right)$. (This kind of 'Taylor' expansion actually holds under a mild condition of differentiability in quadratic mean which is weaker than the twice continuous differentiability of the likelihood that appears necessary.) Models with log likelihood ratios obeying this kind of convergence are called 'locally asymptotically normal'. Now, consider the statistical model consisting of a single observation on a random variable $X \sim N(h, J(\theta_0)^{-1})$. Notably, the log

likelihood ratio for this simple statistical model $\{N(h, J(\theta_0)^{-1}) : h \in \mathbb{R}^k\}$ has the same distribution as the asymptotic distribution for the log likelihood ratio of the general model above. Since the log likelihood ratio captures all the statistical information in a given statistical model, there is an equivalence between the asymptotic behaviour of the original model with densities $\prod_{i=1}^{n} f(z_i; \theta)$ and the much simpler model given by a single observation from a normal with unknown mean h (and known variance-covariance, $J(\theta_0)^{-1}$). This equivalence is formalized in the limits of experiments theory (Le Cam 1986). Intuitively, one might expect that the MLE for the local parameter $\hat{h}_{ML} = \sqrt{n}\left(\hat{\theta}_{ML} - \theta_0\right)$ in the original model will behave (asymptotically) like the MLE of the 'limit' normal model, which is simply given by X. The normality of X and the efficiency (minimax) of the mean in a normal model then corresponds to the asymptotic normality and asymptotic efficiency of the MLE in the original model.

Other important properties of the MLE are invariance and sufficiency. The MLE is necessarily a function of all sufficient statistics. The MLE is also invariant to parametrization of the family of distributions. So, if the distributions are reparametrized in terms of $\lambda = T(\theta)$, then $\hat{\lambda}_{ML} = T\left(\hat{\theta}_{ML}\right)$. Additionally, the MLE satisfies a group equivariance property (Eaton 1989). Suppose the family of distributions is invariant under the group of transformations $\mathcal{G}$ defined on both the sample and parameter spaces. if $g \in \mathcal{G}$, then $\hat{\theta}_{ML}(gz) = g\,\hat{\theta}_{ML}(z)$ where the MLE is written as a function of the observations.

Limitations

Since densities are not uniquely defined, the likelihood criterion on which the MLE is based is not uniquely defined. For a given likelihood, a solution to the maximization problem that defines the MLE need not necessarily exist (or multiple solutions are also possible).

The consistency, asymptotic normality and efficiency properties (discussed above) are all asymptotic, leaving the possibility that the small sample behaviour of the MLE may be quite poor in given applications. Even the asymptotic properties themselves are assured under regularity conditions. Neyman and Scott (1948) describe a famous example where maximum likelihood can be poorly behaved in small samples. The random variables x_{ij} are distributed $N(\mu_i, \sigma^2)$ for $i = 1,\ldots, n, j = 1,\ldots, J$, and all random variables are independent. Consider the case with fixed n and $J = 2$. Since $x_{i2} - x_{i1}$ is distributed $N(0, 2\sigma^2)$, $s_n^2 = \frac{1}{2}\ \frac{1}{n}\sum_{i=1}^{n}(x_{i2} - x_{i1})^2$ is a natural and reasonable estimator for σ^2. But $\hat{\sigma}^2{}_{ML} = \frac{1}{2}s_n^2$, which could be a quite poor estimator with significant bias. This poor small sample performance is particularly notable, since this model consists only of independent normally distributed random variables. Asymptotically, if n remains fixed and J grows, then the MLE has all the usual favourable large sample properties. If J is fixed and n grows, then the assumption of a finite dimensional parameter space is violated, and the MLE is not even consistent.

Stein's well-known shrinkage estimator shows that, even in a simple normal model with known variance-covariance and unknown mean, the MLE need not be (mean-squared error) optimal. It is also notable that, outside of regular models, asymptotic efficiency of the MLE can frequently fail. A simple example of such a non-regular model is data drawn from a uniform distribution on $[0, \theta]$. More general, parameter-dependent support models can be found in the auction literature, and the MLE is generally suboptimal by traditional asymptotic efficiency criteria (Hirano and Porter 2003). Le Cam (1990) lists a number of additional examples where the deficiencies of maximum likelihood are highlighted.

Extensions

Suppose the parameter is partitioned, $\theta' = (\theta'_1, \theta'_2)$ and we define $\theta_2^*(\theta_1) = \arg\max_{\theta 2} l_n(\theta_1, \theta_2)$. Then, the profiled likelihood, $l_n\left(\theta_1, \theta_2^*(\theta_1)\right)$ can be maximized to give the MLE for θ_1. Sometimes this is useful for computational purposes.

This formulation has also been useful for conceptual purposes, such as developing semiparametric efficiency bounds, where θ_2 contains nuisance parameters. Maximum likelihood theory also extends immediately to conditional likelihood formulations. Other methods have been developed to ease the computational burden of maximum likelihood in certain problems. The EM algorithm can be especially helpful in missing data cases (MacLachlan and Krishnan 1997). Simulated maximum likelihood is useful when the likelihood can be expressed as high-dimensional integral without a closed form solution (Hajivassiliou and Ruud 1994).

A natural concern with maximum likelihood is its reliance on correct specification of the family of distributions. Quasi-likelihood methods suggest parametric families that have robustness properties beyond the family specified. Exponential linear families often play a prominent role in this approach (Gourieroux et al. 1984). Typically, efficiency is sacrificed, but consistency and asymptotic normality still hold where the asymptotic variance of the limiting normal distribution is given by the 'sandwich' formula, $H(\theta_0)^{-1}J(\theta_0)^{-1}H(\theta_0)^{-1}$.

Extensions of maximum likelihood have also been usefully applied in semiparametric and nonparametric contexts. Ai (1997) considers semiparametric estimation in a model with unknown conditional density that is assumed only to satisfy an index restriction. The conditional density is estimated nonparametrically, and the corresponding score function is constructed to produce a semiparametric maximum likelihood estimate of a finite-dimensional parameter of the model. Tibshirani and Hastie (1987) introduced the notion of local likelihood estimation where regression functions are fit locally according to a maximum likelihood criterion. This idea has been extended to density estimation and other regression-type settings (Fan et al. 1998). Linton and Xiao (2007) develop an adaptive nonparametric regression approach that estimates the unknown density of the disturbance (or its score function) and then uses this estimate for local likelihood estimation of the unknown regression function. Empirical likelihood methods are another offshoot of nonparametric maximum likelihood. The basic insight that the empirical distribution function is the nonparametric MLE for a general cumulative distribution function has led to new approaches to confidence region formation, estimation in regression models, generalized method of moments inference, and bootstrapping (Owen 2001; Brown and Newey 2002).

Maximum Satisfaction

F. Y. Edgeworth

Maximum satisfaction is the object towards which the economic man strives; the margin, which constitutes economic equilibrium. A great part of economic theory may be regarded as a statement of the conditions of maximum satisfaction (cf. Marshall's *Principles*, mathematical appendix, note xiv). Thus the theory of market price – that the demand at that price should equal the supply at it (Mill, Bk. iii, ch. 2) – may be deduced as the condition of the price for which the satisfaction of the buyers and sellers should be a maximum.

It is understood that this maximum is subject, or – as the mathematicians say, *relative* – to certain limitations. Thus, in a market, it is assumed that property passes only by exchange. It is not denied that an equalization of property would – abstracting ulterior consequences – be productive of a greater sum total of utility than is produced by the play of the market under a regime of unequal property (Sidgwick's *Political Economy*, Bk. iii, ch. vii; Jevons's *Theory*, 2nd edn, p. 153; Marshall's *Principles*, Bk. v, ch. xiii).

It should be understood also that the *maximum* value of a function is not necessarily the greatest possible value, but only the greatest of all values in the neighbourhood – a peak, but not the summit. There may be more *maxima* than one; and one *maximum* may be greater than another (Marshall, *loc. cit*. note). Accordingly, while it is true that any disturbance by which trade is shifted from an equilibrium to a neighbouring position, causes a diminution in the sum total of utility, it is also true that a disturbance, by which trade is shifted to the neighbourhood of a new equilibrium, may cause an increase in the sum total of utility. The latter kind of change is apt to occur when, by a stimulus to increased production, the advantages of production on a large scale are secured. Now it is quite conceivable that such a stimulus should be given by governmental interposition. Thus, while it is right to hold with Auspitz and Lieben (*Theorie der Preises*, p. 425) and the classical economists, that a bounty causes a diminution in the sum total of utility, the organization of industry being supposed unchanged; it is also right to hold with Professor Marshall that bounty, by bringing about a re-organization of industry, may cause an increase in the sum total of utility.

Altogether, the doctrine that maximum satisfaction, or the greatest general good, is attained by exchange free from government intervention, is theoretically true in a much narrower sense than has been supposed by many publicists, and even by some theoretical economists. Its validity as a handy rule for practice is not denied.

[There is implied in the preceding argument a certain conception, which it is impossible here to express fully, concerning the modification of the law of supply – or Supply-curves – which is involved in a re-organization of industry,

consequent on an enlarged scale of production. The view expressed on this subject by H. Cunynghame in the *Economic Journal* for March 1892 may be compared with the view expressed by Edgeworth in the *Economic Journal*, vol. iv, p. 436, and vol. xv, p. 62. In his *Mathematical Psychics*, he has pointed out analogies between the principle of maximum utility in economics and the principle of maximum energy in physics.]

Maximum Score Methods

Robert P. Sherman

Abstract

This article describes some aspects of maximum score estimation of parameters of multinomial and, especially, binomial choice models. In the context of binomial choice models, strengths and weaknesses of the estimation procedure are discussed, as well as its relation to classical quantile regression estimation and its nonstandard rate of convergence. The benefits of smoothing the score criterion function are also noted.

Keywords

Binary response models; Bootstrap; Central limit theorems; Heteroskedasticity; Linear median regression; Maximum likelihood; Maximum score methods; Multinomial choice models; Quantile regression; Random utility maximization; Semiparametric estimation

JEL Classification

C14

In a seminal paper, Manski (1975) introduces the maximum score estimator (MSE) of the structural parameters of a multinomial choice model and proves consistency without assuming knowledge of the distribution of the error terms in the model. As such, the MSE is the first instance of a semiparametric estimator of a limited dependent variable model in the econometrics literature.

Maximum score estimation of the parameters of a binary choice model has received the most attention in the literature. Manski (1975) covers this model, but Manski (1985) focuses on it. The key assumption that Manski (1985) makes is that the latent variable underlying the observed binary data satisfies a linear α-quantile regression specification. (He focuses on the linear median regression case, where $\alpha = 0.5$.) This is perhaps an under-appreciated fact about maximum score estimation in the binary choice setting. If the latent variable were observed, then classical quantile regression estimation (Koenker and Bassett 1978), using the latent data, would estimate, albeit more efficiently, the same regression parameters that would be estimated by maximum score estimation using the binary data. In short, the estimands would be the same for these two estimation procedures.

Assuming that the underlying latent variable satisfies a linear α-quantile regression specification is equivalent to assuming that the regression parameters in the linear model do not depend on the regressors and that the error term in the model has zero α-quantile conditional on the regressors. Under these assumptions, Manski (1985) proves strong consistency of the MSE. The zero conditional α-quantile assumption does not require the existence of any error moments and allows heteroskedastic errors of an unknown form. This flexibility is in contrast to many semiparametric estimators of comparable structural parameters for the binary choice model. As discussed in Powell (1994), many of these latter estimators require the existence of error moments and most require more restrictive assumptions governing the relation of errors to regressors.

The weak zero conditional α-quantile assumption comes at a price, however. Extrapolation power is limited: off the observed support of the regressors it is not possible to identify the conditional probability of the choice of interest, but only whether this probability is above or below $1 - \alpha$. See Manski (1995, pp. 149–50). There are also disadvantages associated with the estimation procedure. The maximum score criterion function is a sum of indicator functions of sets involving parameters. This lack of smoothness precludes using standard optimization routines to compute the MSE. Moreover, Kim and Pollard (1990) show that this type of discontinuity leads to a convergence rate of $n^{-1/3}$ rather than the $n^{-1/2}$ convergence rate attained by most semiparametric estimators of parameters in this model. In addition, Kim and Pollard (1990) show that the MSE has a nonstandard limiting distribution. The properties of this distribution are largely unknown, making asymptotic inference problematic. Also, Abrevaya and Huang (2005) prove that the bootstrapped MSE is an inconsistent estimator of the parameters of interest, precluding bootstrap inference.

To repair some of these shortcomings, Horowitz (1992) develops a smoothed MSE (SMSE) for the linear median regression case. This estimator retains the attractive flexibility properties of the MSE, but can be computed using standard optimization routines. In addition, the SMSE converges at a faster rate than the MSE and has a normal limit law allowing first order asymptotic inference. Horowitz (2002) proves that bootstrapped SMSE provides asymptotic refinements and in various simulations demonstrates the superiority of bootstrap tests over first-order asymptotic tests. Kordas (2006) generalizes Horowitz's (1992) SMSE to cover all α-quantiles.

In the next section, we present the multinomial choice model under random utility maximization as well as some intuition behind maximum score estimation in this context. We then discuss the relation between maximum score estimation in the binary response model and quantile regression. Next, we present Kim and Pollard's (1990) heuristic argument for the nonstandard rate of convergence of the MSE in the binary model. Finally, we discuss the method of Horowitz (1992) for smoothing the MSE.

The Random Utility Maximization Model of Choice and the MSE

Manski (1975) developed the MSE for the multinomial choice model in the context of random utility maximization. Suppose the ith individual in a sample of size n from a population of interest must make exactly one of J choices, where $J \geq 2$.

For $i \in \{1, 2, \ldots, n\}$ and $j \in \{1, 2, \ldots, J\}$, let U_{ik} denote the utility to individual i of making choice j. Assume the structural form $U_{ij} = X'_{ij}\beta + \varepsilon_{ij}$ where X_{ij} is an observable $m \times 1$ vector of explanatory variables, β is a unknown $m \times 1$ parameter vector, and ε_{ij} is an unobservable random disturbance. (A more general set-up can be accommodated. For example, there can be a different parameter vector associated with each choice.)

The utilities associated with the choices an individual faces are latent, or unobservable. However, an individual's choice is observable. Suppose we adopt the maximum utility model of choice: if individual i makes choice j then $U_{ij} > U_{ik}$ for all $k \neq j$. For any event E, define the indicator function $\{E\} = 1$ if E occurs and 0 otherwise. Define

M

$$Y_{ij} = \{U_{ij} > U_{ik}, \quad \text{for all } k \neq j\}$$
$$= \left\{X'_{ij} + \varepsilon_{ij} > X'_{ij}\beta + \varepsilon_{ik}, \quad \text{for all } k \neq j\right\}. \tag{1}$$

If choice j has maximum utility, then $Y_{ij} = 1$. Otherwise, $Y_{ij} = 0$. Thus, for each individual i, we observe $X_{ij}, j = 1, 2, \ldots, J$,and Y_{ij}, $j = 1, 2, \ldots, J$.

The traditional approach to estimating β in the multinomial choice model under the assumption of random utility maximization is the method of maximum likelihood in which the errors are iid with a distribution known up to scale. The likelihood function to be maximized has the form

$$\sum_{i=1}^{n}\sum_{j=1}^{J} Y_{ij} \quad \log P\{Y_{ij} = 1|X_{i1}, X_{i2}, \ldots, X_{iJ}, b\}.$$

For example, when εij has the Type 1 extreme-value cdf $F(t) = \exp(-\exp(-t)), \quad t \in R$, McFadden (1974) shows that the likelihood probabilities have the multinomial logit specification $\exp\left(X'_{ij}b\right)\left[\sum_{k=1}^{J}\exp\left(X'_{ij}b\right)\right]^{-1}$. The corresponding likelihood function is analytic and globally concave. Despite the consequent computational advantages, this specification makes very strong assumptions about the distribution of the errors. The MSE is consistent under much weaker assumptions about the errors. Manski (1975) only assumes that the disturbances ε_{ij} are independent and identically distributed (iid) across choices and independent but not necessarily identically distributed across individuals.

Write b for a generic element of the parameter space. It follows trivially from (1) that the infeasible criterion function

$$\sum_{i=1}^{n}\sum_{j=1}^{J} Y_{ij}\left\{X'_{ij}b + \varepsilon_{ij} > X'_{ik}b + \varepsilon_{ik}, k \neq j\right\}.$$

attains its maximum value of n at $b = \beta$. Since, for each i, the disturbances ε_{ij} are iid variates, this suggests estimating β with the maximizer of the so-called score function

$$\sum_{i=1}^{n}\sum_{j=1}^{J} Y_{ij}\left\{X'_{ij}b > X'_{ij}b, k \neq j\right\}.$$

A score for a parameter b is the number of correct predictions made by predicting Y_{ij} to be 1 whenever $X'_{ij}b$ exceeds $X'_{ij}b$ for all $k \neq j$. A maximizer of the score function is an MSE of β. The maximizer need not be unique.

The MSE in the Binary Choice Model and Quantile Regression

Now consider the binary model where $J = 2$. Define $Y_i = Y_{i1}$ (implying $Y_{i2} = 1 - Y$) and $X_i = X_{i1} - i2$. Then the score function in (2) reduces to

$$\sum_{i=1}^{n}\left[Y_i\{X'_ib > 0\} + 1(1 - Y_i)\{X'_ib < 0\}\right]. \tag{3}$$

Substitute $1 - \{X'_ib > 0\}$ for $1 - \{X'_ib < 0\}$ in (3) and expand each summand to see that maximizing (3) is equivalent to maximizing

$$S_n(b) = n^{-1}\sum_{i=1}^{n}(2Y_i - 1)\{X'_ib > 0\}. \tag{4}$$

Note that $Y_i = \{Y_i^* > 0\}$ where $Y_i^* = X'_i\beta + \varepsilon_i$ with $\varepsilon_i = \varepsilon_{i1} - \varepsilon_{i2}$. For ease of exposition, write (Y^*, Y, X, ε) for (Y_1^*, Y_1, X_1, ε_1) and x for an arbitrary point in the support of X. Thus, $Y = \{Y* > 0\}$ where $Y* = X'\beta + \varepsilon$.

Before proceeding further, we must consider what interpretation to give to the parameter β in the last paragraph. The interpretation depends on our assumptions. For example, if we assume that β does not depend on x and that for every x, $E[Y * |x] = x'\beta$, then β is such that the conditional mean of Y^* given $X = x$ is equal to $x'\beta$. However, if we assume that MED $(Y * |x) = x'\beta$, then β is such that the conditional median of Y^* given $X = x$ is equal to $x'\beta$. In general, the β satisfying the conditional mean assumption will be different from the β satisfying the conditional median assumption. Similarly, if we assume that for $a \neq 0{:}5$, the conditional α-quantile of Y^* given x is equal to $x'\beta$, then

this β will, in general, be different from the β satisfying the conditional median assumption.

With this in mind, for $\alpha \in (0,1)$, write $Q_\alpha(Y* | x)$ for the α-quantile of Y^* given $X = x$. Fix an $\alpha \in (0,1)$ and assume the linear α-quantile regression specification. That is, assume that for each x in the support of X, there exists a unique parameter β_α, depending on α but not on x, such that $Q_\alpha(Y* | x) = x'\beta_\alpha$. This implies a zero conditional α-quantile restriction on ε: $Q_\alpha(\varepsilon | x) = 0$ for all x.

For $\alpha \in (0,1)$, define

$$S_n^\alpha(b) = n^{-1}\sum_{i=1}^{n}[(2Y - 1_i) - (1-2\alpha)]\{X_i'b > 0\}. \tag{5}$$

Clearly, $S_n^{0.5}(b) = S_n(b)$ in (4). Assume that the linear α-quantile regression specification holds for some $\alpha \in (0,1)$. To see that it makes sense, under this assumption, to estimate β_α with the maximizer of $S_n^\alpha(b)$, consider $S^\alpha(b) = ES_n^\alpha(b)$

We see that

$$\begin{aligned} S^\alpha(b) &= E^X[E[(2Y-1) - 1(1-2\alpha)\{X'b > 0\}|X] \\ &= E^X\left[\left[2P\{-\varepsilon < X'\beta^\alpha\} - 1\right) - (1-2\alpha)\right]\{X'b > 0\}\right]. \end{aligned}$$

The linear α-quantile regression specification implies a zero conditional α-quantile restriction on ε: for all x, $P\{\varepsilon \le 0|x\} \le \alpha$ and $P\{\varepsilon \ge 0|x\} \ge \alpha$. Thus, $x'\beta_\alpha > 0$ if and only if $P\{-\varepsilon \le x\beta_\alpha|x\} \ge P\{-\varepsilon \le 0|x\} \ge 1 - \alpha$. Deduce that for each possible value of X, the term in outer brackets in the last expression is maximized at $b = \beta_\alpha$. It follows that $S^\alpha(b)$ is maximized at $b = \beta_\alpha$. The analogy principle (Manski 1988) prescribes using a maximizer of $S_n^\alpha(b)$ to estimate β_α.

The Nonstandard Convergence Rate

The summands of the criterion function in (5) depend on b only through indicator functions of sets. As such, each summand has a 'sharp edge', to use the terminology of Kim and Pollard (1990). These authors provide a beautiful heuristic for why estimators that optimize empirical processes with sharp-edge summands converge at rate $n^{-1/3}$, rather than the usual $n^{-1/2}$ rate. They decompose the sample criterion function into a deterministic trend plus noise. Then, for each possible parameter value, they consider how the trend and the noise compete for dominance. Only a parameter value for which the trend does not overwhelm the standard deviation of the noise has a fighting chance of being an optimizer. Sharp edges produce standard errors with nonstandard sizes leading to the nonstandard $n^{-1/3}$ rate. We now examine how their argument works for the MSE for a very simple model.

Assume the median regression specification for the model $Y = \{\beta - X - \varepsilon > 0\}$. Thus, $\beta_{0.5} = (\beta, 1)$ where the slope coefficient is known to equal -1 and the intercept β is the unknown parameter of interest. Assume that ε has median zero and is independent of X, so that the conditional median zero restriction is trivially satisfied. Also, assume that the distributions of X and ε have everywhere positive Lebesgue densities.

Refer to (4). Define $S(b) = ES_n(b) = E(2Y - 1)\{Xb > 0\}$. In the intercept example, $S(b) = E(2\{\varepsilon < \beta - X\} - 1)\{X < b\}$. Simple calculations show that

$$S(b) = 2\int_{-\infty}^{b} F_\varepsilon(\beta - t)f_x(t)dt - F_x(b)$$

where $F_\varepsilon(\cdot)$ is the cdf of ε, $f_x(\cdot)$ is the pdf of X, and $F_x(\cdot)$ is the cdf of X. Write $F_\varepsilon(\cdot)$ for the pdf of ε. Again, simple calculations show that

$$\begin{aligned} S'(b) &= 2E_\varepsilon(\beta - b)f_x(b) - f_x(b)S''(b) \\ &= 2F_\varepsilon(\beta - b)f_x'(b) - f_x(b)2f_\varepsilon(\beta - b) \\ &\quad - f_x'(b). \end{aligned}$$

By the median restriction, we see that $S'(\beta) = 0$ and $S''(\beta) = -2f_x(\beta)f_\varepsilon(0) < 0$. Thus, $S(b)$ is locally maximized at $b = \beta$. In fact, the given assumptions imply that $S(b)$ is globally and uniquely maximized at $b = \beta$. The MSE maximizes $S_n(b) - S_n(\beta)$. For each b, decompose $S_n(b) - S_n(\beta)$ into a sum of a deterministic trend and a random perturbation:

$$S_n(b) - S_n(\beta) = S(b) - S(\beta) + [S_n(b) - S_n(\beta) - [S(b) - S(\beta)]].$$

A Taylor expansion about β shows that for b near β, the trend $S(b) - S(\beta)$ is approximately quadratic with maximum value zero at $b = \beta$:

$$S(b) - S(\beta) \approx S''(\beta)(b - \beta)^2.$$

By a central limit theorem, for large n, the random contribution $S_n(b) - S_n(\beta) - [S(b) - S(\beta)]$ is approximately normally distributed with mean zero and variance σ_b^2/n where

$$\sigma_b^2 = E[(2Y - 1)[\{X < b\} - \{X < \beta\}]]^2 - [E(2Y - 1)[\{X < b\} - \{X < \beta\}]]^2.$$

For b near β, the second term is much smaller than the first. It is the first term that accounts for the sharp-edge effect. It equals

$$F_x(\beta) + F_x(b) - 2[F_x(\beta)\{b > \beta\} + F_x(b)\{b < \beta\}].$$

A Taylor expansion of both $F_x(b)$ terms about β shows that this term is approximately equal to $|b - \beta| f_x(\beta)$ for b near β. Thus, near β, the criterion function $S_n(b) - S_n(\beta)$ is approximately equal to a quadratic maximized at β, namely, $-c_1 (b - \beta)^2$ for $c_1 > 0$, plus a zero-mean random variable with standard deviation equal to $c_2 n^{-1/2} |b - \beta|^{1/2}$ for $c_2 > 0$. Values of b for which $-c_1 (b - \beta)^2$ is much bigger in absolute value than $c_2 n^{-1/2} |b - \beta|^{-1/2}$ have little chance of maximizing $S_n(b) - S_n(\beta)$. Rather, the maximizer is likely to be among those b values for which, for some $c > 0$,

$$(b - \beta)^2 \le c n^{-1/2} |b - \beta|^{1/2}.$$

Rearranging, we see that the maximizer is likely to be among the b values for which

$$|b - \beta| \le c n^{-1/3}.$$

This is the essence of the heuristic presented by Kim and Pollard (1990) for $n^{-1/3}$ convergence rates. These authors also note that, when criterion functions are smooth, the variance of the random perturbation usually has order $|b - \beta|^2$ (instead of $|b - \beta|$) which, by the same heuristic, leads to the faster $n^{-1/2}$ convergence rate.

Smoothing the MSE

In order to remedy some of the shortcomings of the MSE, Horowitz (1992) develops a smoothed maximum score estimator (SMSE) under a linear median regression specification for the latent variable in the binary model. He replaces the indicator function in (4) with a smooth approximation. His SMSE maximizes a criterion function of the form

$$n^{-1} \sum_{i=1}^{n} (2Y_i - 1) K\left(X_i' b \backslash \sigma_n\right)$$

where K is essentially a smooth cdf and σ_n approaches zero as the sample size increases. Thus, $K(X_i' b/\sigma_n)$ approaches the indicator function $\{X_i' b > 0\}$ as $n \to \infty$. By smoothing out the sharp-edge of the indicator function in (4), Horowitz is able to use Taylor expansion arguments to show that the SMSE, under slightly stronger conditions than those required for consistency of the MSE, converges at rate n^{δ} for $2/5 \le \delta < 1/2$ and has a normal limit. The exact rate of convergence depends on certain smoothness assumptions and satisfies an optimality property (see Horowitz 1993). The normality result makes it possible to do standard asymptotic inference with the SMSE. Horowitz (2002) shows that the bootstrapped SMSE provides asymptotic refinements.

Kordas (2006) applies the smoothing technique of Horowitz (1992) to the criterion function in (5) and obtains asymptotic results similar to those of Horowitz (1992) for any $\alpha \in (0, 1)$.

Italian economist, born in Naples on 16 September 1863; died in Courmayeur on 14 August 1899. When he was just 20 years old, he graduated from the University of Naples, where his economic course had been largely based on the ideas of Francesco Ferrara. He did postgraduate research in Berlin, where he came in touch with Adolf Wagner and carried out research on behalf of the Italian Ministry of Agriculture into the problems associated with providing insurance for the working classes. At the age of 24 Mazzola was appointed to the Chair of Public Finance at the University of Pavia, where in 1896 he, with other economists, bought up the *Giornale degli Economisti* and transformed it into a centre of liberal thought. It was in this journal that the most eminent economists of the time, Maffeo Pantaleoni, Antonio De Viti De Marco, and Vilfredo Pareto, had their work published.

Mazzola believed fervently in the concept of free trade and he fought the protectionist trends which were threatening the country as it moved towards industrialization. In economic doctrine he was attracted to marginalist theory, as advocated by Jevons and Menger, and to its more comprehensive version in general equilibrium theory. Using these tools of analysis he wrote *I dati scientifici della finanza pubblica*, published in 1890, and thus made 'a lasting contribution' (to quote Pantaleoni) to the foundation of the theory of public finance. Mazzola was an expert on German fiscal theories, but he disagreed with the rather ambiguous way in which they differentiated between individual and collective aims. Mazzola stressed that, in his view, individual objectives are conditioned by public aims (defence, security, and so on) which can only be achieved by means of political cooperation. He believed that the provision of public welfare was necessary for the attainment of collective aims. So he analysed the characteristics of public welfare and then examined the process of price determination by means of the principles of maximization of utility – characteristics of the marginalist theory. In this way the phenomenon of fiscal theory was brought within the sphere of general economic analysis.

MuCulloch was born in Galloway, Scotland on 1 March 1789. After attending Edinburgh University he secured employment as a lawyer's clerk. In 1816 he began his contributions to economics with two essays on the national debt. He was editor of *The Scotsman*, 1817–21, and a contributor to that paper until 1827. In 1818 he began writing for the *Edinburgh Review* and continued doing so until 1837, contributing nearly 80 articles. He also contributed to *Encyclopaedia Britannica* and was a prolific author, his works including editions of the *Wealth of Nations*, a *Commercial Dictionary, a Geographical Dictionary, Principles of Political Economy,* a *Statistical Account of the British Empire* and a *Treatise on Taxation*. He was a noted bibliophile, and after his death his library was purchased by his friend Lord Overstone and ultimately presented to Reading University.

It was not only as an author that McCulloch was influential; he was also called as an expert witness before the Select Committee on machinery of 1824 and that on Ireland of 1825. He was also one of the first public teachers of economics. He began lecturing in Edinburgh in 1820, and although attempts to establish a chair at Edinburgh University on his behalf in 1825 failed, he had been selected in 1824 to give the Ricardo Memorial lectures in London. In 1828, largely through the agency of James Mill, he was appointed the first professor of political economy at London University. He remained professor until 1837, though largely supporting himself by his pen; but in 1838 he was appointed Comptroller of the Stationery Office, a post he occupied until his death in 1864. This did not prevent him from continuing his literary activities and he remained active as an author, producing new editions of his earlier works and some completely new ones, notably the *Treatise on Taxation* (1845, 1852, 1863) and the *Geographical Dictionary* (1841–2, 1845–6, 1849, 1852, 1854).

As an economist, McCulloch was at one stage very much under the influence of Ricardo, but the influence was transient. He put forward a simple labour theory of value under the influence of Ricardo, while aware that this was a simplified version (assuming away the problem of capital), for popular exposition. But though the emphasis is on labour quantity, and undoubtedly derived from Ricardo, it was a theory of relative (exchangeable) value, and McCulloch's analysis never borrowed from Ricardo the fundamental (to Ricardo)

concept of the invariable measure. Indeed, McCulloch rejected the concept emphatically.

The vicissitudes of McCulloch's exposition over the years included, without doubt, a number of erroneous positions and a strange solution to the origin of profits as being in stored labour continuing to work. He also attempted to make labour cost a real (disutility) cost. But in the second edition (1830) of his *Principles* he advanced an almost complete cost of production theory, where cost was, as in an earlier *Scotsman* article, marginal cost. Labour cost, amortization and profit were now recognized as costs as they had been with Smith; the influences of Ricardo was now largely apparent in treating rent not as a cost but as a price-determined surplus, thus ignoring transfer earnings. Finally, in the 1838 edition of his notes to the *Wealth of Nations*, McCulloch clarified the nature of the profit reward with both waiting (as stressed by Ricardo) and productivity (as stressed by McCulloch) combining to produce a positive return.

McCulloch's treatment of money and banking derived from Smith, Hume and Thornton, though he long followed Ricardo in advancing the idea that the value of commodity money was determined by its cost of production, an idea he finally abandoned in his contributions to the eighth edition of *Encyclopaedia Britannica*. He accepted Hume's theory of the distribution of the precious metals, drawing also on Smith and especially Thornton, though he did accept, at least in relation to external losses of metal, the Ricardian definition of excess. In considering the internal level of activity in relation to money, he accepted Say's identify as an equilibrium proposition; but he also recognized the possibility that excess demand for money in disequilibrium might cause economic dislocation, thus magnifying fluctuations originating in the real side of the economy, such as over-investment. He also recognized, and approved, in contrast to Ricardo, the effects of mild inflation in producing forced saving and economic growth. On the issue of banking control he at first accepted Ricardo's view that convertibility was its own safeguard, but he came to recognize the problems of over-issue of notes much earlier than many writers – he was firmly opposed to laissez-faire in banking – and was one of the earliest writers to put forward the principle that a note issue should fluctuate in amount in response to the balance of payments exactly as an identically circumstanced metallic money would do, though he saw this as providing only a partial solution to monetary control.

McCulloch's analysis of international trade followed Smith rather than Ricardo, in basing trade on absolute advantage assuming international factor mobility. McCulloch may have done this because he saw that the possibility of trade advantage, as explained in comparative cost theory, was incomplete until this was translated into relative costs and prices. At all events he considered Ricardo's treatment of international trade to be faulty. In his view there was a complete parallel between international and inter-regional trade. McCulloch's treatment went well beyond that of Smith in some respects; and in particular, his analysis of the transfer problem, based on the work of Parnell, was an important precursor of modern developments. He discussed not only the effects of a transfer in the form of specie, or of commodities, but also a demand transfer of the kind made famous by Ohlin in his controversy with Keynes after the First World War. On matters of trade policy McCulloch has had the image of a crude free trader: but in fact, though he recognized the harm that protection could do, freedom of trade could, in his view, involve the imposition of substantial import duties – even as high as 25 per cent – as long as these were balanced by home excise duties so as to avoid distortion of choice.

McCulloch's treatment of public finance used the Smithian framework: the analysis inevitably acquired a number of Ricardian accretions, but many of these were ultimately discarded. Moreover, McCulloch drew on a wide range of earlier writers on taxation and was particularly indebted to Hume and to Robert Hamilton. He presented a broad synthetic treatment which did much to give tax theory practicality after the Ricardian detour into the corn model. His main focus of attention was the use of fiscal policy in such a way as to

ensure the maintenance of growth. Heavy taxation could interfere with growth; but if taxation was sensibly used it could be a stimulus to growth, increasing the supply of both effort and savings. A widely based regime of moderate indirect taxes, extending even to postage, was what McCulloch favoured, on ability-to-pay grounds, despite the distortions of the price system and the regressive elements. He opposed Gladstone's taxation policy, not only reliance upon income tax which McCulloch believed to interfere with growth, falling to stimulate effort and, where not proportional, subverting economic motivation.

The basic process of economic development was seen largely in terms of Smith's apparatus involving the accumulation of capital (but including human capital) and division of labour. It also involved the institutional requirements of security of property, internal freedom of trade, and a substantial role for government including education, control of public utilities, and employer liability for accidents. On to this Smithian basis McCulloch grafted specific Ricardian features, notably the Ricardian explanation for the declining rate of profit. However, he finally rejected the idea of inevitably diminishing returns in agriculture, as well as the inverse movement of wages and profits, and the Ricardian stagnation thesis. Writing later than Smith, McCulloch's treatment of development shows a much heavier emphasis on technology. Indeed, this was the basis of a fundamental disagreement with Ricardo over the role of machinery, and led him also to reject the primacy which Smith had afforded to agriculture – he attached key importance to the manufacturing sector though he was worried about the distributional consequences.

On agriculture itself however he wrote a good deal. He believed in large-scale capitalist farming (and supported primogeniture though not entails), and came, after a long period of believing in the (at least ultimate) inevitability of diminishing returns, to the view that under such a system improvements might continuously offset the diminution of returns. Thus his attack on the Corn Laws did not emphasize the Ricardian concept of stagnation but other matters, notably the idea that they encouraged price fluctuation. In this context he employed not only arguments about elasticity of demand and supply but also an agricultural cobweb. On this basis he argued, in contrast to Ricardo, that all classes, including the landlords, lost by the Corn Laws (though he followed Ricardo's argument for a measure of agricultural protection) and he also came to reject Ricardo's argument that improvements were against the interest of the landlords.

Classical economics, unlike modern economics, contained, as an integral part, a theory of population, which served in turn as the basis for various theorems about wages and welfare. McCulloch's population theory initially followed the first two editions of Malthus's celebrated *Essay*. But, probably under the influence of Nassau Senior, he become opposed to the Malthusian argument, believing prudential restraints to predominate. Indeed, amongst mainstream classical economists he was probably the most extreme anti-Malthusian, a development which harmonized with his move away from Ricardo's influence. Having sided with Malthus and Ricardo in opposing the Poor Law, he changed his mind quite openly after 1826 and became a supporter of the old Poor Law, believing that it did not undermine prudential restraint and that it preserved social stability. He opposed the 1834 Poor Law as harsh and over-centralized. As a measure to raise wages generally he supported emigration and colonization, though he did not favour retention of control of colonies, and objected, in particular, to Wakefield's schemes for 'scientific' colonization.

All this raises directly McCulloch's concept of the operation of the labour market. McCulloch is particularly associated with the idea of the wage fund, because of his *Essay on Wages* (1826); and with a given wage fund, reducing supply will raise wages, as implied in McCulloch's treatment of emigration. His analysis of demand for labour thus equated capital with demand for labour, though in his more careful treatments he distinguished total and wage capital (and total population and labour supply). But this only provided half the analysis: on the supply side McCulloch employed four different labour supply functions,

including a rising supply schedule as normal; two negatively inclined short-run schedules (the first when wages rose after excessive hours had been required to survive at the previous level of wages, the second where women and children entered the labour force as wages fell, to maintain family income). Fourthly, there was a secular population function. McCulloch favoured high wages, and his writings in defence of trades unions were important in the successful struggle to secure repeal of the Combination Laws.

As an economist, McCulloch was a fairly representative classical writer in that his work involved a synthesis of elements deriving from Smith and Ricardo. Yet McCulloch's case is particularly interesting because his own evolution over they very long period (48 years) of his writings, mirrors the development of classical economics itself. Starting from a basis of Smith and Malthus, he fell under the influence of Ricardo's magnetic personality and remarkable powers of abstraction; but he gradually passed through this phase, the Smithian elements in his work resuming their predominance and leading in turn to an emphasis on empirical work and a methodological position foreign to the tenor of Ricardo's work.

Abstract

This article reviews the contributions of Daniel L. McFadden, 2000 co-recipient of the Nobel Prize in Economics. The article focuses on his seminal contributions to the theoretical and econometric literatures on discrete choice.

Keywords

Curse of dimensionality; Discrete choice; Duality; Generalized extreme value; Independence of irrelevant alternatives; Infinite horizons; Logit models of individual choice; Mathematical psychology; Maximum likelihood; McFadden, D. L.; Method of simulated moments; Monte Carlo methods; Multinomial logit model; Multinomial probit model; Neural networks; Overlapping generations models; Probabilistic choice theory; Random utility models; Revealed preference; Simulation-based estimation

Introduction

Daniel L. McFadden, the E. Morris Cox Professor of Economics at the University of California at Berkeley, was the 2000 co-recipient of the Nobel Prize in Economics, awarded 'for his development of theory and methods of analyzing discrete choice'. (The prize was split with James J. Heckman, awarded 'for his development of theory and methods for analyzing selective samples'). McFadden was born in North Carolina, USA, in 1937 and received a BS in physics from the University of Minnesota (with highest honors)
