Spontaneous state switching in realistic mean-field model of visual cortex with heteroclinic channel

Manh Nguyen Trong[1,2*], Ingo Bojak[3], Thomas R Knösche1[1]

From Twentieth Annual Computational Neuroscience Meeting: CNS*2011
Stockholm, Sweden. 23-28 July 2011

Spontaneous switching between cortical states in the visual cortex of cat was reported by Kenet *et al.*[1]: a succession of spatial activation patterns normally associated with visual input was observed even in the absence of external input. Using a Wilson-Cowan network, Blumenfeld *et al.*[2] proposed a model for this phenomenon that generated multistability by applying unstructured noise. Here we use the biologically realistic

mean-field model of Jansen & Rit [3], together with the heteroclinic channel theory proposed by Rabinovich *et al.*, cf. Ref. [5], to propose a mechanism how such spontaneous switching between states could occur independent of extrinsic noise.

A hypercolumn in V1 is made up of orientation preference columns (OPC), which selectively respond to specifically oriented stimuli. Our model of an OPC con-

sists of 3 neuronal populations: pyramidal neurons (PN) and excitatory (Ex. IN) / inhibitory interneurons (Inh. IN), see Fig. 1A. Their connectivity decays exponentially with orientation difference, see Fig. 1B. These decays, and the spatial layout shown in Fig. 1C(I,II), are derived from the data of Gilbert & Wiesel [4]. The interactions between the OPCs are described by integral differential equations:

$$\Theta\left(\mathbf{V}(r,t)\right) = -\mathbf{K}\int_R \mathbf{W}(r,\tilde{r})\,\mathbf{S}\left(\mathbf{V}(r,t)\right)d\tilde{r} + \mathbf{I}^{ext}(r,t)$$

[Θ: 2nd order differential operator, **V**: membrane potentials, **W**: connectivity, **S**: sigmoid function, **I**: input, **K**: gain]

Evoked activity was simulated by applying input to a specific hypercolumn, yielding patterns that are very similar to the OPC distribution maps - compare Fig. 1C (Evok.) with 1C(*IV,V*). Importantly however, even without any external stimulus the system spontaneously switches from one state to another, see Fig. 1C(*Spon.*). In state space the system evolves in a heteroclinic channel, made up by the trajectories near a chain of saddle points (representing the OPCs) and associated unstable separatrixes. The inhibitory connectivity governs this sequence of activation. Imposing noise on this connectivity can introduce randomness into the sequence of activation.

In this study we have combined mean-field and heteroclinic channel theory in order to describe the experimental observation of spontaneous state switching [1]. In contrast to Ref. [2], we do not need to impose unstructured noise to create multistability here. Furthermore, manipulations of our inhibitory connectivity matrix can vary the resulting sequence of states, e.g., in order to accommodate expectations about the next stimulus.
