## Abstract

**Background:** The molecular heterogeneity of autoimmune and inflammatory diseases has been one of the main obstacles to the development of safe and specific therapeutic options. Here, we evaluated the diagnostic and clinical value of a robust, inexpensive, immunoassay detecting the circulating soluble form of the monocyte-specific surface receptor sialic acid binding Ig-like lectin 1 (sSIGLEC-1).

**Methods:** We developed an immunoassay to measure sSIGLEC-1 in small volumes of plasma/serum from systemic lupus erythematosus (SLE) patients ( $n = 75$ ) and healthy donors ( $n = 504$ ). Samples from systemic sclerosis patients ( $n = 99$ ) were studied as an autoimmune control. We investigated the correlation between sSIGLEC-1 and both monocyte surface SIGLEC-1 and type I interferon-regulated gene (IRG) expression. Associations of sSIGLEC-1 with clinical features were evaluated in an independent cohort of SLE patients ( $n = 656$ ).

**Results:** Plasma concentrations of sSIGLEC-1 strongly correlated with expression of SIGLEC-1 on the surface of blood monocytes and with IRG expression in SLE patients. We found ancestry-related differences in sSIGLEC-1 concentrations in SLE patients, with patients of non-European ancestry showing higher levels compared to patients of European ancestry. Higher sSIGLEC-1 concentrations were associated with lower serum complement component 3 and increased frequency of renal complications in European patients, but not with the SLE Disease Activity Index clinical score.

**Conclusions:** Our sSIGLEC-1 immunoassay provides a specific and easily assayed marker for monocyte–macrophage activation, and interferonopathy in SLE and other diseases. Further studies can extend its clinical associations and its potential use to stratify patients and as a secondary endpoint in clinical trials.

**Keywords:** Soluble SIGLEC-1, Biomarker, Autoimmunity, Type I interferon, Interferonopathy

## Background

The type I interferon (IFN) pathway was identified as a central feature of the autoimmune disease systemic lupus erythematosus (SLE) when IFN- $\alpha$  was first detected at high levels in patients' sera [1]. Since this initial observation, the development of SLE-like clinical manifestations in patients treated with IFN- $\alpha$  for different malignancies pointed to the involvement of IFN- $\alpha$  in the aetiology of the disease [2]. Furthermore, naturally occurring anti-IFN- $\alpha$  antibodies in SLE patients have been shown to be associated with milder forms of the disease [3]. The identification of a constitutive IFN transcriptional signature comprising hundreds of IFN-regulated genes (IRGs) in peripheral blood from a subset of SLE patients [4, 5] suggested that the IFN signature could be used as a clinical biomarker to stratify patients with autoimmune and inflammatory diseases in which type I IFNs are known to play a pathogenic role, referred to as the interferonopathies. Nevertheless, the precise link between the IFN signature and molecular subtypes of disease or with broader disease severity scores has been put into question [6]. With the development of more sophisticated high-throughput genomic tools, it has become apparent that the IFN signature is a complex composite marker, which can be further stratified into several distinct signatures that are better predictors of disease subtype [7]. Longitudinal analyses have revealed that the IFN signature is highly variable over time as a result of alterations in blood composition caused by therapy or progression of the disease [7, 8]. This is particularly relevant to IFN-driven diseases, as IFN- $\alpha$  is known to significantly alter the relative distribution of immune cell types in blood, which can severely compromise the diagnostic potential of the whole blood IFN signature [8] and lead to the observed lack of correlation between the signature and disease activity over time [9, 10].

These findings have led to the investigation of other potential cell-type specific biomarkers that could be better predictors of disease severity or clinical subtypes. One such IFN-regulated marker that has shown promise for the stratification of SLE patients is sialic acid binding Ig-like lectin 1 (SIGLEC-1) [11–13]. SIGLEC-1 is a cell-adhesion molecule involved in the initial contacts with sialylated pathogens and mediates phagocytosis and endocytosis of pathogens, thereby promoting efficient immune responses to limit infection [14]. Unlike the canonical IFN transcriptional signature, which is a composite of many genes expressed at different levels in different immune cells, SIGLEC-1 is expressed exclusively in cells of the myeloid lineage, namely tissue-resident macrophages and monocyte-derived dendritic cells [15, 16]. In blood, expression of surface SIGLEC-1 is restricted to CD14<sup>+</sup> monocytes, and has been previously reported to be increased in several other autoimmune diseases, including

rheumatoid arthritis [17], systemic sclerosis (SSc) [18] and primary biliary cirrhosis [19]. In addition, a recent study has shown that increased SIGLEC-1 expression on the surface of monocytes was a predictor of congenital heart block during pregnancy in children from Ro/SS-A autoantibody-positive mothers [20].

These data support the use of SIGLEC-1 as a potential cell-type specific biomarker for the stratification of patients with an overt type I IFN response. However, assay of surface SIGLEC-1 requires intact cells and flow cytometry, features that are not conducive for the development of a high-throughput, inexpensive biomarker assay, ideally detectable in plasma/serum. Here we show that a circulating form of SIGLEC-1 can be detected in serum/plasma, and develop a robust and inexpensive immunoassay to measure its concentration. Furthermore, we provide evidence that the concentration of soluble SIGLEC-1 (sSIGLEC-1) is associated with the patient's ancestry and with renal involvement in SLE patients. Therefore, sSIGLEC-1 is a new circulating plasma/serum biomarker of type I IFN activity in systemic autoimmune, inflammatory and infectious diseases that can be used accurately and conveniently in large numbers of samples, and could be used in clinical trials of drugs modulating the IFN signalling pathway for patient stratification and as a secondary endpoint.

## Methods

### Participants

Discovery cohort (cohort 1) study participants included 34 SLE patients (median age 39 years, range 20–72 years; 32/34 female) recruited from Guy's and St Thomas' NHS Foundation Trust. All patients satisfied ACR SLE classification criteria and were allocated a disease activity using SLEDAI-2K at the time of sampling. Patients were recruited from a clinic in which the severity of disease was such that none of the patients was on high-dose oral corticosteroids (> 15 mg/day) or B-cell depleting therapy. Healthy volunteers matched for age and sex ( $n = 24$ ; median age 43 years, range 25–60 years; 23/24 female) were recruited from the Cambridge BioResource.

A replication cohort (cohort 2) of 41 SLE patients (median age 52 years, range 21–82 years; 38/41 female) and 490 healthy volunteers (median age 48 years, range 18–78 years; 320/490 female) was recruited from the Cambridge BioResource. The SLE patients were recruited specifically for this study outside their regular clinic visits, and were otherwise well at the time of bleeding. No additional disease information or ancestry data were available for this cohort of patients.

To investigate the association between sSIGLEC-1 with ancestry and clinical manifestations, a third independent cohort (cohort 3) of SLE patients ( $n = 656$ ; median age 45 years, range 15–82 years; 592/655 female, one unknown)

was recruited from multiple collaborative centres in the UK (St Thomas's Hospital, Newcastle Hospital, City Hospital Sunderland, City Hospital Birmingham, Royal Hallamshire Hospital, Hammersmith Hospital, West Middlesex Hospital and Basildon Hospital). Most patients were of European ( $n = 370$ ), South East Asian ( $n = 134$ ), African/Afro-Caribbean ( $n = 94$ ) and Far East Asian ( $n = 19$ ) ancestries. Twenty-three patients were of other minor ancestry groups (including Middle Eastern, Maori and Fiji ancestry) and 16 had missing ancestry information. The history of patients' clinical manifestations since their disease diagnosis up to the time of their visit is summarised in Table 1.

A cohort of systemic sclerosis (SSc) patients ( $N = 99$ ), stratified into patients with limited cutaneous SSc ( $N = 50$ ) or diffuse SSc ( $N = 49$ ), and a matching cohort of healthy donors ( $N = 50$ ) were recruited from the Royal Free Hospital, UCL, London. All patients had a definite diagnosis of SSc according to the 2013 ACR/EULAR SSc classification criteria [21].

All samples and information were collected with written and signed informed consent after approval from the relevant research ethics committees (REC numbers 05/Q0106/20, 07/H0718/49 and 08/H0308/153; and NHS Health Research Authority, NRES Committee London-Hampstead, HRA, REC number 6398, Investigating the pathogenesis of systemic sclerosis).

#### Flow cytometry

SIGLEC-1 expression was measured in peripheral blood mononuclear cells (PBMCs) from 34 SLE patients and 24 healthy donors from the discovery cohort. PBMCs were thawed in a 37 °C water bath, resuspended in X-VIVO 15 (Lonza) + 1% heat-inactivated, filtered, human AB serum (Sigma) and immunostained for 30 min at room temperature. SIGLEC-1 expression on CD14<sup>+</sup>

monocytes was determined using fluorochrome-conjugated antibodies against CD14 (Clone M5E2; BioLegend) and SIGLEC-1 (Clone 7–239; BioLegend). Immunostained samples were acquired using a BD LSR Fortessa (BD Biosciences) flow cytometer, and data were analysed using FlowJo (Tree Star). Dead cells were excluded based on the eFluor780 Fixable Viability Dye (eBiosciences).

#### Soluble SIGLEC-1 time-resolved fluorescence immunoassay

Plasma/serum sSIGLEC-1 concentrations were measured using a non-isotopic time-resolved fluorescence (TRF) assay based on the dissociation-enhanced lanthanide fluorescent immunoassay technology (DELFI; PerkinElmer). Duplicate test plasma/serum samples diluted 1:10 in assay buffer (PBS, 0.05% Tween-20, 10% FCS) were incubated for 2 h at room temperature and then at 4 °C overnight in 96-well EIA/RIA plates (Corning) coated with 1 µg/ml mouse monoclonal anti-human SIGLEC-1 capture antibody (AB18619; Abcam). Sample detection was performed using a biotinylated sheep polyclonal detection antibody (BAF5197; R&D Systems) diluted to a final concentration of 200 ng/ml. Following incubation with the secondary antibody, europium-labelled streptavidin (PerkinElmer) was added and the concentration of antigen was measured by the amount of disassociated europium that is fluorescent at 615 nm after excitation at 320 nm.

Quantification of test samples was obtained by fitting the readings to a human recombinant SIGLEC-1 (R&D Systems) serial dilution standard curve on each plate ( $r^2 > 0.995$ ). To maintain assay consistency, the recombinant protein was aliquoted and stored at –80 °C immediately following reconstitution and a fresh aliquot from the same lot was used for each assay.

**Table 1** Summary of the history of clinical manifestation of the SLE patients in cohort 3

Phenotype	EUR		Non-EUR

<sup>a</sup>Odds ratio (OR) in non-European patients

<sup>b</sup>*P* values calculated using Pearson's chi-squared test

<sup>c</sup>Admission defined as any patient requiring hospital admission specifically for SLE in the 5 years prior to and including the date of their clinic visit at which the blood sample was taken

<sup>d</sup>Patients treated with biologic drugs at any time since their disease diagnosis

The lower limit of detection of the assay was set as 2x background levels in each plate and corresponded to an average of 1.29 ng/ml across all plates. Samples with measurements below the limit of detection (6/589) were set to 1.29 ng/ml. Assay specificity was confirmed using a biotinylated sheep polyclonal isotype control (R&D Systems). Technical variation was assessed in duplicate measurements of all samples (average CV = 5.0%). Samples with CV > 30% between duplicates (10/589) were excluded from the analysis. To evaluate potential matrix effects, we diluted a sample with high sSIGLEC-1 concentration with assay medium and showed a linear titration between 1:2 and 1:16 dilutions ( $r^2 = 0.94$ ).

#### IFN- $\alpha_{2b}$ single-molecule digital ELISA assay

Circulating levels of IFN- $\alpha_{2b}$  were measured by Single-Molecule Array (SIMOA) digital ELISA (Quanterix) according to the manufacturer's instructions. IFN- $\alpha$  detection was achieved using mouse anti-IFN- $\alpha$  monoclonal antibodies: a neutralising antibody (clone MMHA—capture) and an anti-IFN- $\alpha$  antibody raised against an IFN- $\alpha_{2b}$  antigen (clone 7 N41—detection). Cross-reactivity to the other IFN- $\alpha$  subtypes was not assessed. Measurements were performed in plasma samples, which had never been previously thawed, from the 41 SLE patients of cohort 2.

#### Type I IFN transcriptional signature in PBMCs

RNA from 34 SLE patients and 24 age and sex-matched healthy donors in cohort 1 and from 41 SLE patients and 41 age and sex-matched healthy donors in cohort 2 was extracted from freshly isolated PBMCs stored in TRIZOL immediately after collection, using the Direct-zol RNA Mini-Prep kit (Zymo Research) following the manufacturer's instructions. The RNA concentration was measured by NanoDrop (Thermo Fisher Scientific), and 50 ng of total RNA were hybridised with a custom NanoString CodeSet (NanoString Technologies), containing 56 IRGs previously identified as discriminative of the IFN signature [22]. Expression levels were assessed using an nCounter Flex instrument (NanoString Technologies). Data were processed using the nSolver Analysis Software following normalisation to the geometric mean of positive control spike-ins and the gene expression of eight house-keeping genes.

Expression of 56 IRGs previously identified as discriminative of the IFN signature [22] were assessed, with a custom NanoString CodeSet (NanoString Technologies), using RNA from 34 SLE patients and 24 age and sex-matched healthy donors in cohort 1 and from 41 SLE patients and 41 age and sex-matched healthy donors in cohort 2.

A quantitative metric of the IFN signature was generated using principal component analysis by projection of the expression of the 56 IRGs onto the first principal component (PC1), which was found to explain 86.3% of the

variance of this dataset. A complete list of the 56 IRGs and respective NanoString probe sequences is presented in Additional file 1.

#### Statistical analyses

Statistical analyses were performed using Prism software (GraphPad) and R software (<https://www.r-project.org>). Given that most phenotypes showed moderate to strong right skew that violated the assumption of normality, the phenotypes were log-transformed before statistical testing and all reported values refer to the geometric mean of the respective measurements.

#### Cohorts 1 and 2

The association of sSIGLEC-1 and measured immune parameters in cohorts 1 and 2 was performed using two-tailed non-parametric Mann–Whitney tests. Correlation analyses were performed using linear regression on the log-transformed data.

#### Cohort 3

All statistical analyses with the clinical data available for the 656 patients from cohort 3 were performed using R software. Association between ancestry and sSIGLEC-1 concentration was assessed using a two-tailed Student's *t* test. The odds ratio (OR) of each clinical parameter (history of admission within 5 years; ever having suffered with renal, haematological or neurological disease; requiring biological therapy or active corticosteroid use to control disease) in European and non-European patients was assessed by Pearson's chi-squared test.

Patients were divided into groups based on sSIGLEC-1 serum level centiles (< 50th centile, 51st–74th centile, 75th–95th centile and > 95th centile). Association of each group and clinical parameters was performed using a logistical regression model. Patients of European and non-European ancestry were analysed separately as ethnicity was a major confounding factor.

Association of the sSIGLEC-1 concentration with other serological parameters of disease (levels of C3 and C4 measured within 3 months of the visit at the patient's local centre/hospital, anti-dsDNA antibody titres and C-reactive protein) and the estimated glomerular filtration rate (eGFR) were assessed using linear regression on the log-transformed data. Association of sSIGLEC-1 concentration and renal disease activity was also determined, based on the clinical notes documentation, at the time of the sample collection and the last documented episode of active nephritis. Comparison of the different disease activity groups was done using two-tailed Student's *t* tests comparing the mean sSIGLEC-1 concentration of each group to the control group of patients who never developed renal complications.

## Results

### Soluble SIGLEC-1 assay development

To investigate whether we could detect SIGLEC-1 expression levels in peripheral blood, we developed an immunoassay based on TRF to measure the concentrations of the circulating form of the receptor, which we refer to as sSIGLEC-1. Although *SIGLEC1* is predicted to encode a soluble protein isoform, it has not been previously shown that such a soluble protein can be detected in plasma/serum.

We found that sSIGLEC-1 was detected in the circulation, with concentrations ranging from 1.29 to 276.1 ng/ml in plasma/serum samples from healthy donors and SLE patients. Technical variation of the assay was found to be very low, as assessed by two independent measurements of the same plasma sample from 23 healthy donors performed 308 days apart (median CV = 4.8%,  $r^2 = 0.91$ ; Fig. 1a), indicating minimal inter-assay variability. Similarly, biological sSIGLEC-1 levels were found to be very stable (CV = 11.8%,  $r^2 = 0.67$ ; Fig. 1b) in 19 healthy donors bled at two separate visits (median time between visit 378 days, range 239–519 days), with only two donors showing physiological differences (CV > 20%) between visits, likely due to viral infections [22]. Of note, one donor showed high concentrations of sSIGLEC-1 on the first visit (28.3 ng/ml), which were maintained 343 days after the initial measurement (23.4 ng/ml; Fig. 1b), suggesting that, in addition to viral and possibly non-viral infections, genetic factors regulate the sSIGLEC-1 levels.

To expand the applicability of the sSIGLEC-1 immunoassay, we also developed an electrochemical luminescence-based (ECL) assay on the Meso Scale Discovery (MSD) platform, using the same detection antibodies and experimental protocol. The assay working range was found to be 0.5–1000 ng/ml, with an approximate 92% recovery of recombinant SIGLEC-1 protein spiked into serum samples. Stability of the assay over time was assessed using three pools of serum samples with increasing sSIGLEC-1 concentrations that were measured over six different assays run over a 2-day period. Assay stability was consistent with the TRF assay, with CVs of 7.7%, 5.6% and 8.5% for the low, medium and high QC pools, respectively (Fig. 1c). Furthermore, we found a very high concordance between the TRF and ECL assays ( $r^2 = 0.78$ ; Fig. 1d), as assessed by measuring a subset of 41 SLE patients on both platforms, using two independent serum aliquots.

### Soluble SIGLEC-1 levels are correlated with the surface SIGLEC-1 expression on CD14<sup>+</sup> monocytes

Currently, the surface expression of SIGLEC-1 on monocytes has been suggested as a sensitive cell-type specific biomarker for SLE in blood [13]. To investigate the relationship between surface and soluble SIGLEC-1 levels, we immunophenotyped the expression of this protein on

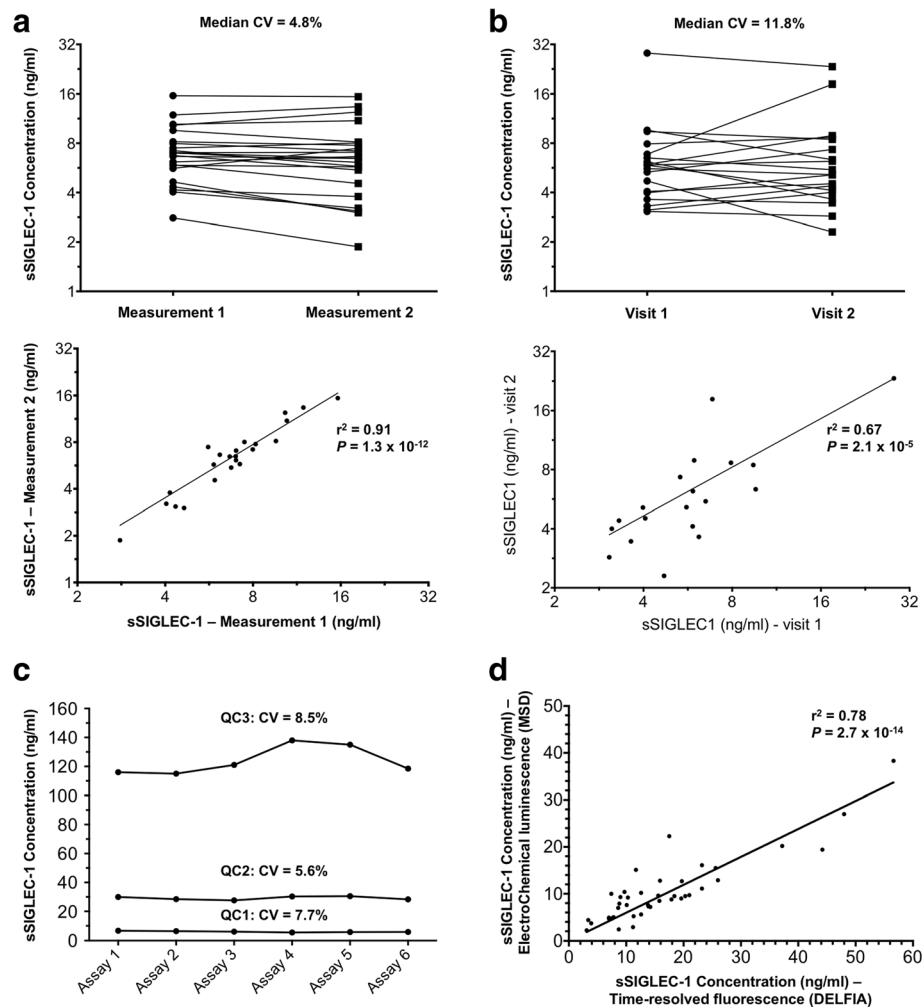

the surface of CD14<sup>+</sup> monocytes in PBMCs collected from a discovery cohort (cohort 1) of 34 SLE patients and 24 matched healthy donors (Fig. 2a). Consistent with previous findings [12, 13], we found that the surface expression of SIGLEC-1 was increased in CD14<sup>+</sup> monocytes from SLE patients compared to healthy controls ( $P = 1.4 \times 10^{-4}$ ; Fig. 2b). However, we found bimodal expression of the surface SIGLEC-1 among SLE patients, with 10 subjects (10/34, 29%; Fig. 2b) presenting low levels of protein expression, similar to the ranges observed in healthy donors, and the rest presenting much higher levels, rarely observed in healthy volunteers (Fig. 2a, b).

We found a strong correlation between the surface expression of SIGLEC-1 on monocytes and the concentration of sSIGLEC-1 in plasma samples from the same donors, particularly among SLE patients ( $r^2 = 0.73$ ,  $P = 7.9 \times 10^{-10}$ ; Fig. 2c). The distribution of sSIGLEC-1 levels recapitulated the same bimodal distribution of the surface SIGLEC-1 expression on SLE patients, ranging from 'low normal' physiological levels observed in healthy donors to the very high levels observed in a subset of patients (Fig. 2c).

### Association of sSIGLEC-1 with the IFN transcriptional signature and SLE Disease Activity Index

To assess whether sSIGLEC-1 was associated with the IFN signature, we measured the transcription of 56 IRGs previously found to recapitulate the IFN signature [22]. We found that sSIGLEC-1 levels were significantly correlated with the IFN transcriptional signature in PBMCs from SLE patients ( $r^2 = 0.67$ ,  $P = 2.9 \times 10^{-9}$ ; Fig. 3a). The correlation was also observed in healthy donors ( $r^2 = 0.34$ ,  $P = 2.8 \times 10^{-3}$ ; Fig. 3a), albeit to a lower extent. These findings were replicated in an independent cohort (cohort 2) of 41 SLE patients ( $r^2 = 0.46$ ,  $P = 1.2 \times 10^{-6}$ ; Fig. 3b), confirming that sSIGLEC-1 is a marker of the peripheral IFN signature. The lower correlation in the replication cohort is consistent with a lower overall disease severity—and concomitant lower sSIGLEC-1 levels—of the patients in the replication cohort, who were recruited outside their regular clinic visits.

Recently, a single-molecule digital ELISA assay has been shown to detect IFN- $\alpha$  at femtomolar levels in the circulation even from healthy individuals [23]. Consistent with its potent biological activity, over a third of the SLE patients showed very low IFN- $\alpha_{2b}$  concentrations (< 10 fg/ml; Fig. 3c), which were close to the reported limit of detection. In our hands, the assay showed good reproducibility (CV = 4.1% between replicates), indicating that it is sensitive to detect even low concentrations of IFN- $\alpha_{2b}$ . We found a significant correlation between the concentrations of IFN- $\alpha_{2b}$  in plasma and sSIGLEC-1 ( $r^2 = 0.27$ ,  $P = 5.1 \times$

**Fig. 1** sSIGLEC-1 stability and assay performance. **a** Data depict the inter-assay (technical) variation of the time-resolved fluorescence (TRF) sSIGLEC-1 immunoassay. Data were obtained from the measurement of the same plasma sample from 23 healthy donors on two independent assays, performed 308 days apart. **b** Data depict the intra-individual (biological) variation of sSIGLEC-1 concentration between two visits of the same donor. Longitudinal variation was assessed in 19 independent healthy donors using plasma samples collected at each separate visit. Median time between visits was 378 days (minimum = 239 days, maximum = 519 days). **c** Technical variation of the electrochemical luminescence (ECL) sSIGLEC-1 immunoassay using the Meso Scale Discovery (MSD) platform. Assay stability was assessed in three reference quality control (QC) pools of serum samples with increasing sSIGLEC-1 concentrations (QC1 = 6.0 ng/ml, QC2 = 29.2 ng/ml and QC3 = 123.9 ng/ml), measured in each assay over a 2-day period. **d** Correlation between TRF (DELFI) and ECL (MSD)-based immunoassays. Measurements were performed in independent serum aliquots from a subset of 41 SLE patients from cohort 3. *P* values were calculated by linear regression. CV coefficient of variation, DELFIA dissociation-enhanced lanthanide fluorescent immunoassay, sSIGLEC-1 soluble sialic acid binding Ig-like lectin 1

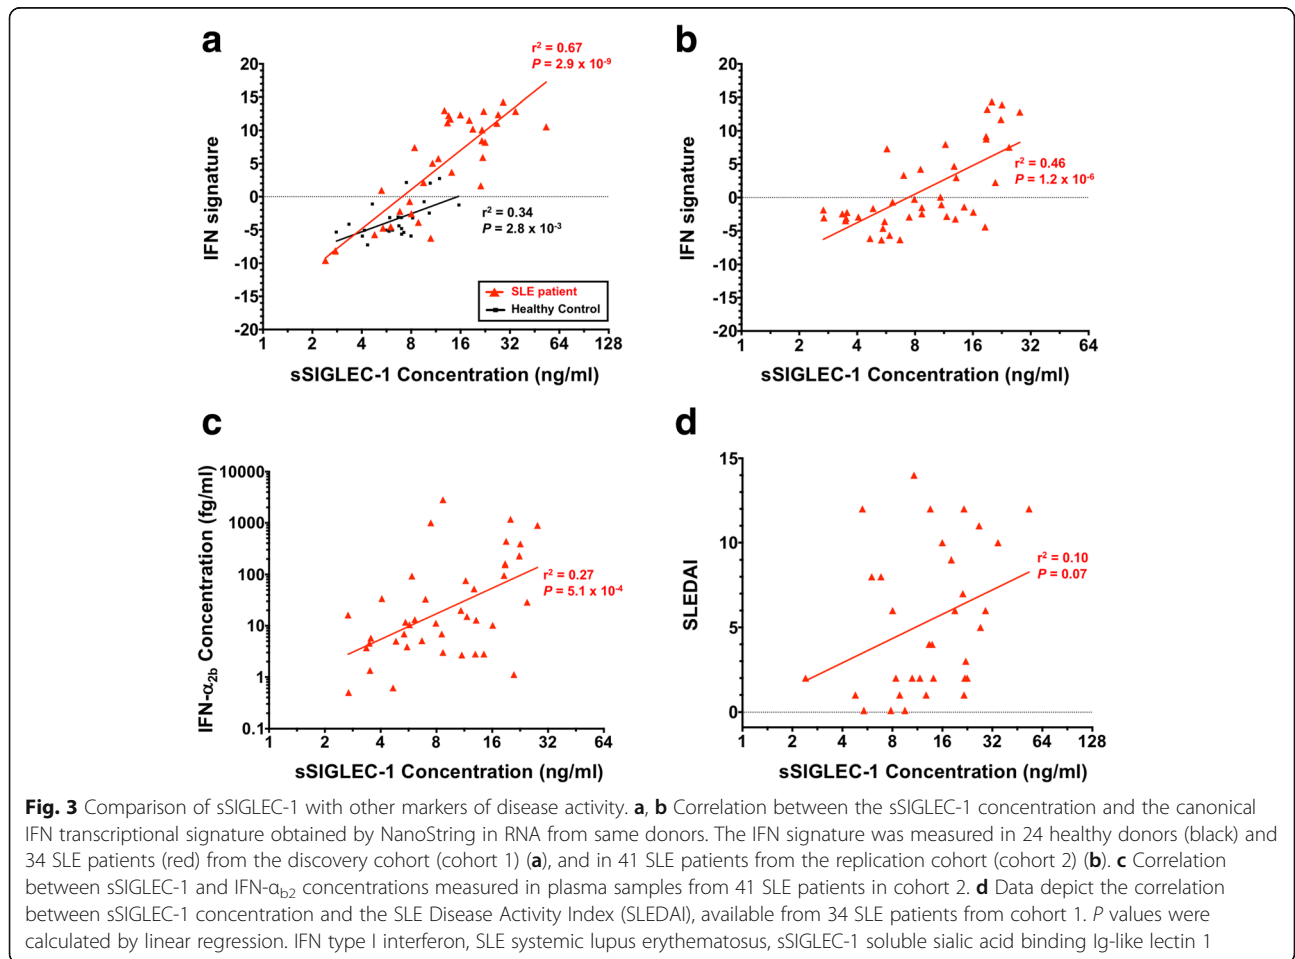

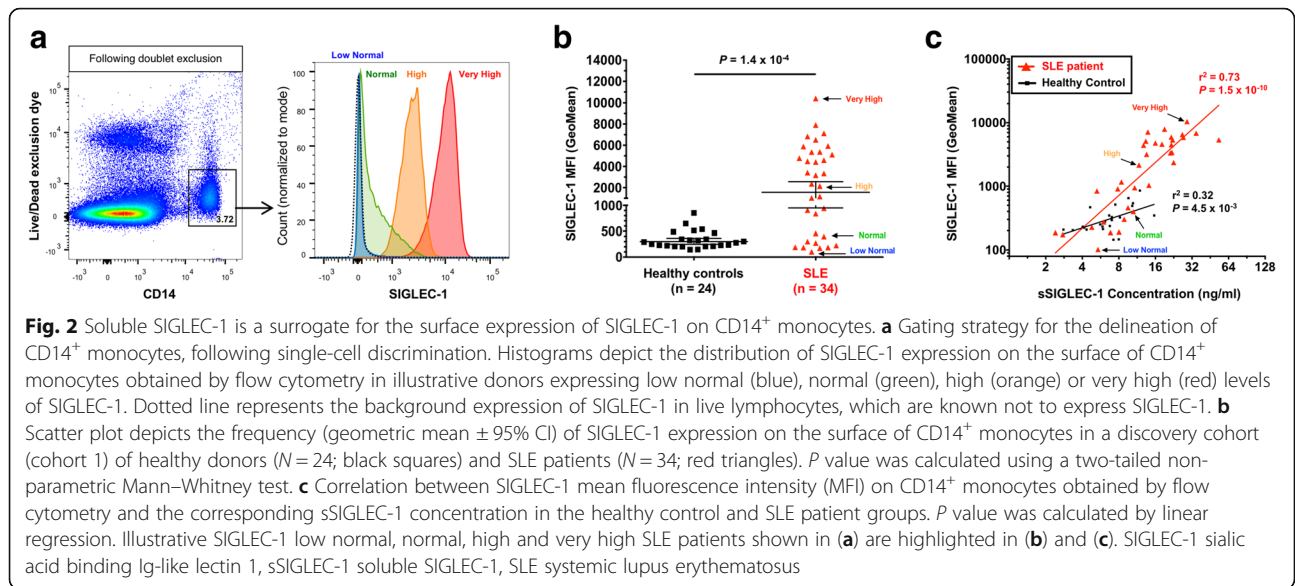

$10^{-4}$ ; Fig. 3c) as well as the IFN signature ( $r^2 = 0.34$ ,  $P = 5.6 \times 10^{-5}$ ; see Additional file 2), although both were less pronounced than the observed correlation between sSIGLEC-1 and the IFN transcriptional signature.

In our sample of 34 SLE patients from the discovery cohort, sSIGLEC-1 concentrations and the SLE Disease Activity Index (SLEDAI) were not correlated ( $r^2 = 0.10$ ,  $P = 0.07$ ; Fig. 3d). This result is consistent with previous evidence showing a lack of association of other common serological disease markers, including various intra-nuclear autoantibodies, elevated B-cell activating factor of the tumour necrosis factor family (BAFF)

levels and hypocomplementaemia, as well as the whole blood IFN signature, with disease activity scores such as the SLEDAI [6].

#### Increased sSIGLEC-1 concentration is associated with renal involvement

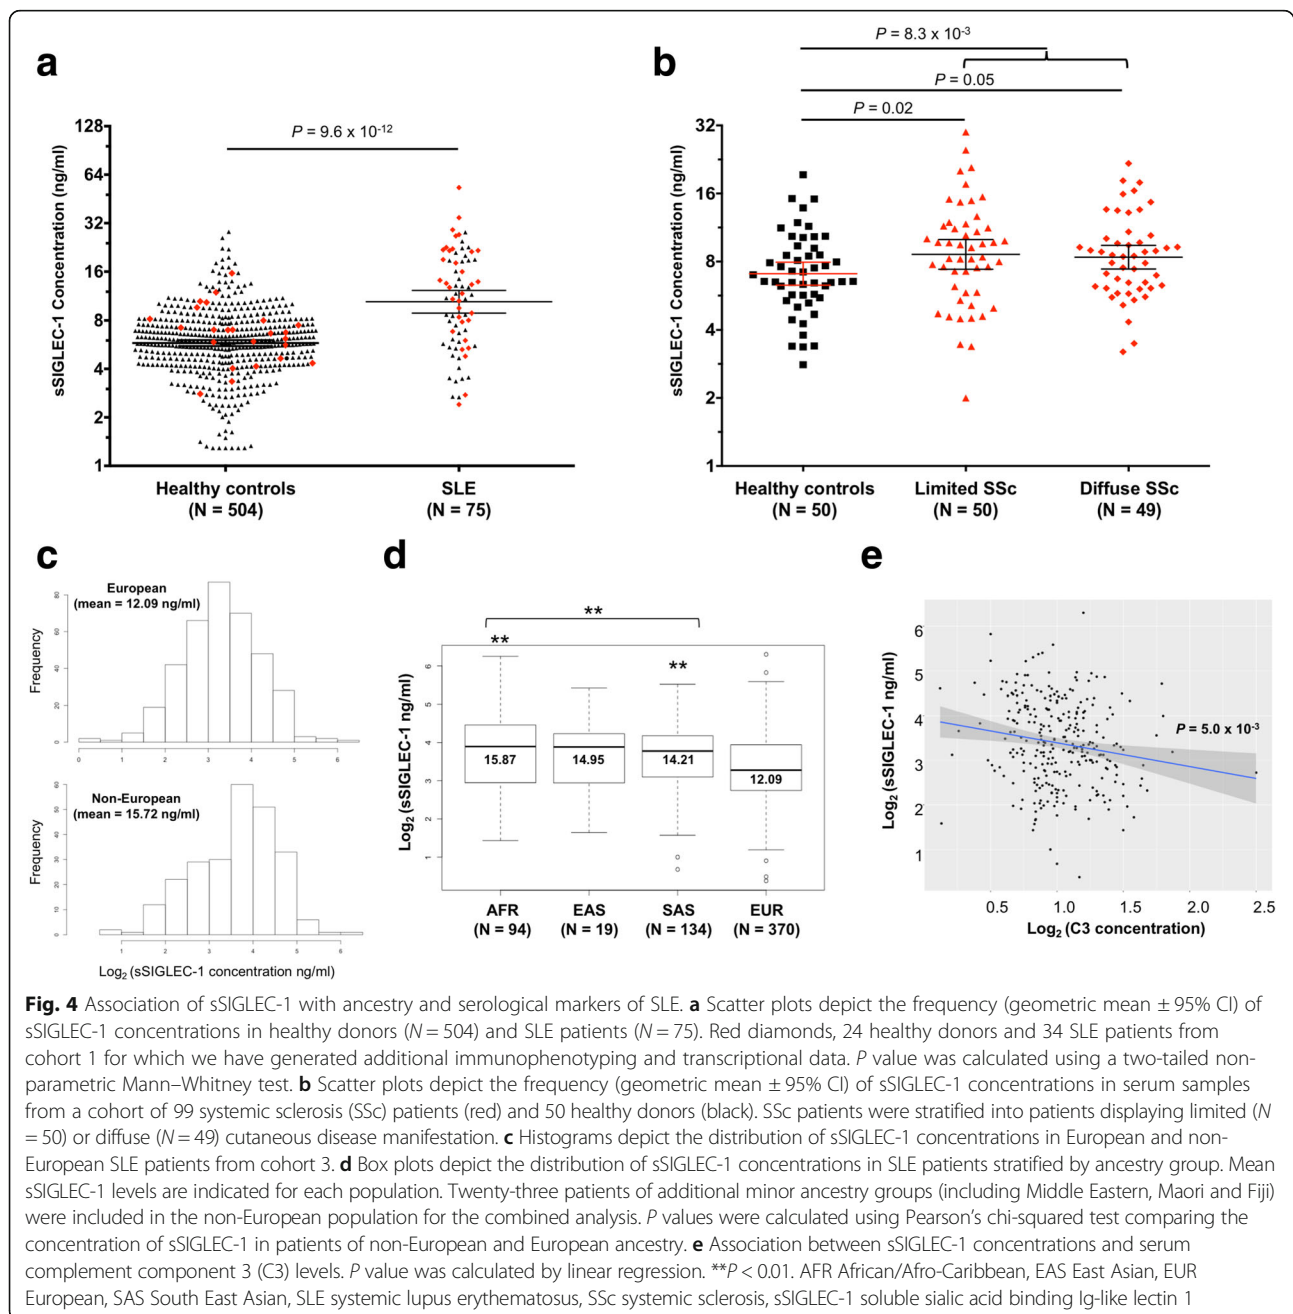

Having assessed that sSIGLEC-1 is an IFN-regulated marker that can be detected in the circulation, we next investigated its potential as a clinical biomarker in SLE. Similarly to surface SIGLEC-1 expression, sSIGLEC-1 concentrations were markedly increased in SLE patients (10.4 ng/ml, 95% CI 8.8–12.2) compared to healthy

controls (5.78 ng/ml, 95% CI 5.5–6.0,  $P = 9.6 \times 10^{-12}$ ; Fig. 4a) in the combined discovery and replication cohorts of 75 SLE patients and 504 healthy donors. In addition to SLE, we also assessed sSIGLEC-1 concentrations in a cohort of SSc patients ( $n = 50$  presenting with limited cutaneous and 49 with diffuse cutaneous SSc), another systemic autoimmune disease where type I IFN and overt monocyte/macrophage activation have been suggested to play an important aetiological role [18, 24]. Consistent with previous data showing an increased expression of SIGLEC-1 on the surface of CD14<sup>+</sup> monocytes in SSc patients [18], we found evidence for an increased

concentration of sSIGLEC-1 in serum samples from SSc (8.49 ng/ml, 95% CI 8.5–10.5) compared to matched healthy controls (7.07, 95% CI 6.7–8.6,  $P = 8.3 \times 10^{-3}$ ; Fig. 4b). The distribution of sSIGLEC-1 in SSc was similar to the SLE patients and the increased concentrations were maintained in both patients with limited cutaneous SSc or diffuse SSc ( $P = 0.02$  and  $P = 0.05$ , respectively; Fig. 4b).

To assess the potential clinical application of sSIGLEC-1, we measured sSIGLEC-1 levels in serum from 656 SLE patients with available clinical information (cohort 3). We observed that the concentrations of sSIGLEC-1 were

significantly higher in non-European patients (15.7 ng/ml, 95% CI 13.52–17.92) compared to those of European ancestry (12.1 ng/ml, 95% CI 11.25–12.94,  $P = 2.7 \times 10^{-3}$ ; Fig. 4c). Soluble SIGLEC-1 levels were similarly elevated among the different non-European populations (Fig. 4d), and were therefore combined into a single group to increase statistical power. Increased disease severity—and particularly incidence of renal disease—has been documented in patients of non-European ancestry [25–27]. In agreement with this observation, in our study, non-European SLE patients presented with an increased history of renal complications (Table 1), thus suggesting that the increased sSIGLEC-1 concentrations reflected the increased disease severity in non-European patients.

In addition to the ancestry-related changes, we found that sSIGLEC-1 levels were associated with lower levels of serum complement component 3 (C3) ( $P = 5.0 \times 10^{-3}$ ; Fig. 4e), but not with other common serological markers of SLE such as C-reactive protein or anti-nuclear auto-antibody levels (see Additional file 3). This association was observed in both European and non-European patients and remained present even when adjusting for the presence of nephritis. Furthermore, we found that increased sSIGLEC-1 concentrations were associated with a history of renal disease in the combined patient population ( $P = 0.01$ ; Table 2). Although the number of patients with active nephritis was limited in our study, we found that sSIGLEC-1 concentrations were strongly associated with duration of renal disease, with significantly higher levels observed in patients with active renal disease, and gradually declining with time (Fig. 5a), likely reflecting improved disease management since the last episode of active nephritis. The risk of renal complications/nephritis in patients with very high concentrations of sSIGLEC-1 was much more pronounced in European patients (OR = 1.65) compared to non-European patients (OR = 1.16; Table 2), and was maintained after adjusting for the

association of sSIGLEC-1 with low C3 and C4 levels, which are predictors for renal disease (OR = 1.96, 95% CI 1.10–3.45;  $P = 0.021$ ). Since sSIGLEC-1 could be physiologically excreted through the kidney, we also investigated whether increased sSIGLEC-1 concentrations could be associated with decreased kidney function in patients with renal disease. We found no evidence for an association between kidney function, as measured by the patients' estimated glomerular filtration rate (eGFR), and sSIGLEC-1 concentration (Fig. 5b). The association of sSIGLEC-1 and renal nephritis was maintained after adjusting for the effect of eGFR (OR = 1.49, 95% CI 1.02–2.17;  $P = 0.04$ ). These data suggest that decreased renal function in patients with renal nephritis does not fully explain the association with increased sSIGLEC-1 concentrations observed in this study.

In addition to the association of sSIGLEC-1 with renal complications, we also observed a similar trend towards increased risk of haematological complications in patients with high concentrations of sSIGLEC-1, although not reaching statistical significance in our analysis (OR = 1.35,  $P = 0.09$ ; Table 2). Further supporting the potential use of sSIGLEC-1 as a biomarker of disease severity, a higher frequency of patients with high levels of sSIGLEC-1 had a history of treatment with biologics (OR = 1.20,  $P = 0.04$  in the combined population; Table 2), usually associated with patients with poor disease management who have not responded to standard treatment options. This remained the case even when we adjusted for history of renal complication as a confounding factor for biologics use.

## Discussion

Recent advances in medical research have led to the development of a breadth of novel treatment options. The characterisation of biomarkers that identify the exact pathophysiological mechanism underpinning the clinical manifestations in each patient has thus become a

priority to allow the advent of a truly personalised medicine approach to human complex diseases. In systemic autoimmune and inflammatory diseases, chronic IFN signalling has been shown to be directly involved in the pathogenesis of the diseases, most notably in SLE [28]. This observation has led to the development of therapeutic strategies to target IFN- $\alpha$ , which are currently being tested in the clinic [29, 30]. There is therefore an urgent need to develop robust and sensitive biomarkers to identify patients with an active IFN response who would be more likely to benefit from anti-IFN- $\alpha$  therapy.

In the present study, we show that a circulating form of the surface-bound SIGLEC-1 receptor can be detected in human plasma/serum, and developed a sensitive immunoassay to measure the circulating concentrations of sSIGLEC-1. To our knowledge we are the first to detect the presence of a soluble SIGLEC-1 isoform in humans. Our current data do not allow us to determine the origin of sSIGLEC-1, and further work is needed to assess whether the soluble isoform is generated through alternative splicing or by proteolytic shedding of the membrane-bound receptor. A key feature of this bioassay is the limited sample requirements, making it amenable—as compared to a flow cytometric assay of surface SIGLEC-1—to screen large numbers of samples. We therefore propose that quantification of sSIGLEC-1 using our immunoassay is an alternative to flow cytometric endpoints, or the classical IFN signature or its PCR-analysed surrogate [6], and will result in a more robust, simpler and less expensive measure of SIGLEC-1 expression and the IFN signature.

Other plasma/serum IFN-regulated biomarkers have been described in the literature, most notably IFN- $\alpha$  and IFN- $\gamma$ -inducible protein 10 (IP-10) [12]. However, the protein stability, cell-type specificity and much higher concentrations of sSIGLEC-1 are major practical

advantages of our immunoassay. Moreover, measuring all 16 different IFN- $\alpha$  subtypes currently requires access to naturally occurring high-affinity anti-IFN- $\alpha$  antibodies that are not readily available [23], which in combination with the much lower sample requirement compared to the SIMOA assay makes the sSIGLEC-1 assay ideally suited for high-throughput screening, including the retrospective testing of samples collected from completed clinical studies or cohorts for flares of IFN signalling and/or response to treatment of large cohorts and retrospective studies. Recently, a study has reported that plasma concentrations of presepsin (PSEP), a product of CD14<sup>+</sup> monocyte cleavage, is increased in patients with SLE and other autoimmune and inflammatory diseases [31]. Although the study was limited to a small sample size and available clinical data, the wide spread of PSEP levels measured in SLE patients and the suggested association with disease activity are consistent with our data and support a role for activated monocyte/macrophages in the aetiology of SLE and other related autoimmune diseases. Further work will be required to investigate the relation between sSIGLEC-1 and PSEP, and the putative diagnostic and/or prognostic value of using a combination of biomarkers associated with exacerbated monocyte activation for the clinical stratification of patients with a systemic activation of the innate immune system.

Clinically, we identified marked ancestry-related differences in sSIGLEC-1 levels among SLE patients, which were consistent with the higher disease severity in patients of non-European ancestry. In agreement with this hypothesis, sSIGLEC-1 levels were also associated with lower levels of C3, a classical serologic marker of the disease. Furthermore, our data provide evidence that high sSIGLEC-1 levels could be predictive of active renal and haematological complications, particularly in patients of European ancestry.

These findings clearly underscore the importance of large, well-characterised, clinical cohorts to estimate the confounding effects of ancestry. In this study we had access to very limited numbers of non-European healthy controls, which prevented us from investigating whether steady-state sSIGLEC-1 levels could also be altered in populations of non-European ancestry. However, the association of sSIGLEC-1 concentrations with overall increased disease severity was consistently maintained in both groups of patients. A possible explanation for the more modest predictive capacity observed in non-European patients is an increased disease heterogeneity, which could reflect a reduced dependency on the type I IFN pathway for disease severity and late-stage organ damage in this group of patients. A limitation of this study was the number of available patients with active disease manifestations—namely, nephritis—which reduced the power to investigate the predictive capacity of high sSIGLEC-1 levels for the identification of patients with active disease. Further work will now be required to validate these findings in additional autoimmune and inflammatory diseases associated with a chronic activation of the innate immune system using large and clinically well-characterised patient populations, as well as to extend the findings to non-European cohorts.

There has been considerable interest in developing drugs targeting the IFN- $\alpha$  signalling pathway to treat conditions associated with chronic IFN signalling. Our assay could also have utility in clinical trials; for example, for the selection of patients who could benefit the most from such inhibition of IFN- $\alpha$ . Conversely, IFN- $\alpha$  is also one of the most used compounds in cytokine therapy. However, its immunomodulatory properties may result in various autoimmune manifestations, with reported incidence of 4–19% in patients undergoing IFN- $\alpha$  therapy [32]. We therefore hypothesise that these adverse events may be avoided if the background IFN signature is known and therapy is adjusted to avoid the excessive IFN signalling known to be a factor in the promotion of secondary autoimmunity in these patients. Moreover, it has been recently suggested that the detection of an IFN signature in peripheral blood is associated with poor response to both B-cell depleting therapy (rituximab) and anti-IL-6R treatment (tocilizumab) in rheumatoid arthritis patients [33, 34]. These data suggest that sSIGLEC-1 could be useful in prediction to therapeutic responses, and supports a broader application of this assay in the context of patient stratification for clinical trials.

## Conclusions

In this study we report the development of a sensitive immunoassay to detect circulating concentrations of sSIGLEC-1 in plasma/serum. Taken together, our findings suggest that sSIGLEC-1 is a marker of monocyte and

macrophage activation, which is critically implicated in the progression of several autoimmune and inflammatory diseases, such as SLE and SSc. In combination with additional available IFN-regulated biomarkers, the sSIGLEC-1 bioassay could help improve our capacity to dissect the molecular and clinical heterogeneity of complex conditions associated with an overt IFN response, and identify subsets of common and rare autoimmune and inflammatory diseases, collectively classified as interferonopathies. We have also shown that increased sSIGLEC-1 concentrations could, with further studies, have a clinical application in predicting increased risk of developing renal complications, one of the most severe clinical complications of SLE.

#### Availability of data and materials

The datasets generated during the present study are available from the corresponding author on reasonable request.

#### Authors' contributions

JAT and RCF conceived the study. TJV, LSW, JAT and RCF designed the experiments. JJO, DBR, CLP, PC, OA-A, KB and RCF performed the experiments. JJO, SK, ARG, KB and RCF analysed the data and interpreted the results. SK, SM, RS and TJV provided patient samples. RCF wrote the manuscript with input from all co-authors. All authors read and approved the final manuscript.

#### Ethics approval and consent to participate

All samples and information were collected with written and signed informed consent after approval from the relevant research ethics committees (REC numbers 05/Q0106/20, 07/H0718/49, 08/H0308/153; and NRES Committee London-Hampstead, HRA, REC number 6398).

#### Consent for publication

Not applicable.

#### Competing interests

JJO is an employee of GlaxoSmithKline pharmaceuticals. The other authors declare that they have no competing interests.
