Abstract

Assessing products prior to remanufacture is an important part of the remanufacturing process, ensuring that unsuitable cores are removed at an early stage to avoid unnecessary processing. In particular, understanding the economic cost of remanufacturing a product can be an important aspect of the assessment, especially for businesses operating in low volumes and on high value products, where the risk associated with unexpected costs or failure to complete remanufacture are much greater. Estimating these costs can however be difficult, as important information required to make a prediction is often uncertain, such as the product design, its condition and also the understanding of the resource requirements for remanufacture. Within this research a method has been developed to estimate the economic cost and risks of conducting a remanufacturing activity to a product when information is uncertain. Summation of the individual activities can then be conducted to determine the economic cost and risks of the entire remanufacturing process. The method utilises a combination of case based reasoning and probability theory to identify similarities between historical data records and the product under assessment, to predict the cost and risks of remanufacture. In particular this method enables cost estimation when important product information is missing including the manufacturer, model or condition. Additionally estimates can be made when exact historical information is not present, which can be useful to business remanufacturing bespoke or rare products. The method is then implemented within a service oriented architecture and functionally demonstrated using an example of an independent wind turbine gearbox remanufacturer.

Introduction

The rate at which data is being generated is increasing. In 2011 the amount of information created and replicated by mankind was predicted to have surpassed 1.8 zettabytes (1.8 trillion gigabytes), increasing by a factor of 9 in just 5 years [1]. For an industry such as remanufacturing, technologies such as embedded sensors and communication and information network technologies (such as RFID tags) can enable increased information capture about products and processes [2]. When connected to the internet of things, a plethora of information can potentially be accessed which until recently would not have been possible.

Utilising this information in an effective manner has the potential to support a decision maker and thus provide a competitive advantage [3].

However, whilst taking advantage of this information is important, it should not be assumed that this data is always complete, available or accurate, particularly in the remanufacturing domain where information uncertainty can be common place [4]. It is important therefore that methods developed to utilise this information are robust and can handle uncertainties within the data. Within this research utilising information to estimate the cost to remanufacture has been addressed. Quantifying the cost of remanufacture is an important part of the remanufacturing process as it can enable businesses to decide whether to remanufacture a specific product.

Within the literature several examples of cost modelling for remanufacture have been demonstrated, shown in Table 1. Analytical techniques are often used within these examples to estimate the cost of remanufacture, by breaking the entire process into key activities, such as disassembly, repair, assembly and testing. However, a challenge occurs when estimating the individual costs of these particular activities. Many of these examples directly use an expert's opinion to estimate the cost of each activity for a particular product based upon their knowledge. Whilst this may be an applicable method for certain situations, challenges arise when multiple estimates are required for differing products that can exhibit high levels of variability and uncertainty. Collecting this information can be time-consuming and costly as it often requires consulting with key personal [5], whilst the accuracy of the information is questionable as it may be subject to human bias [6] or become obsolete over time. Parametric methods have been used by Jun et al. [7], to derive activity cost as a function of condition of a component. However this method is again limited when key information is missing or inaccurate and requires large data sets from which the relationships can be derived.

This research therefore attempts to bridge the gap by developing a method to enable cost estimation of a remanufacturing activity with incomplete or uncertain information. The approach developed, based upon the analogical technique of case based reasoning, utilises historical record sets of previous remanufacturing activities from which jobs

Table 1 List of cost estimation methods developed for remanufacturing

with contextual similarities are identified and used to derive estimated costs for new proposed remanufacturing jobs.

The rest of the paper is laid out as follows: Firstly details of the cost estimation algorithm are presented within the method development section. This is followed by an explanation of the implementation of the cost estimation method within service oriented architecture. A case study example is then shown to demonstrate how the method works, after which conclusions are presented.

Cost estimation development

Outline

The purpose of this estimation method is to predict the cost of a remanufacturing activity for a particular product, even when product or cost information maybe uncertain. Specifically the method produced here will estimate the cost of one particular activity identified rather than the entire remanufacturing process.

To facilitate this, information is to be utilised from databases in which historical records of previously conducted remanufacturing activities are stored. An algorithm has been developed based upon case based reasoning to derive a cost estimate by identifying similarities in historical examples on which to base an estimate. Information is required to describe the product to be remanufactured. The attributes required to describe a product will be specific to a particular activity and are identified and assigned by an expert. For example disassembly cost may be most influenced by the manufacturer and model of a particular product type, whilst a repair activity could be most related to its physical condition. Multiple attributes can be associated with each activity and assigned a unique importance weighting. This method is robust in that it can still compute an estimate with missing product attributes or historical cost information, at the expense of accuracy.

The output of this method is a cost distribution for the remanufacturing activity. From this distribution key metrics can be identified such as the average expected cost and the variation. The variation indicates the level of uncertainty associated with the estimation, a high variation indicating that a high degree of uncertainty and therefore risk. A detailed description of the algorithm developed to estimate the remanufacturing activity cost is described in detail in the next section (Fig. 1).

Fig. 1 Outline of the cost estimation method

Algorithm design

This method uses analogy to find similarities within past experience to the cost of the new target case. The algorithm used to estimate a cost for this method is shown in Fig. 2.

The first step requires a dataset to be identified, such as historical job records, where details about the product and the activity costs have been recorded. The similarity of the new target case is then measured against each of the historical cases of past activities. The method used to obtain the similarity score is shown in Eq. 1.

$$Sim(T, l) = \frac{\sum_{m \in M} f(T, l_m) W_m}{\sum_{m \in M} W_m} \tag{1}$$

Where $Sim(T, l)$ is the similarity score between target case T and historical case l , $f(T, l_m)$ is the individual attribute similarity between target case T and historical case l for attribute m , W_m is the weighted value of attributed m in the set of M .

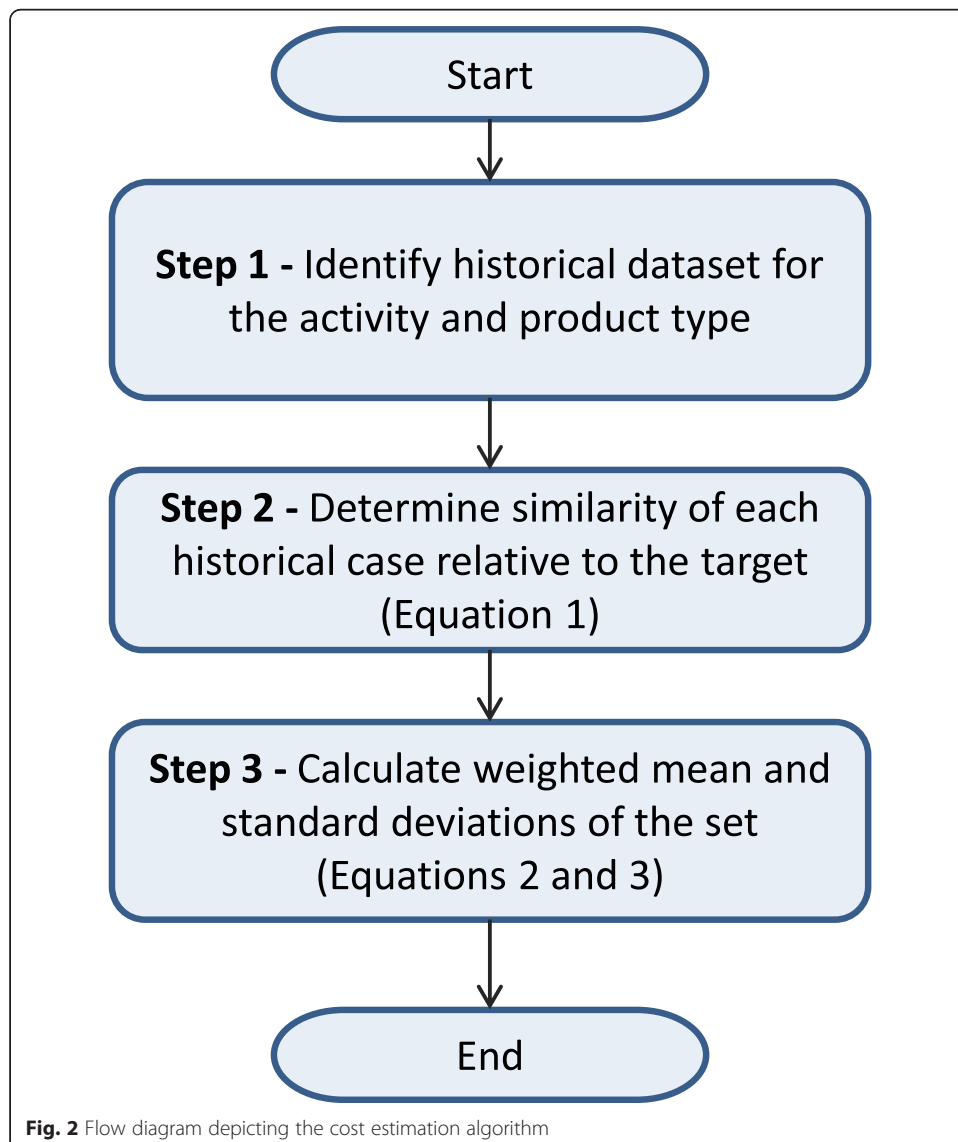

Fig. 2 Flow diagram depicting the cost estimation algorithm

Users are required to select product attributes to base the similarity score upon and apply weighting factors to the attributes. Individual weightings are scored between 0 and 1, with 0 indicating no importance and 1 indicating high importance. The selection and weighting of attributes requires understanding of factors which may affect the cost of performing these activities. Examples of key attributes include the manufacturer, model, condition and power rating of a product or component.

A single method of calculating individual attribute similarity would be unsuitable due to the range of data types and values possible. For example assessing the similarity of texted attributes, such as a manufacturers name or model code requires a different method than comparing the similarity of numerical values, such as power. Within this research two simple methods of calculating attribute similarity are used, although scope is available to add further methods within future work.

The first method allows text values to be compared, and simply determines if the two values are the same. If a match exists $f(T_m, l_m)$ is set to 1, else it is set to 0.

The second method compares numerical values and assigns a weighting if the values are within a pre-determined percentage range, for example $\pm 20\%$ of the target case. An exact match scores a value of 1, whilst all other values are based upon a linear equation which results in a 0 value at $\pm 20\%$ of the target. All other values outside of the $\pm 20\%$ are also assigned 0.

When no information about the particular attribute is provided, a value of 0.5 is assigned. It was chosen to give an uncertain attribute a non 0 value as the historical case both may or may not be of importance, therefore it should be considered within the calculation. Equally it was chosen not to use a value of 1 as this reduces the importance of a true match.

The similarity calculation in Eq. 1 is then applied to every case within the database. Each similarity score is then used as a weighting value to derive a statistical distribution from the database. The mean value is calculated using Eq. 2 whilst the variance is calculated using Eq. 3.

$$\mu_w = \frac{\sum_{l \in L} Sim(T, l) a(l)}{\sum_{l \in L} Sim(T, l)} \tag{2}$$

Where μ_w is the weighted mean cost of the activity, and a is the cost of the historical activity l .

$$\sigma_w = \sqrt{\frac{\sum_{l \in L} Sim(T, l) (a(l) - \mu_w)^2}{\sum_{l \in L} Sim(T, l)}} \tag{3}$$

Where σ_w is the weighted standard variance of the mean cost of the activity.

Using these statistical properties, a distribution can be created to describe the cost of activity i . By describing the cost as a Probability Density Function (PDF) the uncertainty within the estimate can be described. By weighting the historical data set using case based reasoning, similar cases can influence the cost estimate more significantly. A normal distribution was chosen as a suitable PDF, although future work can expand upon this by matching suitable distributions to the data set.

Implementation

This research forms part of the PREMANUS project, an ICT project funded as part of the European Union (EU) Seventh Framework Programme (FP7), with the aim to overcome the asymmetric distribution of information in the End of Life recovery of products by connecting OEMs and subcontractors, with a special emphasis on remanufacturing [8]. This is realised through the development of a service middleware consisting of three technological pillars;

- Remanufacturing Information Services (RIS)
- Remanufacturing Services Gateway (RSG)
- Business Decision Support System (BDSS)

The cost estimation method described in this paper forms a part of the BDSS pillar and thus has been implemented within a service oriented architecture employed by the PREMANUS eco system. The cost estimation method has been programed in an object oriented paradigm within the Net framework using the Visual Basic language and was deployed as a RESTful web service. Historical remanufacturing data has been stored using a Microsoft Access relational database and is remotely queried by the service using SQL language.

A separate client was developed independently by an industrial use case partner SKF to act as a custom user interface using the ARIS MashZone platform, shown in Fig. 3.

Case study example

Case study introduction

To demonstrate the method, an example of a small independent remanufacturer of wind turbine gearboxes is presented. Gearboxes within wind turbines are used to transform the relatively low input rotation of the blades to the higher rotation required by the generator for electricity generation. However, failure rates on these gearboxes have

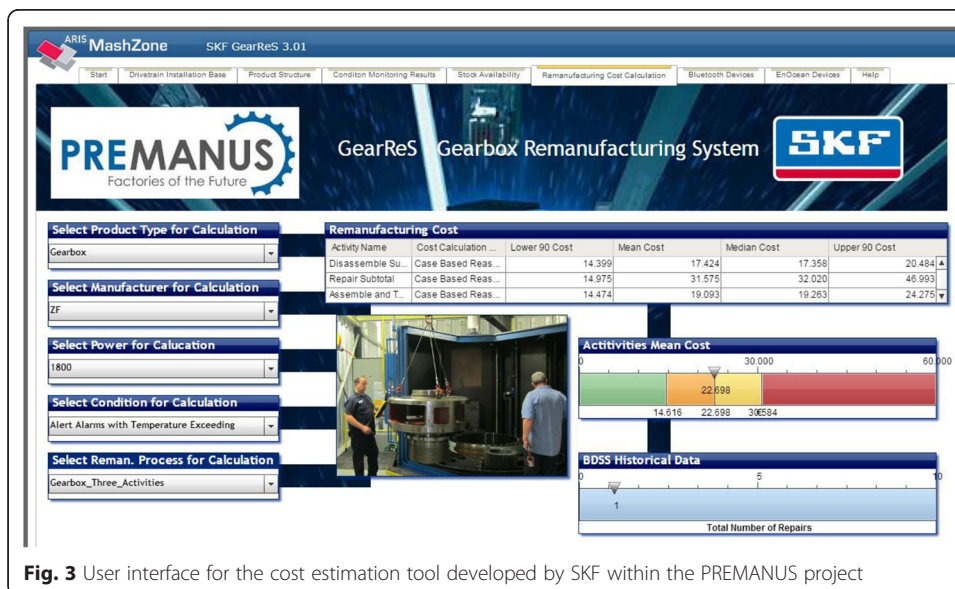

Fig. 3 User interface for the cost estimation tool developed by SKF within the PREMANUS project

created a demand for aftermarket services such as remanufacturing. The wind turbine gearbox aftermarket demonstrates many of the issues highlighted in the introduction that can make cost estimation for remanufacture challenging. High variability in product types exist due to the relatively small number of particular models produced, meaning that limited cost information exists regarding the resource requirements for remanufacture. Information supplied to the remanufacturer to assess the product to be remanufactured can also vary significantly. Many gearboxes are equipped with condition monitoring systems which can provide detailed lifecycle information related to the condition of the gearbox. However, many older gearboxes do not have this equipment and thus limited information to assess cost is available. Being an independent remanufacture also means that product design information, detailing the product structure, number of components and fittings can also be difficult to obtain as the customer will not always have this information whilst OEM's will be hesitant to release it.

Cost estimation is required to assess whether remanufacturing is a viable option for a particular gearbox compared to other solutions such as replacement with a different unit.

Demonstration

The purpose of this demonstration is to highlight how different levels of uncertainty within a cost estimate can be computed using this method. The same gearbox is represented several times with differing levels of uncertainty shown in each row (Table 2). For simplicity within this demonstration, only three attributes have been used to describe the gearbox which are; manufacturer, power rating and condition. A single number is used to describe the condition on a scale of 1 to 5, with 1 indicating bad condition and 5 indicating a good condition.

Three key activities have been identified within the remanufacturing process, shown in Fig. 4. For demonstration purposes the cost estimation has only been conducted for the *Disassembly and Inspection* activity, however the approach is the same for other activities. Based upon expert knowledge, weightings have been assigned to each of the three attributes used to describe the product, from their perceived influence upon the cost of remanufacture, shown in Table 3.

Activity cost information is contained within historical job records, shown in Table 4. Every time a gearbox is remanufactured, information about the costs incurred for each activity is recorded along with information about the gearbox. The method will use these historical records to estimate a cost based upon similarities to the cases identified.

Cost calculation was performed using the information outlined above. Firstly a similarity score was calculated to compare each historical record with the target information (from Table 2) using Eq. 1, with the results displayed in Table 5.

Table 2 Information requirements for gearbox product model, with four product examples showing varying amounts of uncertainty

	Manufacturer	Power rating (MW)	Condition rating (1–5)
Gearbox_A	ZF	1.6	2
Gearbox_B	ZF	1.6	<i>Unknown</i>
Gearbox_C	ZF	<i>Unknown</i>	<i>Unknown</i>
Gearbox_D	<i>Unknown</i>	<i>Unknown</i>	<i>Unknown</i>

Table 3 Similarity attributes for the Disassembly and Inspection activity

Attribute	Weighting	Match type
Manufacturer	1	Semantic
Power	0.6	Number
Condition	0.1	Number

Table 4 Sample historical case data for Disassembly and inspection

	Manufacturer	Power (MW)	Condition	Total cost
GearboxRecord_1	Eickhoff	1.0	4	£9,605
GearboxRecord_2	Eickhoff	1.0	5	£10,478
GearboxRecord_3	Eickhoff	1.5	1	£12,375
GearboxRecord_4	ZF	1.5	1	£15,850
GearboxRecord_5	Eickhoff	1.7	3	£15,582
GearboxRecord_6	ZF	1.8	3	£18,344
GearboxRecord_7	Bosch/Rexroth	1.8	4	£19,444
GearboxRecord_8	Bosch/Rexroth	1.8	5	£17,772
GearboxRecord_9	Eickhoff	2.0	3	£17,698
GearboxRecord_10	ZF	2.0	3	£19,868
GearboxRecord_11	Bosch/Rexroth	2.1	1	£19,444
GearboxRecord_12	Eickhoff	2.1	1	£16,865

Table 5 Similarity Score of each historical gearbox record (Table 4) for the target estimation case (Calculated through Eq. 1)

	Similarity score (Calculated through Eq. 1)			
	Gearbox_A	Gearbox_B	Gearbox_C	Gearbox_D
GearboxRecord_1	0	0.03	0.21	0.5
GearboxRecord_2	0	0.03	0.21	0.5
GearboxRecord_3	0.27	0.27	0.21	0.5
GearboxRecord_4	0.86	0.86	0.79	0.5
GearboxRecord_5	0.27	0.27	0.21	0.5
GearboxRecord_6	0.75	0.75	0.79	0.5
GearboxRecord_7	0.13	0.16	0.21	0.5
GearboxRecord_8	0.13	0.16	0.21	0.5
GearboxRecord_9	0.03	0.03	0.21	0.5
GearboxRecord_10	0.62	0.62	0.79	0.5
GearboxRecord_11	0.03	0.03	0.21	0.5
GearboxRecord_12	0.03	0.03	0.21	0.5

Table 6 Cost and risk results for the disassembly and inspection activity

	Lower σ (£)	Mean Cost (£) (Eq. 2)	Upper σ (£)	Range (Upper σ —Lower σ) (£)
Gearbox_A	15031	17211	19391	4360
Gearbox_B	14749	17106	19463	4714
Gearbox_C	13971	16906	19841	5870
Gearbox_D	12750	16110	19470	6720

Using the results of Eq. 1, weighted mean costs and standard variance were then calculated for each gearbox using Eqs. 2 and 3 respectively. Lower and upper standard variations were then calculated about the mean, based upon a normally distributed PDF. Results for the disassembly activity are numerically and graphically displayed in Table 6 and Fig. 5 respectively. Within the results it can be seen when more information is provided for the predicted case (Gearbox_A) a more certain estimate is provided, with a lower standard variation. However, even when limited information is provided (Gearbox_D), an estimate can still be calculated, all be it with increased risk. The results demonstrate the ability of the method to calculate cost and risk metrics with incomplete information regarding both the product description and also the cost knowledge.

Conclusions

Within this research a method has been presented for forecasting the cost of a remanufacturing activity in the presence of uncertain or limited information. The method utilises historical data records to compare the target costing case to previous job records for which it can identify similarities to predict a new cost estimate. The method can be applied to each activity required in the remanufacturing process and summated to determine the total process cost.

The implications of this research is that it may allow businesses operating in the remanufacturing domain a method of estimating cost of an activity when information is limited or uncertain, an area which has so far been neglected within the remanufacturing domain. The utilisation of historical cost records rather than expert knowledge, which has frequently been used in past cost estimation methods, can avoid human

knowledge bias and, because it is connected to a live data base will provide the method with update information.

There is much potential for future work related to this research area. As this method is largely in the prototype phase, there is a great deal of research that could be conducted to test and optimise its performance and accuracy. Automation of key attributes selection and their weighting could also enhance the accuracy and usability of the method, removing the need for direct input of expert knowledge and bias. Additionally there is a great deal of potential within the remanufacturing domain to utilise information to support their decisions. This is a much broader area of work which industry and academia should address to support the challenges of uncertainty within remanufacturing and other end of life and aftermarket activities.

Competing interests

The authors declare that they have no competing interests.

Authors' contributions

PG carried out the majority of the research and development, analysis, and writing. IG manages the project, was involved in the initial case-based reasoning research, and made recommendations on the manuscript. PC and AW direct Loughborough University's activities in the project and were involved in its conception. JH, AW and PC cosupervised PG PhD research on which this publication is based. SS was the industrial contact from SKF within the PREMANUS project and led the user interface development shown in this work. All authors read and approved the final manuscript.

Acknowledgements

The PREMANUS project (grant agreement number 285541) is co-funded (alongside the project consortium members) by the European Union under the Information and Communication Technologies (ICT) theme of the Seventh Framework Programme (FP7) for research, technological development, and demonstration.

The following companies have contributed as consortium members:
